Atomic formulas may be combined with truth-functional operators to give formulas such as $\varphi x \vee \psi y$ [Example: "Either the customer (x) is friendly (φ) or else John (y) is disappointed (ψ)"]; $\varphi xy \supset \sim\psi x$ [Example: "If the road (x) is above (φ) the flood line (y), then the road is not wet ($\sim\psi$)"]; and so on. Formulas so formed, however, are valid when and only when they are substitution-instances of valid wffs of PC and hence in a sense do not transcend PC. More interesting formulas are formed by the use, in addition, of quantifiers. There are two kinds of quantifiers: universal quantifiers, written as "$(\forall \_\_)$" or often simply as "$(\_\_)$," where the blank is filled by a variable, which may be read "For all ___"; and existential quantifiers, written as "$(\exists \_\_)$." which may be read "For some ___" or "There is a ___ such that." ("Some" is to be understood as meaning "at least one.") Thus $(\forall x)\varphi x$ is to mean "For all x, x is φ" or, more simply, "Everything is φ"; and $(\exists x)\varphi x$ is to mean "For some x, x is φ" or, more simply, "Something is φ" or "There is a φ." Slightly more complex examples are $(\forall x)(\varphi x \supset \psi x)$ for "Whatever is φ is ψ," $(\exists x)(\varphi x \cdot \psi x)$ for "Something is both φ and ψ," $(\forall x)(\exists y)\varphi xy$ for "Everything bears the relation φ to at least one thing," and $(\exists x)(\forall y)\varphi xy$ for "There is something that bears the relation φ to everything." To take a concrete case, if φxy means "x loves y" and the values of x and y are taken to be human beings, then the last two formulas mean, respectively, "Everybody loves somebody" and "Somebody loves everybody."

Quantifiers ∀ and ∃

Intuitively, the notions expressed by the words "some" and "every" are connected in the following way: to assert that something has a certain property amounts to denying that everything lacks that property (for example, to say that something is white is to say that not everything is nonwhite); and, similarly, to assert that everything has a certain property amounts to denying that there is something that lacks it. These intuitive connections are reflected in the usual practice of taking one of the quantifiers as primitive and defining the other in terms of it. Thus ∀ may be taken as primitive, and ∃ introduced by the definition

$$(\exists \mathbf{a})\alpha =_{\text{Df}} \sim(\forall \mathbf{a})\sim\alpha$$

in which **a** is any variable and α is any wff; or, alternatively, ∃ may be taken as primitive, and ∀ introduced by the definition

$$(\forall \mathbf{a})\alpha =_{\text{Df}} \sim(\exists \mathbf{a})\sim\alpha.$$

The lower predicate calculus. A predicate calculus in which the only variables that occur in quantifiers are individual variables is known as a lower (or first-order) predicate calculus. Various lower predicate calculi have been constructed. In the most straightforward of these, to which the most attention will be devoted in this discussion and which subsequently will be referred to simply as LPC, the wffs can be specified as follows: Let the primitive symbols be (1) $x, y, \ldots$ (individual variables), (2) $\varphi, \psi, \ldots$, each of some specified degree (predicate variables), and (3) the symbols $\sim$, $\vee$, $\forall$, (, and). An infinite number of each type of variable can now be secured as before by the use of numerical subscripts. The symbols $\cdot$, $\supset$, and $\equiv$ are defined as in PC, and ∃ as explained above. The formation rules are:

1. An expression consisting of a predicate variable of degree n followed by n individual variables is a wff.
2. If α is a wff, so is $\sim\alpha$.
3. If α and β are wffs, so is $(\alpha \vee \beta)$.
4. If α is a wff and **a** is an individual variable, then $(\forall \mathbf{a})\alpha$ is a wff. (In such a wff, α is said to be the scope of the quantifier.)

Bound and free variables

If **a** is any individual variable and α is any wff, every occurrence of **a** in α is said to be bound (by the quantifiers) when occurring in the wffs $(\forall \mathbf{a})\alpha$ and $(\exists \mathbf{a})\alpha$. Any occurrence of a variable that is not bound is said to be free. Thus, in $(\forall x)(\varphi x \vee \varphi y)$ the x in φx is bound, since it occurs within the scope of a quantifier containing x, but

y is free. In the wffs of a lower predicate calculus, every occurrence of a predicate variable (φ, ψ, χ, . . .) is free. A wff containing no free individual variables is said to be a closed wff of LPC. If a wff of LPC is considered as a proposition form, instances of it are obtained by replacing all free variables in it by predicates or by names of individuals, as appropriate. A bound variable, on the other hand, indicates not a point in the wff where a replacement is needed but a point (so to speak) at which the relevant quantifier applies.

For example, in φx, in which both variables are free, each variable must be replaced appropriately if a proposition of the form in question (such as "Socrates is white") is to be obtained; but in $(\exists x)\varphi x$, in which x is bound, it is necessary only to replace φ by a predicate in order to obtain a complete proposition (*e.g.*, replacing φ by "is white" yields the proposition "Something is white").

Validity in LPC. Intuitively, a wff of LPC is valid if and only if all its instances are true—*i.e.*, if and only if every result of replacing each of its free variables appropriately and uniformly is a true proposition. A formal definition of validity in LPC to express this intuitive notion more precisely can be given as follows: for any wff of LPC, any number of LPC models can be formed. An LPC model has two elements: One is a set, D, of objects, known as a domain. D may contain as many or as few objects as one chooses, but it must contain at least one, and the objects may be of any kind. The other element, V, is a system of value assignments satisfying the following conditions. To each individual variable there is assigned some member of D (not necessarily a different one in each case). Assignments are next made to the predicate variables in the following way: if φ is monadic, there is assigned to it some subset of D (possibly the whole of D); intuitively this subset can be viewed as the set of all the objects in D that have the property φ. If φ is dyadic, there is assigned to it some set of ordered pairs (*i.e.*, pairs of objects of which one is marked out as the first and the other as the second) drawn from D; intuitively these can be viewed as all the pairs of objects in D in which the relation φ holds between the first object in the pair and the second. In general, if φ is of degree n, there is assigned to it some set of ordered n-tuples (groups of n objects) of members of D. It is then stipulated that an atomic formula is to have the value 1 in the model if the members of D assigned to its individual variables form, in that order, one of the n-tuples assigned to the predicate variable in it; otherwise, it is to have the value 0. Thus in the simplest case, φx will have the value 1 if the object assigned to x is one object in the set of objects assigned to φ; and, if it is not, then φx will have the value 0. The values of truth functions are determined by the values of their arguments as in PC. Finally, the value of $(\forall x)\alpha$ is to be 1 if both (1) the value of α itself is 1 and (2) α would always still have the value 1 if a different assignment were made to x but all the other assignments were left precisely as they were; otherwise $(\forall x)\alpha$ is to have the value 0. Since $\exists$ can be defined in terms of $\forall$, these rules cover all the wffs of LPC. A given wff may of course have the value 1 in some LPC models but the value 0 in others. But a valid wff of LPC may now be defined as one that has the value 1 in every LPC model. If 1 and 0 are viewed as representing truth and falsity, respectively, then validity is defined as truth in every model.

Value assignments in the domain of a model

Although the above definition of validity in LPC is quite precise, it does not yield, as did the corresponding definition of PC validity in terms of truth tables, an effective decision procedure. It can, indeed, be shown that no generally applicable decision procedure for LPC is possible—*i.e.*, that LPC is not a decidable system. This does not mean that it is never possible to prove that a given wff of LPC is valid—the validity of an unlimited number of such wffs can in fact be demonstrated—but it does mean that in the case of LPC, unlike that of PC, there is no general procedure, stated in advance, that would enable one to determine, for any wff whatever, whether it is valid or not (see also below *Model theory*).

Logical manipulations in LPC. The intuitive connections between *some* and *every* noted earlier are reflected in the fact that the following equivalences are valid:

Laws concerning quantifiers

$$(\exists x)\varphi x \equiv \sim(\forall x)\sim\varphi x$$
$$(\forall x)\varphi x \equiv \sim(\exists x)\sim\varphi x$$

These equivalences remain valid when φx is replaced by any wff, however complex; *i.e.*, for any wff α whatsoever,

$$(\exists x)\alpha \equiv \sim(\forall x)\sim\alpha$$

and

$$(\forall x)\alpha \equiv \sim(\exists x)\sim\alpha$$

are valid. Because the rule of substitution of equivalents can be shown to hold in LPC, it follows that $(\exists x)$ may be replaced anywhere in a wff by $\sim(\forall x)\sim$, or $(\forall x)$ by $\sim(\exists x)\sim$, and the resulting wff will be equivalent to the original. Similarly, because the law of double negation permits the deletion of a pair of consecutive negation signs, $\sim(\exists x)$ may be replaced by $(\forall x)\sim$, and $\sim(\forall x)$ by $(\exists x)\sim$.

These principles are easily extended to more complex cases. To say that there is a pair of objects satisfying a certain condition is equivalent to denying that every pair of objects fails to satisfy that condition, and to say that every pair of objects satisfies a certain condition is equivalent to denying that there is any pair of objects that fails to satisfy that condition. These equivalences are expressed formally by the validity, again for any wff α, of

$$(\exists x)(\exists y)\alpha \equiv \sim(\forall x)(\forall y)\sim\alpha$$

and

$$(\forall x)(\forall y)\alpha \equiv \sim(\exists x)(\exists y)\sim\alpha$$

and by the resulting replaceability anywhere in a wff of $(\exists x)(\exists y)$ by $\sim(\forall x)(\forall y)\sim$, or of $(\forall x)(\forall y)$ by $\sim(\exists x)(\exists y)\sim$.

Analogously, $(\exists x)(\forall y)$ can be replaced by $\sim(\forall x)(\exists y)\sim$ [*e.g.*, $(\exists x)(\forall y)(x$ loves $y)$—"There is someone who loves everyone"—is equivalent to $\sim(\forall x)(\exists y)\sim(x$ loves $y)$—"It is not true of everyone that there is someone whom he does not love"]; $(\forall x)(\exists y)$ can be replaced by $\sim(\exists x)(\forall y)\sim$; and in general the following rule, covering sequences of quantifiers of any length, holds:

1. If a wff contains an unbroken sequence of quantifiers, then the wff that results from replacing $\forall$ by $\exists$ and vice versa throughout that sequence and inserting or deleting $\sim$ at each end of it is equivalent to the original wff.

   This may be called the rule of quantifier transformation. It reflects, in a generalized form, the intuitive connections between "some" and "every" that were noted above.

The following are also valid, again where α is any wff:

$$(\forall x)(\forall y)\alpha \equiv (\forall y)(\forall x)\alpha$$
$$(\exists x)(\exists y)\alpha \equiv (\exists y)(\exists x)\alpha$$

The extensions of these lead to the following rule:

2. If a wff contains an unbroken sequence either of universal or of existential quantifiers, these quantifiers may be rearranged in any order and the resulting wff will be equivalent to the original wff.

   This may be called the rule of quantifier rearrangement.

Two other important rules concern implications, not equivalences:

3. If a wff β begins with an unbroken sequence of quantifiers, and β' is obtained from β by replacing $\forall$ by $\exists$ at one or more places in the sequence, then β is stronger than β'—in the sense that $(\beta \supset \beta')$ is valid but $(\beta' \supset \beta)$ is in general not valid.
4. If a wff β begins with an unbroken sequence of quantifiers in which some existential quantifier Q_1 precedes some universal quantifier Q_2, and if β' is obtained from β by moving Q_1 to the right of Q_2, then β is stronger than β'.

As illustrations of these rules, the following are valid for any wff α:

$(\forall x)(\forall y)\alpha \supset (\exists x)(\forall y)\alpha$	rule 3
$(\exists x)(\forall y)(\forall z)\alpha \supset (\exists x)(\forall y)(\exists z)\alpha$	rule 3
$(\exists x)(\forall y)\alpha \supset (\forall y)(\exists x)\alpha$	rule 4
$(\exists x)(\exists y)(\forall z)\alpha \supset (\exists y)(\forall z)(\exists x)\alpha$	rule 4

In each case the converses are not valid (though they may be valid in particular cases in which α is of some special form).

Application of the rules

Some of the uses of the above rules can be illustrated by considering a wff α that contains precisely two free individual variables. By prefixing to α two appropriate quantifiers and possibly one or more negation signs, it is possible to form a closed wff (called a closure of α) that will express a determinate proposition when a meaning is assigned to the predicate variables. The above rules can be used to list exhaustively the nonequivalent closures of α and the implication relations between them. The simplest example is φxy, which for illustrative purposes can be taken to mean "x loves y." Application of rules 1 and 2 will show that every closure of φxy is equivalent to one or another of the following 12 wffs (none of which is in fact equivalent to any of the others):

(a) $(\forall x)(\forall y)\varphi xy$ ("Everybody loves everybody");
(b) $(\exists x)(\forall y)\varphi xy$ ("Somebody loves everybody");
(c) $(\exists y)(\forall x)\varphi xy$ ("There is someone whom everyone loves");
(d) $(\forall y)(\exists x)\varphi xy$ ("Each person is loved by at least one person");
(e) $(\forall x)(\exists y)\varphi xy$ ("Each person loves at least one person");
(f) $(\exists x)(\exists y)\varphi xy$ ("Somebody loves somebody"); and
(g)–(l) the respective negations of each of the above.

Rules 3 and 4 show that the following implications among formulas (a)–(f) are valid:

$(a) \supset (b)$ $\quad (d) \supset (f)$ $\quad (c) \supset (e)$
$(b) \supset (d)$ $\quad (a) \supset (c)$ $\quad (e) \supset (f)$

The implications holding among the negations of (a)–(f) follow from these by the law of transposition; *e.g.*, since $(a) \supset (b)$ is valid, so is $\sim(b) \supset \sim(a)$. The quantification of wffs containing three, four, etc., variables can be dealt with by the same rules.

Intuitively, $(\forall x)\varphi x$ and $(\forall y)\varphi y$ both "say the same thing"—namely, that everything is φ—and $(\exists x)\varphi x$ and $(\exists y)\varphi y$ both mean simply that something is φ. Clearly, so long as the same variable occurs both in the quantifier and as the argument of φ, it does not matter what letter is chosen for this purpose. The procedure of replacing some variable in a quantifier, together with every occurrence of that variable in its scope, by some other variable that does not occur elsewhere in its scope is known as relettering a bound variable. If β is the result of relettering a bound variable in a wff α, then α and β are said to be bound alphabetical variants of each other, and bound alphabetical variants are always equivalent. The reason for restricting the replacement variable to one not occurring elsewhere in the scope of the quantifier can be seen from an example: If φxy is taken as before to mean "x loves y," the wff $(\forall x)\varphi xy$ expresses the proposition form "Everyone loves y," in which the identity of y is left unspecified, and so does its bound alphabetical variant $(\forall z)\varphi zy$. If x were replaced by y, however, the closed wff $(\forall y)\varphi yy$ would be obtained, which expresses the proposition that everyone loves himself and is clearly not equivalent to the original.

Prenex normal form

A wff in which all the quantifiers occur in an unbroken sequence at the beginning, with the scope of each extending to the end of the wff, is said to be in prenex normal form (PNF). Wffs that are in PNF are often more convenient to work with than those that are not. For every wff of LPC, however, there is an equivalent wff in PNF (often simply called its PNF). One effective method for finding the PNF of any given wff is the following:

1. Reletter bound variables as far as is necessary to ensure (a) that each quantifier contains a distinct variable and (b) that no variable in the wff occurs both bound and free.
2. Use definitions or PC equivalences to eliminate all operators except $\sim$, $\cdot$, and $\vee$.
3. Use the De Morgan laws and the rule of quantifier transformation to eliminate all occurrences of $\sim$ immediately before parentheses or quantifiers.
4. Gather all of the quantifiers into a sequence at the beginning in the order in which they appear in the wff and take the whole of what remains as their scope. Example:

$$(\forall x)\{[\varphi x \cdot (\exists y)\psi xy] \supset (\exists y)\chi xy\} \supset (\exists z)(\varphi z \supset \psi zx).$$

Step 1 can be achieved by relettering the third and fourth occurrences of y and every occurrence of x except the last (which is free); thus

$$(\forall w)\{[\varphi w \cdot (\exists y)\psi wy] \supset (\exists u)\chi wu\} \supset (\exists z)(\varphi z \supset \psi zx).$$

Step 2 now yields

$$\sim(\forall w)\{\sim[\varphi w \cdot (\exists y)\psi wy] \vee (\exists u)\chi wu\} \vee (\exists z)(\sim\varphi z \vee \psi zx).$$

By step 3 this becomes

$$(\exists w)\{[\varphi w \cdot (\exists y)\psi wy] \cdot (\forall u)\sim\chi wu\} \vee (\exists z)(\sim\varphi z \vee \psi zx).$$

Finally, step 4 yields

$$(\exists w)(\exists y)(\forall u)(\exists z)\{[(\varphi w \cdot \psi wy) \cdot \sim\chi wu] \vee (\sim\varphi z \vee \psi zx)\},$$

which is in PNF.

Classification of dyadic relations. Consider the closed wff,

$$(\forall x)(\forall y)(\varphi xy \supset \varphi yx),$$

which means that, whenever the relation φ holds between one object and a second, it also holds between that second object and the first. This expression is not valid, since it is true for some relations but false for others. A relation for which it is true is called a symmetrical relation (example: "is parallel to"). If the relation φ is such that, whenever it holds between one object and a second, it fails to hold between the second and the first—*i.e.*, if φ is such that

Symmetry, transitivity, reflexivity

$$(\forall x)(\forall y)(\varphi xy \supset \sim\varphi yx)$$

—then φ is said to be asymmetrical (example: "is greater than"). A relation that is neither symmetrical nor asymmetrical is said to be nonsymmetrical. Thus φ is nonsymmetrical if

$$(\exists x)(\exists y)(\varphi xy \cdot \varphi yx) \cdot (\exists x)(\exists y)(\varphi xy \cdot \sim\varphi yx)$$

(example: "loves").

Dyadic relations can also be characterized in terms of another threefold division: A relation φ is said to be transitive if, whenever it holds between one object and a second and also between that second object and a third, it holds between the first and the third—*i.e.*, if

$$(\forall x)(\forall y)(\forall z)[(\varphi xy \cdot \varphi yz) \supset \varphi xz]$$

(example: "is greater than"). An intransitive relation is one that, whenever it holds between one object and a second and also between that second and a third, fails to hold between the first and the third; *i.e.*, φ is intransitive if

$$(\forall x)(\forall y)(\forall z)[(\varphi xy \cdot \varphi yz) \supset \sim\varphi xz]$$

(example: "is father of"). A relation that is neither transitive nor intransitive is said to be nontransitive. Thus φ is nontransitive if

$$(\exists x)(\exists y)(\exists z)(\varphi xy \cdot \varphi yz \cdot \varphi xz) \cdot (\exists x)(\exists y)(\exists z)(\varphi xy \cdot \varphi yz \cdot \sim\varphi xz)$$

(example: "is a first cousin of").

A relation φ that always holds between any object and itself is said to be reflexive; *i.e.*, φ is reflexive if

$$(\forall x)\varphi xx$$

(example: "is identical with"). If φ never holds between any object and itself—*i.e.*, if

$$\sim(\exists x)\varphi xx$$

—then φ is said to be irreflexive (example: "is greater than"). If φ is neither reflexive nor irreflexive—*i.e.*, if

$$(\exists x)\varphi xx \cdot (\exists x)\sim\varphi xx$$

—then φ is said to be nonreflexive (example: "admires").

A relation such as "is of the same length as" is not strictly reflexive, as some objects do not have a length at all and thus are not of the same length as anything, even themselves. But this relation is reflexive in the weaker sense that whenever an object is of the same length as anything it is of the same length as itself. Such a relation is said to be quasi-reflexive. Thus φ is quasi-reflexive if

$$(\forall x)[(\exists y)\varphi xy \supset \varphi xx].$$

A reflexive relation is of course also quasi-reflexive.

For the most part, these three classifications are independent of each other; thus a symmetrical relation may be transitive (like "is equal to") or intransitive (like "is perpendicular to") or nontransitive (like "is one mile distant from"). There are, however, certain limiting principles, of which the most important are:

1. Every relation that is symmetrical and transitive is at least quasi-reflexive.
2. Every asymmetrical relation is irreflexive.
3. Every relation that is transitive and irreflexive is asymmetrical.

A relation that is reflexive, symmetrical, and transitive is called an equivalence relation.

Axiomatization of LPC. Rules of uniform substitution for predicate calculi, though formulable, are mostly very complicated, and, to avoid the necessity for these rules, axioms for these systems are therefore usually given by axiom schemata in the sense explained earlier in *Axiomatization of PC.* Given the formation rules and definitions stated in the introductory paragraph of *The lower predicate calculus,* the following is presented as one standard axiomatic basis for LPC:

Axiomatic basis and undecidability of theorems

Axiom schemata:

1. Any LPC substitution-instance of any valid wff of PC is an axiom.
2. Any wff of the form $(\forall \mathbf{a})\alpha \supset \beta$ is an axiom, if β is either identical with α or differs from it only in that, wherever α has a free occurrence of **a**, β has a free occurrence of some other individual variable **b**.
3. Any wff of the form $(\forall \mathbf{a})(\alpha \supset \beta) \supset [\alpha \supset (\forall \mathbf{a})\beta]$ is an axiom, provided that α contains no free occurrence of **a**.

Transformation rules:

1. Modus ponens (as given above in *Axiomatization of PC*).
2. If α is a theorem, so is $(\forall \mathbf{a})\alpha$, where **a** is any individual variable (rule of universal generalization).

The axiom schemata call for some explanation and comment. By an LPC substitution-instance of a wff of PC is meant any result of uniformly replacing every propositional variable in that wff by a wff of LPC. Thus one LPC substitution-instance of $(p \supset \sim q) \supset (q \supset \sim p)$ is $[\varphi xy \supset \sim(\forall x)\psi x] \supset [(\forall x)\psi x \supset \sim\varphi xy]$. Axiom schema 1 makes available in LPC all manipulations such as commutation, transposition, and distribution, which depend only on PC principles. Examples of wffs that are axioms by axiom schema 2 are $(\forall x)\varphi x \supset \varphi x$, $(\forall x)\varphi x \supset \varphi y$, and $(\forall x)(\exists y)\varphi xy \supset (\exists y)\varphi zy$. To see why it is necessary for the variable that replaces **a** to be free in β, consider the last example: Here **a** is x, α is $(\exists y)\varphi xy$, in which x is free, and β is $(\exists y)\varphi zy$, in which z is free and replaces x. But had y, which would become bound by the quantifier $(\exists y)$, been chosen as a replacement instead of z, the result would have been $(\forall x)(\exists y)\varphi xy \supset (\exists y)\varphi yy$, the invalidity of which can be seen intuitively by taking φxy to mean "x is a child of y": for then $(\forall x)(\exists y)\varphi xy$ will mean that everyone is a child of someone, which is true, but $(\exists y)\varphi yy$ will mean that someone is a child of himself, which is false. The need for the proviso in axiom schema 3 can also be seen from an example. Defiance of the proviso would give as an axiom $(\forall x)(\varphi x \supset \psi x) \supset [\varphi x \supset (\forall x)\psi x]$; and, if φx were taken to mean "x is a Spaniard," ψx to mean "x is a European," and the free occurrence of x (the first occurrence in the consequent) to stand for General Franco, then the antecedent would mean that every Spaniard is a European, but the consequent would mean that, if General Franco is a Spaniard, then everyone is a European.

It can be proved—though the proof is not an elementary one—that the theorems derivable from the above basis are precisely the wffs of LPC that are valid by the definition of validity given above in *Validity in LPC.* Several other bases for LPC are known that also have this property. The axiom schemata and transformation rules here given are such that any purported proof of a theorem can be effectively checked to determine whether it really is a proof or not; nevertheless, theoremhood in LPC, like validity in LPC, is not effectively decidable, in that there is no effective method of telling with regard to any arbitrary wff whether it is a theorem or not. In this respect, axiomatic bases for LPC contrast with those for PC.

Semantic tableaux. Since the 1980s another technique for determining the validity of arguments in either PC or LPC has gained some popularity, owing both to its ease of learning and to its straightforward implementation by computer programs. Originally suggested by the Dutch logician Evert W. Beth (1908–64), it was more fully developed and publicized by the American mathematician and logician Raymond M. Smullyan (b. 1919). Resting on the observation that it is impossible for the premises of a valid argument to be true while the conclusion is false, this method attempts to interpret (or evaluate) the premises in such a way that they are all simultaneously satisfied and the negation of the conclusion is also satisfied. Success in such an effort would show the argument to be invalid, while failure to find such an interpretation would show it to be valid.

Constructing a tableau

The construction of a semantic tableau proceeds as follows: Express the premises and negation of the conclusion of an argument in PC using only negation ($\sim$) and disjunction ($\vee$) as propositional connectives. Eliminate every occurrence of two negation signs in a sequence (*e.g.*, $\sim\sim\sim\sim\sim a$ becomes $\sim a$). Now construct a tree diagram branching downward such that each disjunction is replaced by two branches, one for the left disjunct and one for the right. The original disjunction is true if either branch is true. Reference to De Morgan's laws shows that a negation of a disjunction is true just in case the negations of both disjuncts are true (*i.e.*, $\sim(p \vee q) \equiv (\sim p \cdot \sim q)$). This semantic observation leads to the rule that the negation of a disjunction becomes one branch containing the negation of each disjunct:

$$\begin{array}{c} \sim(a \vee b) \\ | \\ \sim a \\ \sim b \end{array}$$

Consider the following argument:

$$\begin{array}{l} a \vee b \\ \underline{\sim a} \\ b \end{array}$$

Write:

$$\begin{array}{l} a \vee b \\ \sim a \\ \sim b \end{array}$$

Now strike out the disjunction and form two branches:

$$\begin{array}{ccc} \sim a & & \\ \sim b & & \\ / & \backslash & \\ a & & b \end{array}$$

Only if all the sentences in at least one branch are true is it possible for the original premises to be true and the conclusion false (equivalently for the negation of the conclusion). By tracing the line upward in each branch to the top of the tree, one observes that no valuation of a in the left branch will result in all the sentences in that branch receiving the value true (because of the presence of a and $\sim a$). Similarly, in the right branch the presence of b and $\sim b$ makes it impossible for a valuation to result in all the sentences of the branch receiving the value true. These are all the possible branches; thus, it is impossible to find a situation in which the premises are true and the conclusion false. The original argument is therefore valid.

This technique can be extended to deal with other connectives:

$$\begin{array}{c} (a \cdot b) \\ | \\ a \\ b \end{array} \qquad \begin{array}{ccc} \sim(a \cdot b) & & \\ / & \backslash & \\ \sim a & & \sim b \end{array}$$

$$\begin{array}{ccc} a \supset b & & \\ / & \backslash & \\ \sim a & & b \end{array} \qquad \begin{array}{c} \sim(a \supset b) \\ | \\ a \\ \sim b \end{array}$$

Furthermore, in LPC, rules for instantiating quantified wffs need to be introduced. Clearly, any branch containing both $(\forall x)\varphi x$ and $\sim\varphi y$ is one in which not all the sentences in that branch can be simultaneously satisfied (under the assumption of ω-consistency; see below *Metalogic*). Again, if all the branches fail to be simultaneously satisfiable, the original argument is valid.

Special systems of LPC. LPC as expounded above may be modified by either restricting or extending the range of wffs in various ways.

1. Partial systems of LPC. Some of the more important systems produced by restriction are here outlined:

Monadic LPC and subsystem

   a. It may be required that every predicate variable be monadic, while still allowing an infinite number of individual and predicate variables. The atomic wffs are then simply those consisting of a predicate variable followed by a single individual variable. Otherwise, the formation rules remain as before, and the definition of validity is also as before, though simplified in obvious ways. This system is known as the monadic LPC; it provides a logic of properties but not of relations. One important characteristic of this system is that it is decidable. (The introduction of even a single dyadic predicate variable, however, would make the system undecidable, and, in fact, even the system that contains only a single dyadic predicate variable and no other predicate variables at all has been shown to be undecidable.)

   b. A still simpler system can be formed by requiring (1) that every predicate variable be monadic, (2) that only a single individual variable (*e.g.*, x) be used, (3) that every occurrence of this variable be bound, and (4) that no quantifier occur within the scope of any other. Examples of wffs of this system are $(\forall x)[\varphi x \supset (\psi x \cdot \chi x)]$ ("Whatever is φ is both ψ and χ"); $(\exists x)(\varphi x \cdot \sim\psi x)$ ("There is something that is φ but not ψ"); and $(\forall x)(\varphi x \supset \psi x) \supset (\exists x)(\varphi x \cdot \psi x)$ ("If whatever is φ is ψ, then something is both φ and ψ"). The notation for this system can be simplified by omitting x everywhere and writing $\exists\varphi$ for "Something is φ," $\forall(\varphi \supset \psi)$ for "Whatever is φ is ψ," and so on. Although this system is more rudimentary even than the monadic LPC (of which it is a fragment), the forms of a wide range of inferences can be represented in it. It is also a decidable system, and decision procedures of an elementary kind can be given for it.

2. Extensions of LPC. More elaborate systems, in which a wider range of propositions can be expressed, have been constructed, by adding to LPC new symbols of various types. The most straightforward of such additions are:

   a. One or more individual constants (say $a, b, \ldots$): these constants are interpreted as names of specific individuals; formally they are distinguished from individual variables by the fact that they cannot occur within quantifiers: *e.g.*, $(\forall x)$ is a quantifier but $(\forall a)$ is not.

   b. One or more predicate constants (say $A, B, \ldots$), each of some specified degree, thought of as designating specific properties or relations.

Definitions: "function," "degree," "term"

A further possible addition, which calls for somewhat fuller explanation, consists of symbols designed to stand for functions. The notion of a function may be sufficiently explained for present purposes as follows: There is said to be a certain function of n arguments (or, of degree n) when there is a rule that specifies a unique object (called the value of the function) whenever all the arguments are specified. In the domain of human beings, for example, "the mother of —" is a monadic function (a function of one argument), since for every human being there is a unique individual who is his mother; and in the domain of the natural numbers (*i.e.*, 0, 1, 2, . . .), "the sum of — and —" is a function of two arguments, since for any pair of natural numbers there is a natural number that is their sum. A function symbol can be thought of as forming a name out of other names (its arguments): thus, whenever x and y name numbers, "the sum of x and y" also names a number, and similarly for other kinds of functions and arguments.

To enable functions to be expressed in LPC there may be added:

   c. One or more function variables (say $f, g, \ldots$) or one or more function constants (say, $F, G, \ldots$) or both, each of some specified degree. The former are interpreted as ranging over functions of the degrees specified, and the latter as designating specific functions of that degree.

When any or all of *a*–*c* are added to LPC, the formation rules listed in the first paragraph of the section *The lower predicate calculus* need to be modified to enable the new symbols to be incorporated into wffs. This can be done as follows: A term is first defined as either (1) an individual variable or (2) an individual constant or (3) any expression formed by prefixing a function variable or function constant of degree n to any n terms (these terms—the arguments of the function symbol—are usually separated by commas and enclosed in parentheses). Formation rule 1 is then replaced by:

1′. An expression consisting of a predicate variable or predicate constant of degree n followed by n terms is a wff.

The axiomatic basis given in *Axiomatization of LPC* also requires the following modification: in axiom schema 2 any term is allowed to replace **a** when β is formed, provided that no variable that is free in the term becomes bound in β. The following examples will illustrate the use of the aforementioned additions to LPC: Let the values of the individual variables be the natural numbers; let the individual constants a and b stand for the numbers 2 and 3, respectively; let A mean "is prime"; and let F represent the dyadic function "the sum of." Then $AF(a,b)$ expresses the proposition "The sum of 2 and 3 is prime," and $(\exists x)$ $AF(x,a)$ expresses the proposition "There exists a number such that the sum of it and 2 is prime."

Special axioms

The introduction of constants is normally accompanied by the addition, to the axiomatic basis, of special axioms containing those constants, designed to express principles that hold of the objects, properties, relations, or functions represented by them—though they do not hold of objects, properties, relations, or functions in general. It may be decided, for example, to use the constant A to represent the dyadic relation "is greater than" (so that Axy is to mean "x is greater than y," and so forth). This relation, unlike many others, is transitive; *i.e.*, if one object is greater than a second and that second is in turn greater than a third, then the first is greater than the third. Hence, the following special axiom schema might be added: If t_1, t_2, and t_3 are any terms, then

$$(At_1t_2 \cdot At_2t_3) \supset At_1t_3$$

is an axiom. By such means systems can be constructed to express the logical structures of various particular disciplines. The area in which most work of this kind has been done is that of natural-number arithmetic (see below *Axiomatization of arithmetic*).

PC and LPC are sometimes combined into a single system. This may be done most simply by adding propositional variables to the list of LPC primitives, adding a formation rule to the effect that a propositional variable standing alone is a wff, and deleting "LPC" in axiom schema 1. This yields as wffs such expressions as $(p \vee q) \supset (\forall x)\varphi x$ and $(\exists x)[p \supset (\forall y)\varphi xy]$.

3. LPC-with-identity. The word "is" is not always used in the same way. In a proposition such as (1) "Socrates is snub-nosed," the expression preceding the "is" names an individual and the expression following it stands for a property attributed to that individual. But, in a proposition such as (2) "Socrates is the Athenian philosopher who drank hemlock," the expressions preceding and following the "is" both name individuals, and the sense of the whole proposition is that the individual named by the first is the same individual as the individual named by the second. Thus in (2) "is" can be expanded to "is the same individual as," whereas in (1) it cannot. As used in (2), "is" stands for a dyadic relation—namely, identity—that the propo-

Identity propositions

sition asserts to hold between the two individuals. An identity proposition is to be understood in this context as asserting no more than this; in particular it is not to be taken as asserting that the two naming expressions have the same meaning. A much discussed example to illustrate this last point is "The morning star is the evening star." It is false that the expressions "the morning star" and "the evening star" mean the same, but true that the object referred to by the former is the same as that referred to by the latter.

To enable the forms of identity propositions to be expressed, a dyadic predicate constant is added to LPC, for which the most usual notation is = (written between, rather than before, its arguments). The intended interpretation of $x = y$ is that x is the same individual as y, and the most convenient reading is "x is identical with y." Its negation $\sim(x = y)$ is commonly abbreviated to $x \neq y$. To the definition of an LPC model in *Validity in LPC* there is now added the rule (which accords in an obvious way with the intended interpretation) that the value of $x = y$ is to be 1 if the same member of D is assigned to both x and y and that otherwise its value is to be 0; validity can then be defined as before. The following additions (or some equivalent ones) are made to the axiomatic basis for LPC: the axiom (I1) $x = x$ and the axiom schema (I2) that, where **a** and **b** are any individual variables and α and β are wffs that differ only in that, at one or more places where α has a free occurrence of a, β has a free occurrence of **b**, $(\mathbf{a} = \mathbf{b}) \supset (\alpha \supset \beta)$ is an axiom. Such a system is known as a lower-predicate-calculus-with-identity; it may of course be further augmented in the other ways referred to above in *Extensions of LPC*, in which case any term may be an argument of =.

Identity is an equivalence relation; *i.e.*, it is reflexive, symmetrical, and transitive. Its reflexivity is directly expressed in axiom I1, and theorems expressing its symmetry and transitivity can easily be derived from the basis given.

Numerical quantification

Certain wffs of LPC-with-identity express propositions about the number of things that possess a given property. "At least one thing is φ" could, of course, already be expressed by $(\exists x)\varphi x$; "At least two distinct (nonidentical) things are φ" can now be expressed by $(\exists x)(\exists y)(\varphi x \cdot \varphi y \cdot x \neq y)$; and the sequence can be continued in an obvious way. "At most one thing is φ," (*i.e.*, "No two distinct things are both φ") can be expressed by the negation of the last mentioned wff or by its equivalent, $(\forall x)(\forall y)[(\varphi x \cdot \varphi y) \supset x = y]$, and the sequence can again be easily continued. A formula for "Exactly one thing is φ" may be obtained by conjoining the formulas for "At least one thing is φ" and "At most one thing is φ," but a simpler wff equivalent to this conjunction is $(\exists x)[\varphi x \cdot (\forall y)(\varphi y \supset x = y)]$, which means "There is something that is φ, and anything that is φ is that thing." The proposition "Exactly two things are φ" can be represented by

$$(\exists x)(\exists y)\{\varphi x \cdot \varphi y \cdot x \neq y \cdot (\forall z)[\varphi z \supset (z = x \vee z = y)]\};$$

i.e., "There are two nonidentical things each of which is φ, and anything that is φ is one or the other of these." Clearly, this sequence can also be extended to give a formula for "Exactly n things are φ" for every natural number n. It is convenient to abbreviate the wff for "Exactly one thing is φ" to $(\exists!x)\varphi x$. This special quantifier is frequently read aloud as "E-Shriek x."

Definite descriptions

When a certain property φ belongs to one and only one object, it is convenient to have an expression that names that object. A common notation for this purpose is $(\imath x)\varphi x$, which may be read as "the thing that is φ" or more briefly as "the φ." In general, where a is any individual variable and α is any wff, $(\imath a)\alpha$ then stands for the single value of a that makes α true. An expression of the form "the so-and-so" is called a definite description; and $(\imath x)$, known as a description operator, can be thought of as forming a name of an individual out of a proposition form. $(\imath x)$ is analogous to a quantifier in that, when prefixed to a wff α, it binds every free occurrence of x in α. Relettering of bound variables is also permissible: in the simplest case, $(\imath x)\varphi x$ and $(\imath y)\varphi y$ can each be read simply as "the φ."

As far as formation rules are concerned, definite descriptions can be incorporated into LPC by letting expressions of the form $(\imath\mathbf{a})\alpha$ count as terms; rule 1′ of *Extensions of LPC* will then allow them to occur in atomic formulas (including identity formulas). "The φ is (*i.e.*, has the property) ψ" can then be expressed as $\psi(\imath x)\varphi x$; "y is (the same individual as) the φ" as $y = (\imath x)\varphi x$; "The φ is (the same individual as) the ψ" as $(\imath x)\varphi x = (\imath y)\psi y$; and so forth. The correct analysis of propositions containing definite descriptions has been the subject of considerable philosophical controversy. One widely accepted account, however—substantially that presented in *Principia Mathematica* and known as Russell's theory of descriptions, after Bertrand Russell—holds that "The φ is ψ" is to be understood as meaning that exactly one thing is φ and that thing is also ψ. In that case it can be expressed by a wff of LPC-with-identity that contains no description operators—namely,

$$(\exists x)[\varphi x \cdot (\forall y)(\varphi y \supset x = y) \cdot \psi x]. \tag{1}$$

Analogously, "y is the φ" is analyzed as "y is φ and nothing else is φ," and hence as expressible by

$$\varphi y \cdot (\forall x)(\varphi x \supset x = y); \tag{2}$$

and "The φ is the ψ" is analyzed as "Exactly one thing is φ, exactly one thing is ψ, and whatever is φ is ψ," and hence as expressible by

$$(\exists x)[\varphi x \cdot (\forall y)(\varphi y \supset x = y)] \cdot (\exists x)[\psi x \cdot (\forall y)(\psi y \supset x = y)] \cdot (\forall x)(\varphi x \supset \psi x) \tag{3}$$

$\psi(\imath x)\varphi x$, $y = (\imath x)\varphi x$ and $(\imath x)\varphi x = (\imath y)\psi y$ can then be regarded as abbreviations for (1), (2), and (3), respectively; and by generalizing to more complex cases, all wffs that contain description operators can be regarded as abbreviations for longer wffs that do not.

Negations with differing scopes

The analysis that leads to (1) as a formula for "The φ is ψ" leads to the following for "The φ is not ψ":

$$(\exists x)[\varphi x \cdot (\forall y)(\varphi y \supset x = y) \cdot \sim\psi x]. \tag{4}$$

It is important to note that (4) is not the negation of (1); this negation is, instead,

$$\sim(\exists x)[\varphi x \cdot (\forall y)(\varphi y \supset x = y) \cdot \psi x]. \tag{5}$$

The difference in meaning between (4) and (5) lies in the fact that (4) is true only when there is exactly one thing that is φ and that thing is not ψ, but (5) is true both in this case and also when nothing is φ at all and when more than one thing is φ. Neglect of the distinction between (4) and (5) can result in serious confusion of thought: in ordinary speech it is frequently unclear whether someone who denies that the φ is ψ is conceding that exactly one thing is φ but denying that it is ψ, or denying that exactly one thing is φ.

The basic contention of Russell's theory of descriptions is that a proposition containing a definite description is not to be regarded as an assertion about an object of which that description is a name but rather as an existentially quantified assertion that a certain (rather complex) property has an instance. Formally, this is reflected in the rules for eliminating description operators that were outlined above.

Higher-order predicate calculi. A feature shared by LPC and all its extensions so far mentioned is that the only variables that occur in quantifiers are individual variables. It is in virtue of this feature that they are called lower (or first-order) calculi. Various predicate calculi of higher order can be formed, however, in which quantifiers may contain other variables as well, hence binding all free occurrences of these that lie within their scope. In particular, in the second-order predicate calculus, quantification is permitted over both individual and predicate variables; hence wffs such as $(\forall\varphi)(\exists x)\varphi x$ can be formed. This last formula, since it contains no free variables of any kind, expresses a determinate proposition—namely, the proposition that every property has at least one instance. One important feature of this system is that in it identity need not be taken as primitive but can be introduced by defining $x = y$ as $(\forall\varphi)(\varphi x \equiv \varphi y)$—*i.e.*, "Every property possessed by x is also possessed by y and vice versa." Whether such a definition is acceptable as a general account of identity

Binding of predicate variables

is a question that raises philosophical issues too complex to be discussed here; they are substantially those raised by the principle of the identity of indiscernibles, best known for its exposition in the 17th century by Leibniz.

(G.E.H./M.L.Sc.)

MODAL LOGIC

True propositions can be divided into those—like "2 + 2 = 4"—that are true by logical necessity (necessary propositions), and those—like "France is a republic"—that are not (contingently true propositions). Similarly, false propositions can be divided into those—like "2 + 2 = 5"—that are false by logical necessity (impossible propositions), and those—like "France is a monarchy"—that are not (contingently false propositions). Contingently true and contingently false propositions are known collectively as contingent propositions. A proposition that is not impossible (*i.e.*, one that is either necessary or contingent) is said to be a possible proposition. Intuitively, the notions of necessity and possibility are connected in the following way: to say that a proposition is necessary is to say that it is not possible for it to be false; and to say that a proposition is possible is to say that it is not necessarily false.

If it is logically impossible for a certain proposition, p, to be true without a certain proposition, q, being also true (*i.e.*, if the conjunction of p and not-q is logically impossible), then it is said that p strictly implies q. An alternative, equivalent way of explaining the notion of strict implication is by saying that p strictly implies q if and only if it is necessary that p materially implies q. "John's tie is scarlet," for example, strictly implies "John's tie is red," because it is impossible for John's tie to be scarlet without being red (or: it is necessarily true that if John's tie is scarlet it is red); and in general, if p is the conjunction of the premises, and q the conclusion, of a deductively valid inference, p will strictly imply q.

The notions just referred to—necessity, possibility, impossibility, contingency, strict implication—and certain other closely related ones are known as modal notions, and a logic designed to express principles involving them is called a modal logic.

The most straightforward way of constructing such a logic is to add to some standard nonmodal system a new primitive operator intended to represent one of the modal notions mentioned above, to define other modal operators in terms of it, and to add certain special axioms or transformation rules or both. A great many systems of modal logic have been constructed, but attention will be restricted here to a few closely related ones in which the underlying nonmodal system is ordinary PC.

Alternative systems of modal logic. All the systems to be considered here have the same wffs but differ in their axioms. The wffs can be specified by adding to the symbols of PC a primitive monadic operator L and to the formation rules of PC the rule that if α is a wff, so is $L\alpha$. L is intended to be interpreted as "It is necessary that," so that Lp will be true if and only if p is a necessary proposition. The monadic operator M and the dyadic operator $\dashv\!\supset$ (to be interpreted as "It is possible that" and "strictly implies," respectively) can then be introduced by the following definitions, which reflect in an obvious way the informal accounts given above of the connections between necessity, possibility, and strict implication: if α is any wff, then $M\alpha$ is to be an abbreviation of $\sim L\sim\alpha$; and if α and β are any wffs, then $\alpha \dashv\!\supset \beta$ is to be an abbreviation of $L(\alpha \supset \beta)$ [or alternatively of $\sim M(\alpha \cdot \sim\beta)$].

The system **T**

The modal system known as **T** has as axioms some set of axioms adequate for PC (such as those of PM), and in addition

1. $Lp \supset p$
2. $L(p \supset q) \supset (Lp \supset Lq)$

Axiom 1 expresses the principle that whatever is necessarily true is true, and 2 the principle that, if q logically follows from p, then, if p is a necessary truth, so is q (*i.e.*, that whatever follows from a necessary truth is itself a necessary truth). These two principles seem to have a high degree of intuitive plausibility, and 1 and 2 are theorems in almost all modal systems. The transformation rules of **T** are uniform substitution, modus ponens, and a rule to the effect that if α is a theorem so is $L\alpha$ (the rule of necessitation). The intuitive rationale of this rule is that, in a sound axiomatic system, it is expected that every instance of a theorem α will be not merely true but necessarily true—and in that case every instance of $L\alpha$ will be true.

Among the simpler theorems of **T** are

$p \supset Mp$,
$L(p \cdot q) \equiv (Lp \cdot Lq)$,
$M(p \vee q) \equiv (Mp \vee Mq)$,
$(Lp \vee Lq) \supset L(p \vee q)$ (but not its converse),
$M(p \cdot q) \supset (Mp \cdot Mq)$ (but not its converse),

and

$LMp \equiv \sim ML\sim p$,
$(p \dashv\!\supset q) \supset (Mp \supset Mq)$,
$(\sim p \dashv\!\supset p) \equiv Lp$,
$L(p \vee q) \supset (Lp \vee Mq)$.

There are many modal formulas that are not theorems of **T** but that have a certain claim to express truths about necessity and possibility. Among them are

$$Lp \supset LLp,\ Mp \supset LMp, \text{ and } p \supset LMp.$$

The first of these means that if a proposition is necessary, its being necessary is itself a necessary truth; the second means that if a proposition is possible, its being possible is a necessary truth; and the third means that if a proposition is true, then not merely is it possible but its being possible is a necessary truth. These are all various elements in the general thesis that a proposition's having the modal characteristics it has (such as necessity, possibility) is not a contingent matter but is determined by logical considerations. Although this thesis may be philosophically controversial, it is at least plausible, and its consequences are worth exploring. One way of exploring them is to construct modal systems in which the formulas listed above are theorems. None of these formulas, as was said, is a theorem of **T**; but each could be consistently added to **T** as an extra axiom to produce a new and more extensive system. The system obtained by adding $Lp \supset LLp$ to **T** is known as **S4**; that obtained by adding $Mp \supset LMp$ to **T** is known as **S5**; and the addition of $p \supset LMp$ to **T** gives the Brouwerian system, here called **B** for short.

The systems **S4, S5,** and **B**

The relations between these four systems are as follows: **S4** is stronger than **T**—*i.e.*, it contains all the theorems of **T** and others besides. **B** is also stronger than **T**. **S5** is stronger than **S4** and also stronger than **B**. **S4** and **B**, however, are independent of each other in the sense that each contains some theorems that the other does not have. It is of particular importance that if $Mp \supset LMp$ is added to **T** then $Lp \supset LLp$ can be derived as a theorem but that if one merely adds the latter to **T** the former cannot then be derived.

Examples of theorems of **S4** that are not theorems of **T** are $Mp \equiv MMp$, $MLMp \supset Mp$, and $(p \dashv\!\supset q) \supset (Lp \dashv\!\supset Lq)$. Examples of theorems of **S5** that are not theorems of **S4** are $Lp \equiv MLp$, $L(p \vee Mq) \equiv (Lp \vee Mq)$, $M(p \cdot Lq) \equiv (Mp \cdot Lq)$, and $(Lp \dashv\!\supset Lq) \vee (Lq \dashv\!\supset Lp)$. One important feature of **S5** but not of the other systems mentioned is that any wff that contains an unbroken sequence of monadic modal operators (Ls or Ms or both) is provably equivalent to the same wff with all these operators deleted except the last.

Considerations of space preclude an account of the many other axiomatic systems of modal logic that have been investigated. Some of these are weaker than **T**; such systems normally contain the axioms of **T** either as axioms or as theorems but have only a restricted form of the rule of necessitation. Another group comprises systems that are stronger than **S4** but weaker than **S5**; some of these have proved fruitful in developing a logic of temporal relations. Yet another group includes systems that are stronger than **S4** but independent of **S5** in the sense explained above.

Modal predicate logics can be formed also by making analogous additions to LPC instead of to PC.

Validity in modal logic. The task of defining validity for modal wffs is complicated by the fact that, even if the truth values of all of the variables in a wff are given, it is not obvious how one should set about calculating the truth value of the whole wff. Nevertheless, a number of defini-

tions of validity applicable to modal wffs have been given, each of which turns out to match some axiomatic modal system, in the sense that it brings out as valid those wffs, and no others, that are theorems of that system. Most, if not all, of these accounts of validity can be thought of as variant ways of giving formal precision to the idea that necessity is truth in every "possible world" or "conceivable state of affairs." The simplest such definition is this:

Models for the four systems

Let a model be constructed by first assuming a (finite or infinite) set W of "worlds." In each world, independently of all the others, let each propositional variable then be assigned either the value 1 or the value 0. In each world the values of truth functions are calculated in the usual way from the values of their arguments in that world. In each world, however, $L\alpha$ is to have the value 1 if α has the value 1 not only in that world but in every other world in W as well and is otherwise to have the value 0; and in each world $M\alpha$ is to have the value 1 if α has value 1 either in that world or in some other world in W and is otherwise to have the value 0. These rules enable one to calculate a value (1 or 0) in any world in W for any given wff, once the values of the variables in each world in W are specified. A model is defined as consisting of a set of worlds together with a value assignment of the kind just described. A wff is valid if and only if it has the value 1 in every world in every model. It can be proved that the wffs that are valid by this criterion are precisely the theorems of **S5**; for this reason models of the kind here described may be called **S5**-models, and validity as just defined may be called **S5**-validity.

A definition of **T**-validity (*i.e.,* one that can be proved to bring out as valid precisely the theorems of **T**) can be given as follows: a T-model consists of a set of worlds W and a value assignment to each variable in each world, as before. It also includes a specification, for each world in W, of some subset of W as the worlds that are "accessible" to that world. Truth functions are evaluated as before; but in each world in the model, $L\alpha$ is to have the value 1 if α has value 1 in that world and in every other world in W accessible to it and is otherwise to have value 0. And in each world, $M\alpha$ is to have the value 1 if α has value 1 either in that world or in some other world accessible to it and is otherwise to have value 0. (In other words, in computing the value of $L\alpha$ or $M\alpha$ in a given world, no account is taken of the value of α in any other world not accessible to it.) A wff is **T**-valid if and only if it has the value 1 in every world in every T-model.

An **S4**-model is defined as is a T-model except that it is required that the accessiblity relation be transitive—*i.e.,* that, where w_1, w_2, and w_3 are any worlds in W, if w_1 is accessible to w_2 and w_2 is accessible to w_3, then w_1 is accessible to w_3. A wff is **S4**-valid if and only if it has the value 1 in every world in every **S4**-model. The **S4**-valid wffs can be shown to be precisely the theorems of **S4**. Finally, a definition of validity is obtained that will match the system **B** by requiring that the accessibility relation be symmetrical but not that it be transitive.

Adaptations to other systems

For all four systems, effective decision procedures for validity can be given. Further modifications of the general method described have yielded validity definitions that match many other axiomatic modal systems, and the method can be adapted to give a definition of validity for intuitionistic PC. For a number of axiomatic modal systems, however, no satisfactory account of validity has been devised. Validity can also be defined for various modal predicate logics by combining the definition of LPC-validity given above in *Validity in LPC* with the relevant accounts of validity for modal systems, but a modal logic based on LPC is, like LPC itself, an undecidable system.

SET THEORY

Only a sketchy account of set theory is given here; for further information see the article SET THEORY. Set theory is a logic of classes—*i.e.,* of collections (finite or infinite) or aggregations of objects of any kind, which are known as the members of the classes in question. Some logicians use the terms "class" and "set" interchangeably; others distinguish between them, defining a set (for example) as a class that is itself a member of some class and defining a proper class as one that is not a member of any class. It is usual to write "$\in$" for "is a member of" and to abbreviate $\sim(x \in y)$ to $x \notin y$. A particular class may be specified either by listing all its members or by stating some condition of membership, in which (latter) case the class consists of all those things and only those that satisfy that condition (it is used, for example, when one speaks of the class of inhabitants of London or the class of prime numbers). Clearly, the former method is available only for finite classes and may be very inconvenient even then; the latter, however, is of more general applicability. Two classes that have precisely the same members are regarded as the same class or are said to be identical with each other, even if they are specified by different conditions; *i.e.,* identity of classes is identity of membership, not identity of specifying conditions. This principle is known as the principle of extensionality. A class with no members, such as the class of Chinese popes, is said to be null. Since the membership of all such classes is the same, there is only one null class, which is therefore usually called *the* null class (or sometimes the empty class); it is symbolized by Λ or $\varnothing$. The notation $x = y$ is used for "x is identical with y," and $\sim(x = y)$ is usually abbreviated to $x \neq y$. The expression $x = \Lambda$ therefore means that the class x has no members, and $x \neq \Lambda$ means that x has at least one member.

Interrelations of classes

A member of a class may itself be a class. The class of dogs, for example, is a member of the class of species of animals. An individual dog, however, though a member of the former class, is not a member of the latter—because an individual dog is not a species of animal (if the number of dogs increases, the number of species of animals does not thereby increase). Class membership is therefore not a transitive relation. The relation of class inclusion, however (to be carefully distinguished from class membership), is transitive. A class x is said to be included in a class y (written: $x \subseteq y$) if and only if every member of x is also a member of y. (This is not meant to exclude the possibility that x and y may be identical.) If x is included in, but is not identical with, y—*i.e.,* if every member of x is a member of y but some members of y are not members of x—x is said to be properly included in y (written: $x \subset y$).

It is perhaps natural to assume that for every statable condition there is a class (null or otherwise) of objects that satisfy that condition. This assumption is known as the principle of comprehension. In the unrestricted form just mentioned, however, this principle has been found to lead to inconsistencies and hence cannot be accepted as it stands. One statable condition, for example, is non-self-membership—*i.e.,* the property possessed by a class if and only if it is not a member of itself. This in fact appears to be a condition that most classes do fulfill; the class of dogs, for example, is not itself a dog and hence is not a member of the class of dogs.

Let it now be assumed that the class of all classes that are not members of themselves can be formed and let this class be y. Then any class x will be a member of y if and only if it is not a member of itself; *i.e.,* for any class x, $(x \in y) \equiv (x \notin x)$. The question can then be asked whether y is a member of itself or not, with the following awkward result: If it is a member of itself, then it fails to fulfill the condition of membership of y, and hence it is not a member of y—*i.e.,* not a member of itself. On the other hand, if y is not a member of itself, then it does fulfill the required condition, and therefore it is a member of y—*i.e.,* of itself. Hence the equivalence $(y \in y) \equiv (y \notin y)$ results, which is self-contradictory. This perplexing conclusion, which was pointed out by Bertrand Russell, is known as Russell's paradox. Russell's own solution to it and to other similar difficulties was to regard classes as forming a hierarchy of types and to posit that a class could only be regarded sensibly as a member, or a nonmember, of a class at the next higher level in the hierarchy. The effect of this theory is to make $x \in x$, and therefore $x \notin x$, ill-formed. Another kind of solution, however, is based upon the distinction made earlier between two kinds of classes, those that are sets and those that are not—a set being defined as a class that is itself a member of some class. The unrestricted principle of comprehension is then replaced by the weaker principle that for every condition

Russell's paradox: theory of types

there is a class the members of which are the individuals or sets that fulfill that condition. Other solutions have also been devised, but none has won universal acceptance, with the result that several different versions of set theory are found in the literature of the subject.

Formally, set theory can be derived by the addition of various special axioms to a rather modest form of LPC that contains no predicate variables and only a single primitive dyadic predicate constant ($\in$) to represent membership. Sometimes LPC-with-identity is used, and there are then two primitive dyadic predicate constants ($\in$ and $=$). In some versions the variables $x, y, \ldots$ are taken to range only over sets or classes; in other versions they range over individuals as well. The special axioms vary, but the basis normally includes the principle of extensionality and some restricted form of the principle of comprehension, or some elements from which these can be deduced.

Notation, definitions, theorems

A notation to express theorems about classes can be either defined in various ways (not detailed here) in terms of the primitives mentioned above or else introduced independently. The main elements of one widely used notation are the following: if α is an expression containing some free occurrence of x, the expression $\{x : \alpha\}$ is used to stand for the class of objects fulfilling the condition expressed by α—*e.g.*, $\{x : x$ is a prime number$\}$ represents the class of prime numbers; $\{x\}$ represents the class the only member of which is x; $\{x, y\}$ the class the only members of which are x and y; and so on. $\langle x, y\rangle$ represents the class the members of which are x and y in that order (thus $\{x, y\}$ and $\{y, x\}$ are identical; but $\langle x, y\rangle$ and $\langle y, x\rangle$ are in general not identical). Let x and y be any classes, as (for example) those of the dots on the two arms of a stippled cross. The intersection of x and y, symbolized as $x \cap y$, is the class the members of which are the objects common to x and y—in this case the dots within the area where the arms cross—*i.e.*, $\{z : z \in x \cdot z \in y\}$. Similarly, the union of x and y, symbolized as $x \cup y$, is the class the members of which are the members of x together with those of y—in this case all the dots on the cross—*i.e.*, $\{z : z \in x \vee z \in y\}$; the complement of x, symbolized as $-x$, is the class the members of which are all those objects that are not members of x—*i.e.*, $\{y : y \notin x\}$; the complement of y in x, symbolized as $x - y$, is the class of all objects that are members of x but not of y—*i.e.*, $\{z : z \in x \cdot z \notin y\}$; the universal class, symbolized as V, is the class of which everything is a member, definable as the complement of the null class—*i.e.*, as $-\Lambda$. Λ itself is sometimes taken as a primitive individual constant, sometimes defined as $\{x : x \neq x\}$—the class of objects that are not identical with themselves.

Among the simpler theorems of set theory are

$$(\forall x)(x \cap x = x),$$
$$(\forall x)(\forall y)(x \cap y = y \cap x);$$

and corresponding theorems for $\cup$:

$$(\forall x)(\forall y)(\forall z)[x \cap (y \cup z) = (x \cap y) \cup (x \cap z)],$$
$$(\forall x)(\forall y)[-(x \cap y) = -x \cup -y];$$

and corresponding theorems with $\cap$ and $\cup$ interchanged:

$$(\forall x)(- -x = x),$$
$$(\forall x)(\forall y)(x - y = x \cap -y),$$
$$(\forall x)(\Lambda \subset x),$$
$$(\forall x)(x \cap \Lambda = \Lambda),$$
$$(\forall x)(x \cup \Lambda = x).$$

In these theorems, the variables range over classes. In several cases, there are obvious analogies to valid wffs of PC.

Apart from its own intrinsic interest, set theory has an importance for the foundations of mathematics in that it is widely held that the natural numbers can be adequately defined in set-theoretic terms. Moreover, given suitable axioms, standard postulates for natural-number arithmetic can be derived as theorems within set theory.

Metalogic

Metalogic is the study of the syntax and the semantics of formal languages and formal systems. It is related to, but does not include, the formal treatment of natural languages. (For a discussion of the syntax and semantics of natural languages, see the article LINGUISTICS.)

NATURE, ORIGINS, AND INFLUENCES OF METALOGIC

Syntax and semantics. A formal language usually requires a set of formation rules—*i.e.*, a complete specification of the kinds of expressions that shall count as well-formed formulas (sentences or meaningful expressions), applicable mechanically, in the sense that a machine could check whether a candidate satisfies the requirements. This specification usually contains three parts: (1) a list of primitive symbols (basic units) given mechanically, (2) certain combinations of these symbols, singled out mechanically as forming the simple (atomic) sentences, and (3) a set of inductive clauses—inductive inasmuch as they stipulate that natural combinations of given sentences formed by such logical connectives as the disjunction "or," which is symbolized "$\vee$"; "not," symbolized "$\sim$"; and "for all ___," symbolized "$(\forall$ ___$)$," are again sentences. ["$(\forall$ ___$)$" is called a quantifier, as is also "there is some ___," symbolized "$(\exists$ ___$)$".] Since these specifications are concerned only with symbols and their combinations and not with meanings, they involve only the syntax of the language.

Specification of a formal language

An interpretation of a formal language is determined by formulating an interpretation of the atomic sentences of the language with regard to a domain of objects—*i.e.*, by stipulating which objects of the domain are denoted by which constants of the language and which relations and functions are denoted by which predicate letters and function symbols. The truth-value (whether "true" or "false") of every sentence is thus determined according to the standard interpretation of logical connectives. For example, $p \cdot q$ is true if and only if p and q are true. (Here, the dot means the conjunction "and," not the multiplication operation "times.") Thus, given any interpretation of a formal language, a formal concept of truth is obtained. Truth, meaning, and denotation are semantic concepts.

If, in addition, a formal system in a formal language is introduced, certain syntactic concepts arise—namely, axioms, rules of inference, and theorems. Certain sentences are singled out as axioms. These are (the basic) theorems. Each rule of inference is an inductive clause, stating that, if certain sentences are theorems, then another sentence related to them in a suitable way is also a theorem. If p and "either not-p or q" ($\sim p \vee q$) are theorems, for example, then q is a theorem. In general, a theorem is either an axiom or the conclusion of a rule of inference whose premises are theorems.

In 1931 Gödel made the fundamental discovery that, in most of the interesting (or significant) formal systems, not all true sentences are theorems. It follows from this finding that semantics cannot be reduced to syntax: thus syntax, which is closely related to proof theory, must often be distinguished from semantics, which is closely related to model theory. Roughly speaking, syntax—as conceived in the philosophy of mathematics—is a branch of number theory, and semantics is a branch of set theory, which deals with the nature and relations of aggregates.

Historically, as logic and axiomatic systems became more and more exact, there emerged, in response to a desire for greater lucidity, a tendency to pay greater attention to the syntactic features of the languages employed rather than to concentrate exclusively on intuitive meanings. In this way, logic, the axiomatic method (such as that employed in geometry), and semiotic (the general science of signs) converged toward metalogic.

The axiomatic method. The best known axiomatic system is that of Euclid for geometry. In a manner similar to that of Euclid, every scientific theory involves a body of meaningful concepts and a collection of true or believed assertions. The meaning of a concept can often be explained or defined in terms of other concepts, and, similarly, the truth of an assertion or the reason for believing it can usually be clarified by indicating that it can be deduced from certain other assertions already accepted. The axiomatic method proceeds in a sequence of steps, beginning with a set of primitive concepts and propositions and then defining or deducing all other concepts and propositions in the theory from them.

The realization which arose in the 19th century that there are different possible geometries led to a desire to separate abstract mathematics from spatial intuition; in consequence, many hidden axioms were uncovered in Euclid's geometry. These discoveries were organized into a more rigorous axiomatic system by David Hilbert in his *Grundlagen der Geometrie* (1899; *The Foundations of Geometry*). In this and related systems, however, logical connectives and their properties are taken for granted and remain implicit. If the logic involved is taken to be that of the predicate calculus, the logician can then arrive at such formal systems as that discussed above.

Transformations from semantics to syntax

Once such formal systems are obtained, it is possible to transform certain semantic problems into sharper syntactic problems. It has been asserted, for example, that non-Euclidean geometries must be self-consistent systems because they have models (or interpretations) in Euclidean geometry, which in turn has a model in the theory of real numbers. It may then be asked, however, how it is known that the theory of real numbers is consistent in the sense that no contradiction can be derived within it. Obviously, modeling can establish only a relative consistency and has to come to a stop somewhere. Having arrived at a formal system (say, of real numbers), however, the consistency problem then has the sharper focus of a syntactic problem: that of considering all the possible proofs (as syntactic objects) and asking whether any of them ever has (say) $0 = 1$ as the last sentence.

As another example, the question whether a system is categorical—that is, whether it determines essentially a unique interpretation in the sense that any two interpretations are isomorphic—may be explored. This semantic question can to some extent be replaced by a related syntactic question, that of completeness: whether there is in the system any sentence having a definite truth-value in the intended interpretation such that neither that sentence nor its negation is a theorem. Even though it is now known that the semantic and syntactic concepts are different, the vague requirement that a system be "adequate" is clarified by both concepts. The study of such sharp syntactic questions as those of consistency and completeness, which was emphasized by Hilbert, was named "metamathematics" (or "proof theory") by him about 1920.

Logic and metalogic. In one sense, logic is to be identified with the predicate calculus of the first order, the calculus in which the variables are confined to individuals of a fixed domain—though it may include as well the logic of identity, symbolized "=," which takes the ordinary properties of identity as part of logic. In this sense Gottlob Frege achieved a formal calculus of logic as early as 1879. Sometimes logic is construed, however, as including also higher-order predicate calculi, which admit variables of higher types, such as those ranging over predicates (or classes and relations) and so on. But then it is a small step to the inclusion of set theory, and, in fact, axiomatic set theory is often regarded as a part of logic. For the purposes of this article, however, it is more appropriate to confine the discussion to logic in the first sense.

It is hard to separate out significant findings in logic from those in metalogic, because all theorems of interest to logicians are about logic and therefore belong to metalogic. If p is a mathematical theorem—in particular, one about logic—and P is the conjunction of the mathematical axioms employed for proving p, then every p can be turned into a theorem, "either not-P or p," in logic. Mathematics is not done, however, by carrying out explicitly all the steps as formalized in logic; the selection and intuitive grasp of the axioms is important both for mathematics and for metamathematics. Actual derivations in logic, such as those carried out just prior to World War I by Alfred North Whitehead and Bertrand Russell, are of little intrinsic interest to logicians. It might therefore appear redundant to introduce the term metalogic. In the present classification, however, metalogic is conceived as dealing not only with findings about logical calculi but also with studies of formal systems and formal languages in general.

Formal systems and logical calculi

An ordinary formal system differs from a logical calculus in that the system usually has an intended interpretation, whereas the logical calculus deliberately leaves the possible interpretations open. Thus, one speaks, for example, of the truth or falsity of sentences in a formal system, but with respect to a logical calculus one speaks of validity (*i.e.*, being true in all interpretations or in all possible worlds) and of satisfiability (or having a model—*i.e.*, being true in some particular interpretation). Hence, the completeness of a logical calculus has quite a different meaning from that of a formal system: a logical calculus permits many sentences such that neither the sentence nor its negation is a theorem because it is true in some interpretations and false in others, and it requires only that every valid sentence be a theorem.

Semiotic. Originally, the word "semiotic" meant the medical theory of symptoms; however, an empiricist, John Locke, used the term in the 17th century for a science of signs and significations. The current usage was recommended especially by Rudolf Carnap—see his *Introduction to Semantics* (1942) and his reference there to Charles William Morris, who suggested a threefold distinction. According to this usage, semiotic is the general science of signs and languages, consisting of three parts: (1) pragmatics (in which reference is made to the user of the language), (2) semantics (in which one abstracts from the user and analyzes only the expressions and their meanings), and (3) syntax (in which one abstracts also from the meanings and studies only the relations between expressions).

Considerable effort since the 1970s has gone into the attempt to formalize some of the pragmatics of natural languages. The use of indexical expressions to incorporate reference to the speaker, his or her location, or the time of either the utterance or the events mentioned was of little importance to earlier logicians, who were primarily interested in universal truths or mathematics. With the increased interest in linguistics there has come an increased effort to formalize pragmatics.

At first Carnap exclusively emphasized syntax. But gradually he came to realize the importance of semantics, and the door was thus reopened to many difficult philosophical problems.

Logical positivism and the formalization of science

Certain aspects of metalogic have been instrumental in the development of the approach to philosophy commonly associated with the label of logical positivism. In his *Tractatus Logico-Philosophicus* (1922; originally published under another title, 1921), Ludwig Wittgenstein, a seminal thinker in the philosophy of language, presented an exposition of logical truths as sentences that are true in all possible worlds. One may say, for example, "It is raining or it is not raining," and in every possible world one of the disjuncts is true. On the basis of this observation and certain broader developments in logic, Carnap tried to develop formal treatments of science and philosophy.

It has been thought that the success that metalogic had achieved in the mathematical disciplines could be carried over into physics and even into biology or psychology. In so doing, the logician gives a branch of science a formal language in which there are logically true sentences having universal logical ranges and factually true sentences having universal logical ranges and factually true ones having more restricted ranges. (Roughly speaking, the logical range of a sentence is the set of all possible worlds in which it is true.)

A formal solution of the problem of meaning has also been proposed for these disciplines. Given the formal language of a science, it is possible to define a notion of truth. Such a truth definition determines the truth condition for every sentence—*i.e.*, the necessary and sufficient conditions for its truth. The meaning of a sentence is then identified with its truth condition because, as Carnap wrote:

> To understand a sentence, to know what is asserted by it, is the same as to know under what conditions it would be true. . . . To know the truth condition of a sentence is (in most cases) much less than to know its truth-value, but it is the necessary starting point for finding out its truth-value.

Influences in other directions. Metalogic has led to a great deal of work of a mathematical nature in axiomatic set theory, model theory, and recursion theory (in which functions that are computable in a finite number of steps are studied).

In a different direction, the devising of Turing computing

Turing machines, philosophy of logic, and ontology

machines, involving abstract designs for the explication of mechanical logical procedures, has led to the investigation of idealized computers, with ramifications in the theory of finite automata and mathematical linguistics.

Among philosophers of language, there is a widespread tendency to stress the philosophy of logic. The contrast, for example, between intensional concepts and extensional concepts; the role of meaning in natural languages as providing truth conditions; the relation between formal and natural logic (*i.e.*, the logic of natural languages); and the relation of ontology, the study of the kinds of entities that exist, to the use of quantifiers—all these areas are receiving extensive consideration and discussion. There are also efforts to produce formal systems for empirical sciences such as physics, biology, and even psychology. Many scholars have doubted, however, whether these latter efforts have been fruitful.

NATURE OF A FORMAL SYSTEM AND OF ITS FORMAL LANGUAGE

Example of a formal system. In order to clarify the abstract concepts of metalogic, a formal system N (with its formal language) may be considered for illustration.

Formation rules. The system may be set up by employing the following formation rules:

1. The following are primitive symbols: "~," "∨," "∀," and "=" and the symbols used for grouping, "(" and ")"; the function symbols for "successor," "S," and for arithmetical addition and multiplication, "+" and "·"; constants 0, 1; and variables $x, y, z, \ldots$.
2. The following are terms: a constant is a term; a variable is a term; if a is a term, Sa is a term; and, if a and b are terms, $a + b$ and $a \cdot b$ are terms.
3. Atomic sentences are thus specified: if a and b are terms, $a = b$ is a sentence.
4. Other sentences can be defined as follows: if A and B are sentences and v is a variable, then $\sim A$, $A \vee B$, and $(\forall v)A$ are sentences.

Axioms and rules of inference. The system may be developed by adopting certain sentences as axioms and following certain rules of inference.

1. The basic axioms and rules are to be those of the first-order predicate calculus with identity (see above *Formal logic*).
2. The following additional axioms of N are stipulated:
   a. Zero (0) is not a successor:
   $$\sim Sx = 0$$
   b. No two different numbers have the same successor:
   $$\sim(Sx = Sy) \vee x = y$$
   c. Recursive definition of addition:
   $$x + 0 = x$$
   $$x + Sy = S(x + y)$$
   (From this, with the understanding that 1 is the successor of 0, one can easily show that $Sx = x + 1$.)
   d. Recursive definition of multiplication:
   $$x \cdot 0 = 0$$
   $$x \cdot Sy = (x \cdot y) + x$$
3. Rule of inference (the principle of mathematical induction): If zero has some property p and it is the case that if any number has p then its successor does, then every number has p. With some of the notation from above, this can be expressed: If $A(0)$ and $(\forall x)(\sim A(x) \vee A(Sx))$ are theorems, then $(\forall x)A(x)$ is a theorem.

The system N as specified by the foregoing rules and axioms is a formal system in the sense that, given any combination of the primitive symbols, it is possible to check mechanically whether it is a sentence of N, and, given a finite sequence of sentences, it is possible to check mechanically whether it is a (correct) proof in N—*i.e.*, whether each sentence either is an axiom or follows from preceding sentences in the sequence by a rule of inference. Viewed in this way, a sentence is a theorem if and only if there exists a proof in which it appears as the last sentence. It is not required of a formal system, however, that it be possible to decide mechanically whether or not a given sentence is a theorem; and, in fact, it has been proved that no such mechanical method exists.

Truth definition of the given language. The formal system N admits of different interpretations, according to findings of Gödel (from 1931) and of the Norwegian mathematician Thoralf Skolem, a pioneer in metalogic (from 1933). The originally intended, or standard, interpretation takes the ordinary nonnegative integers $\{0, 1, 2, \ldots\}$ as the domain, the symbols 0 and 1 as denoting zero and one, and the symbols + and · as standing for ordinary addition and multiplication. Relative to this interpretation, it is possible to give a truth definition of the language of N.

Open and closed sentences

It is necessary first to distinguish between open and closed sentences. An open sentence, such as $x = 1$, is one that may be either true or false depending on the value of x, but a closed sentence, such as $0 = 1$ and $(\forall x)(x = 0)$ or "All x's are zero," is one that has a definite truth-value—in this case, false (in the intended interpretation).

1. A closed atomic sentence is true if and only if it is true in the intuitive sense; for example, $0 = 0$ is true, $0 + 1 = 0$ is false.

This specification as it stands is not syntactic, but, with some care, it is possible to give an explicit and mechanical specification of those closed atomic sentences that are true in the intuitive sense.

2. A closed sentence $\sim A$ is true if and only if A is not true.
3. A closed sentence $A \vee B$ is true if and only if either A or B is true.
4. A closed sentence $(\forall v)A(v)$ is true if and only if $A(v)$ is true for every value of v—*i.e.*, if $A(0)$, $A(1)$, $A(1 + 1)$, . . . are all true.

The above definition of truth is not an explicit definition; it is an inductive one. Using concepts from set theory, however, it is possible to obtain an explicit definition that yields a set of sentences that consists of all the true ones and only them. If Gödel's method of representing symbols and sentences by numbers is employed, it is then possible to obtain in set theory a set of natural numbers that are just the Gödel numbers of the true sentences of N.

There is a definite sense in which it is impossible to define the concept of truth within a language itself. This is proved by the liar paradox: if the sentence "I am lying," or alternatively

This sentence is not true. (1)

is considered, it is clear—since (1) is "This sentence"—that if (1) is true, then (1) is false; on the other hand, if (1) is false, then (1) is true. In the case of the system N, if the concept of truth were definable in the system itself, then (using a device invented by Gödel) it would be possible to obtain in N a sentence that amounts to (1) and that thereby yields a contradiction.

DISCOVERIES ABOUT FORMAL MATHEMATICAL SYSTEMS

The two central questions of metalogic are those of the completeness and consistency of a formal system based on axioms. In 1931 Gödel made fundamental discoveries in these areas for the most interesting formal systems. In particular, he discovered that, if such a system is ω-consistent—*i.e.*, devoid of contradiction in a sense to be explained below—then it is not complete and that, if a system is consistent, then the statement of its consistency, easily expressible in the system, is not provable in it.

Recursive functions and decidability

Soon afterward, in 1934, Gödel modified a suggestion that had been offered by Jacques Herbrand, a French mathematician, and introduced a general concept of recursive functions—*i.e.*, of functions mechanically computable by a finite series of purely combinatorial steps. In 1936 Alonzo Church, a mathematical logician, Alan Mathison Turing, originator of a theory of computability, and Emil L. Post, a specialist in recursive unsolvability, all argued for this concept (and certain equivalent notions), thereby arriving at stable and exact conceptions of "mechanical," "computable," "recursive," and "formal" that explicate the intuitive concept of what a mechanical computing procedure is. As a result of the development of recursion theory, it is now possible to prove not only that certain classes of problems are mechanically solvable

(which could be done without the theory) but also that certain others are mechanically unsolvable (or absolutely unsolvable). The most notable example of such unsolvability is the discovery, made in 1970, that there is no algorithm, or rule of repetitive procedure, for determining which Diophantine equations (*i.e.,* polynomial equations of which the coefficients are whole numbers) have integer solutions. This solution gives a negative solution to the 10th problem in the famous list presented by Hilbert at the International Mathematical Congress in 1900.

In this way, logicians have finally arrived at a sharp concept of a formal axiomatic system, because it is no longer necessary to leave "mechanical" as a vague nonmathematical concept. In this way, too, they have arrived at sharp concepts of decidability. In one sense, decidability is a property of sets (of sentences): that of being subject (or not) to mechanical methods by which to decide in a finite number of steps, for any closed sentence of a given formal system (*e.g.,* of N), whether it is true or not or—as a different question—whether it is a theorem or not. In another sense, decidability can refer to a single closed sentence: the sentence is called undecidable in a formal system if neither it nor its negation is a theorem. Using this concept, Gödel's incompleteness theorem is sometimes stated thus: "Every interesting (or significant) formal system has some undecidable sentences."

Given these developments, it was easy to extend Gödel's findings, as Church did in 1936, to show that interesting formal systems such as N are undecidable (both with regard to theorems and with regard to true sentences).

The two incompleteness theorems. The first and most central finding in this field is that systems such as N are incomplete and incompletable because Gödel's theorem applies to any reasonable and moderately rich system. The proof of this incompleteness may be viewed as a modification of the liar paradox, which shows that truth cannot be defined in the language itself. Since provability in a formal system can often be expressed in the system itself, one is led to the conclusion of incompleteness.

Let us consider the sentence

This sentence is not provable in the system. (2)

In particular, N may be thought of as the system being studied. Representing expressions by numbers and using an ingenious substitution function, Gödel was able to find in the system a sentence p that could be viewed as expressing (2).

Once such a sentence is obtained, some strong conclusions result. If the system is complete, then either the sentence p or its negation is a theorem of the system. If p is a theorem, then intuitively p or (2) is false, and there is in some sense a false theorem in the system. Similarly, if $\sim p$ is a theorem, then it says that $\sim(2)$ or that p is provable in the system. Since $\sim p$ is a theorem, it should be true, and there seem then to be two conflicting sentences that are both true—namely, p is provable in the system and $\sim p$ is provable in it. This can be the case only if the system is inconsistent.

Gödel's exact theorem

A careful examination of this inexact line of reasoning leads to Gödel's exact theorem, which says that, if a system is reasonably rich and ω-consistent, then p is undecidable in it. The notion of ω-consistency is stronger than consistency, but it is a very reasonable requirement, since it demands merely that one cannot prove in a system both that some number does not have the property A and yet for each number that it does have the property A—*i.e.,* that $(\exists x)\sim A(x)$ and also all of $A(0), A(1), \ldots$ are theorems. The American mathematician J. Barkley Rosser, who also contributed to number theory and applied mathematics, weakened the hypothesis to mere consistency in 1936, at the expense of complicating somewhat the initial sentence (2).

More exactly, Gödel showed that, if the system is consistent, then p is not provable; if it is ω-consistent, then $\sim p$ is not provable. The first half leads to Gödel's theorem on consistency proofs, which says that if a system is consistent, then the arithmetic sentence expressing the consistency of the system cannot be proved in the system. This is usually stated briefly thus: that no interesting system can prove its own consistency or that there exists no consistency proof of a system that can be formalized in the system itself.

The proof of this theorem consists essentially of a formalization in arithmetic of the arithmetized version of the proof of the statement, "If a system is consistent, then p is not provable"; *i.e.,* it consists of a derivation within number theory of p itself from the arithmetic sentence that says that the system is consistent. Hence, if the arithmetic sentence were provable, p would also be provable—contradicting the previous result. This proof, which was only briefly outlined by Gödel, has been carried out in detail by Paul Bernays in his joint work with Hilbert. Moreover, the undecidable sentence p is always of a relatively simple form—namely, the form $(\forall x)A(x)$, "For every x, x is A," in which A is a recursive, in fact a primitive recursive, predicate.

Decidability and undecidability. The first incompleteness theorem yields directly the fact that truth in a system (*e.g.,* in N) to which the theorem applies is undecidable. If it were decidable, then all true sentences would form a recursive set, and they could be taken as the axioms of a formal system that would be complete. This claim depends on the reasonable and widely accepted assumption that all that is required of the axioms of a formal system is that they make it possible to decide effectively whether a given sentence is an axiom.

Undecidability of truth and theoremhood

Alternatively, the above assumption can be avoided by resorting to a familiar lemma, or auxiliary truth: that all recursive or computable functions and relations are representable in the system (*e.g.,* in N). Since truth in the language of a system is itself not representable (definable) in the system, it cannot, by the lemma, be recursive (*i.e.,* decidable).

The same lemma also yields the undecidability of such systems with regard to theorems. Thus, if there were a decision procedure, there would be a computable function f such that $f(i)$ equals 1 or 0 according as the ith sentence is a theorem or not. But then what $f(i) = 0$ says is just that the ith sentence is not provable. Hence, using Gödel's device, a sentence (say the tth) is again obtained saying of itself that it is not provable. If $f(t) = 0$ is true, then, because f is representable in the system, it is a theorem of the system. But then, because $f(t) = 0$ is (equivalent to) the tth sentence, $f(t) = 1$ is also true and therefore provable in the system. Hence, the system, if consistent, is undecidable with regard to theorems.

Although the system N is incompletable and undecidable, it has been discovered by the Polish logician M. Presburger and by Skolem (both in 1930) that arithmetic with addition alone or multiplication alone is decidable (with regard to truth) and therefore has complete formal systems. Another well-known positive finding is that of the Polish-American semanticist and logician Alfred Tarski, who developed a decision procedure for elementary geometry and elementary algebra (1951).

Consistency proofs. The best-known consistency proof is that of the German mathematician Gerhard Gentzen (1936) for the system N of classical (or ordinary, in contrast to intuitionistic) number theory. Taking ω (omega) to represent the next number beyond the natural numbers (called the "first transfinite number"), Gentzen's proof employs an induction in the realm of transfinite numbers $(\omega + 1,\ \omega + 2, \ldots;\ 2\omega,\ 2\omega + 1, \ldots;\ \omega^2,\ \omega^2 + 1, \ldots)$, which is extended to the first epsilon-number, ε_0 (defined as the limit of $\omega, \omega^{\omega}, \omega^{\omega^{\omega}}, \ldots$), which is not formalizable in N. This proof, which has appeared in several variants, has opened up an area of rather extensive work.

Intuitionistic number theory, which denies the classical concept of truth and consequently eschews certain general laws such as "either A or $\sim A$," and its relation to classical number theory have also been investigated (see MATHEMATICS, THE FOUNDATIONS OF: *Intuitionism*). This investigation is considered significant, because intuitionism is believed to be more constructive and more evident than classical number theory. In 1932 Gödel found an interpretation of classical number theory in the intuitionistic theory (also found by Gentzen and by Bernays). In 1958 Gödel extended his findings to obtain constructive

interpretations of sentences of classical number theory in terms of primitive recursive functionals.

More recently, work has been done to extend Gentzen's findings to ramified theories of types and to fragments of classical analysis and to extend Gödel's interpretation and to relate classical analysis to intuitionistic analysis. Also, in connection with these consistency proofs, various proposals have been made to present constructive notations for the ordinals of segments of the German mathematician Georg Cantor's second number class, which includes ω and the first epsilon-number and much more. A good deal of discussion has been devoted to the significance of the consistency proofs and the relative interpretations for epistemology (the theory of knowledge).

DISCOVERIES ABOUT LOGICAL CALCULI

The calculi of formal logic. The two main branches of formal logic are the propositional calculus and the predicate calculus (see above *Formal logic*).

The propositional calculus. It is easy to show that the propositional calculus is complete in the sense that every valid sentence in it—*i.e.*, every tautology, or sentence true in all possible worlds (in all interpretations)—is a theorem, as may be seen in the following example. "Either p or not-p" ($p \vee \sim p$) is always true because p is either true or false. In the former case, $p \vee \sim p$ is true because p is true; in the latter case, because $\sim p$ is true. One way to prove the completeness of this calculus is to observe that it is sufficient to reduce every sentence to a conjunctive normal form—*i.e.*, to a conjunction of disjunctions of single letters and their negations. But any such conjunction is valid if and only if every conjunct is valid; and a conjunct is valid if and only if it contains some letter p as well as $\sim p$ as parts of the whole disjunction. Completeness follows because (1) such conjuncts can all be proved in the calculus and (2) if these conjuncts are theorems, then the whole conjunction is also a theorem.

Consistency and decidability of PC

The consistency of the propositional calculus (its freedom from contradiction) is more or less obvious, because it can easily be checked that all its axioms are valid—*i.e.*, true in all possible worlds—and that the rules of inference carry from valid sentences to valid sentences. But a contradiction is not valid; hence, the calculus is consistent. The conclusion, in fact, asserts more than consistency, for it holds that only valid sentences are provable.

The calculus is also easily decidable. Since all valid sentences, and only these, are theorems, each sentence can be tested mechanically by putting true and false for each letter in the sentence. If there are n letters, there are 2^n possible substitutions. A sentence is then a theorem if and only if it comes out true in every one of the 2^n possibilities.

The independence of the axioms is usually proved by using more than two truth values. These values are divided into two classes: the desired and the undesired. The axiom to be shown independent can then acquire some undesired value, whereas all the theorems that are provable without this axiom always get the desired values. This technique is what originally suggested the many-valued logics.

The first-order predicate calculus. The problem of consistency for the predicate calculus is relatively simple. A world may be assumed in which there is only one object a. In this case, both the universally quantified and the existentially quantified sentences $(\forall x)A(x)$ and $(\exists x)A(x)$ reduce to the simple sentence $A(a)$, and all quantifiers can be eliminated. It may easily be confirmed that, after the reduction, all theorems of the calculus become tautologies (*i.e.*, theorems in the propositional calculus). If F is any predicate, such a sentence as "Every x is F and not every x is F"—*i.e.*, $(\forall x)F(x) \cdot \sim(\forall x)F(x)$—is then reduced to "$a$ is both A and not-A"—$A(a) \cdot \sim A(a)$—which is not a tautology; therefore, the original sentence is not a theorem; hence, no contradiction can be a theorem. If F is simple, then F and A are the same. If F is complex and contains $(\forall y)$ or $(\exists z)$, etc., then A is the result obtained by iterating the transformation of eliminating $(\forall y)$, etc. In fact, it can be proved quite directly not only that the calculus is consistent but also that all its theorems are valid.

The discoveries that the calculus is complete and undecidable are much more profound than the discovery of its consistency. Its completeness was proved by Gödel in 1930; its undecidability was established with quite different methods by Church and Turing in 1936. Given the general developments that occurred up to 1936, its undecidability also follows in another way from Theorem X of Gödel's paper of 1931.

Completeness means that every valid sentence of the calculus is a theorem. It follows that if $\sim A$ is not a theorem, then $\sim A$ is not valid; and, therefore, A is satisfiable; *i.e.*, it has an interpretation, or a model. But to say that A is consistent means nothing other than that $\sim A$ is not a theorem. Hence, from the completeness, it follows that if A is consistent, then A is satisfiable. Therefore, the semantic concepts of validity and satisfiability are seen to coincide with the syntactic concepts of derivability and consistency.

The Löwenheim-Skolem theorem. A finding closely related to the completeness theorem is the Löwenheim-Skolem theorem (1915, 1920), named after Leopold Löwenheim, a German schoolteacher, and Skolem, which says that if a sentence (or a formal system) has any model, it has a countable or enumerable model (*i.e.*, a model whose members can be matched with the positive integers). In the most direct method of proving this theorem, the logician is provided with very useful tools in model theory and in studies on relative consistency and independence in set theory.

In the predicate calculus there are certain reduction or normal-form theorems. One useful example is the prenex normal form: every sentence can be reduced to an equivalent sentence expressed in the prenex form—*i.e.*, in a form such that all the quantifiers appear at the beginning. This form is especially useful for displaying the central ideas of some of the proofs of the Löwenheim-Skolem theorem.

As an illustration, one may consider a simple schema in prenex form, "For every x, there is some y such that x bears the (arbitrary) relation M to y"; *i.e.*,

$$(\forall x)(\exists y)Mxy. \tag{3}$$

If (3) now has a model with a nonempty domain D, then, by a principle from set theory (the axiom of choice), there exists a function f of x, written $f(x)$, that singles out for each x a corresponding y. Hence, "For every x, x bears the relation M to $f(x)$"; *i.e.*,

$$(\forall x)Mxf(x). \tag{4}$$

If a is now any object in D, then the countable subdomain $\{a, f(a), f[f(a)], \ldots\}$ already contains enough objects to satisfy (4) and therefore to satisfy (3). Hence, if (3) has any model, it has a countable model, which is in fact a submodel of the original.

Proof independent of set theory

An alternative proof, developed by Skolem in 1922 to avoid appealing to the principles of set theory, has turned out to be useful also for establishing the completeness of the calculus. Instead of using the function f as before, a can be arbitrarily denoted by 1. Since equation (3) is true, there must be some object y such that the number 1 bears the relation M to y, or symbolically $M1y$, and one of these y's may be called 2. When this process is repeated indefinitely, one obtains

$$M12;\ M12 \cdot M23;\ M12 \cdot M23 \cdot M34; \ldots, \tag{5}$$

all of which are true in the given model. The argument is elementary, because in each instance one merely argues from "There exists some y such that n is M of y"—*i.e.*, $(\exists y)Mny$—to "Let one such y be $n+1$." Consequently, every member of (5) is true in some model. It is then possible to infer that all members of (5) are simultaneously true in some model—*i.e.*, that there is some way of assigning truth values to all its atomic parts so that all members of (5) will be true. Hence, it follows that (3) is true in some countable model.

The completeness theorem. Gödel's original proof of the completeness theorem is closely related to the second proof above. Consideration may again be given to all the sentences in (5) that contain no more quantifiers. If they are all satisfiable, then, as before, they are simultaneously satisfiable and (3) has a model. On the other hand, if (3) has no model, some of its terms—say $M12 \cdot \ldots \cdot M89$—are not satisfiable; *i.e.*, their negations

are tautologies (theorems of the propositional calculus). Thus, $\sim M12 \vee \ldots \vee \sim M89$ is a tautology, and this remains true if 1, 2, . . . , 9 are replaced by variables, such as $r, s, \ldots, z$; hence, $\sim Mrs \vee \ldots \vee \sim Myz$, being a tautology expressed in the predicate calculus as usually formulated, is a theorem in it. It is then easy to use the usual rules of the predicate calculus to derive also the statement, "There exists an x such that, for every y, x is not M of y"; *i.e.*, $(\exists x)(\forall y)\sim Mxy$. In other words, the negation of (3) is a theorem of the predicate calculus. Hence, if (3) has no model, then its negation is a theorem of the predicate calculus. And, finally, if a sentence is valid (*i.e.*, if its negation has no model), then it is itself a theorem of the predicate calculus.

The undecidability theorem and reduction classes. Given the completeness theorem, it follows that the task of deciding whether any sentence is a theorem of the predicate calculus is equivalent to that of deciding whether any sentence is valid or whether its negation is satisfiable.

Turing's undecidability proof

Turing's method of proving that this class of problems is undecidable is particularly suggestive. Once the concept of mechanical procedure was crystallized, it was relatively easy to find absolutely unsolvable problems—*e.g.*, the halting problem, which asks for each Turing machine the question of whether it will ever stop, beginning with a blank tape. In other words, each Turing machine operates in a predetermined manner according to what is given initially on the (input) tape; we consider now the special case of a blank tape and ask the special question whether the machine will eventually stop. This infinite class of questions (one for each machine) is known to be unsolvable.

Turing's method shows that each such question about a single Turing machine can be expressed by a single sentence of the predicate calculus so that the machine will stop if and only if that sentence is not satisfiable. Hence, if there were a decision procedure of validity (or satisfiability) for all sentences of the predicate calculus, then the halting problem would be solvable.

In more recent years (1962), Turing's formulation has been improved to the extent that all that is needed are sentences of the relatively simple form $(\forall x)(\exists y)(\forall z)Mxyz$, in which all the quantifiers are at the beginning; *i.e.*, M contains no more quantifiers. Hence, given the unsolvability of the halting problem, it follows that, even for the simple class of sentences in the predicate calculus having the quantifiers $\forall\, \exists\, \forall$, the decision problem is unsolvable. Moreover, the method of proof also yields a procedure by which every sentence of the predicate calculus can be correlated with one in the simple form given above. Thus, the class of $\forall\, \exists\, \forall$ sentences forms a "reduction class." (There are also various other reduction classes.)

MODEL THEORY

Background and typical problems. In model theory one studies the interpretations (models) of theories formalized in the framework of formal logic, especially in that of the first-order predicate calculus with identity—*i.e.*, in elementary logic. A first-order language is given by a collection S of symbols for relations, functions, and constants, which, in combination with the symbols of elementary logic, single out certain combinations of symbols as sentences. Thus, for example, in the case of the system N (see above *Example of a formal system*), the formation rules yield a language that is determined in accordance with a uniform procedure by the set (indicated by braces) of uninterpreted extralogical symbols:

$$L = \{S, +, \cdot, 0, 1\}.$$

A first-order theory is determined by a language and a set of selected sentences of the language—those sentences of the theory that are, in an arbitrary, generalized sense, the "true" ones (called the "distinguished elements" of the set). In the particular case of the system N, one theory T_a is built up on the basis of the language and the set of theorems of N, and another theory T_b is determined by the true sentences of N according to the natural interpretation or meaning of its language. In general, the language of N and any set of sentences of the language can be used to make up a theory.

Satisfaction of a theory by a structure: finite and infinite models. A realization of a language (for example, the one based on L) is a structure $\mathfrak{A}$ identified by the six elements so arranged

$$\mathfrak{A} = <A, S_{\mathfrak{A}}, +_{\mathfrak{A}}, \cdot_{\mathfrak{A}}, 0_{\mathfrak{A}}, 1_{\mathfrak{A}}>,$$

in which the second term is a function that assigns a member of the set A to each member of the set A, the next two terms are functions correlating each member of the Cartesian product $A \times A$ (*i.e.*, from the set of ordered pairs $<a, b>$ such that a and b belong to A) with a member of A, and the last two terms are members of A. The structure $\mathfrak{A}$ satisfies, or is a model of, the theory T_a (or T_b) if all of the distinguished sentences of T_a (or T_b) are true in $\mathfrak{A}$ (or satisfied by $\mathfrak{A}$). Thus, if $\mathfrak{A}$ is the structure of the ordinary nonnegative integers $<\omega, S, +, \cdot, 0, 1>$, in which ω is the set of all such integers and S, $+$, $\cdot$, 0, and 1 the elements for their generation, then it is not only a realization of the language based on L but also a model of both T_a and T_b. Gödel's incompleteness theorem permits nonstandard models of T_a that contain more objects than ω but in which all the distinguished sentences of T_a (namely, the theorems of the system N) are true. Skolem's constructions (related to ultraproducts, see below) yield nonstandard models for both theory T_a and theory T_b.

Integers as a structure

The use of the relation of satisfaction, or being-a-model-of, between a structure and a theory (or a sentence) can be traced to the book *Wissenschaftslehre* (1837; *Theory of Science*) by Bernhard Bolzano, a Bohemian theologian and mathematician, and, in a more concrete context, to the introduction of models of non-Euclidean geometries about that time. In the mathematical treatment of logic, these concepts can be found in works of the late 19th-century German mathematician Ernst Schröder and in Löwenheim (in particular, in his paper of 1915). The basic tools and results achieved in model theory—such as the Löwenheim-Skolem theorem, the completeness theorem of elementary logic, and Skolem's construction of nonstandard models of arithmetic—were developed during the period from 1915 to 1933. A more general and abstract study of model theory began after 1950, in the work of Tarski and others.

One group of developments may be classified as refinements and extensions of the Löwenheim-Skolem theorem. These developments employ the concept of a "cardinal number," which—for a finite set—is simply the number at which one stops in counting its elements. For infinite sets, however, the elements must be matched from set to set instead of being counted, and the "sizes" of these sets must thus be designated by transfinite numbers. A rather direct generalization can be drawn that says that, if a theory has any infinite model, then, for any infinite cardinal number, it has a model of that cardinality. It follows that no theory with an infinite model can be categorical or such that any two models of the theory are isomorphic (*i.e.*, matchable in one-to-one correspondence), because models of different cardinalities can obviously not be so matched. A natural question is whether a theory can be categorical in certain infinite cardinalities—*i.e.*, whether there are cardinal numbers such that any two models of the theory of the same cardinality are isomorphic. According to a central discovery made in 1963 by the American mathematician Michael Morley, if a theory is categorical in any uncountable cardinality (*i.e.*, any cardinality higher than the countable), then it is categorical in every uncountable cardinality. On the other hand, examples are known for all four combinations of countable and uncountable cardinalities: specifically, there are theories that are categorical (1) in every infinite cardinality, (2) in the countable cardinality but in no uncountable cardinality, (3) in every uncountable cardinality but not in the countable, and (4) in no infinite cardinality.

Categorical theories in various cardinalities

In another direction, there are "two-cardinal" problems that arise from the possibilities of changing, from one model to another, not only the cardinality of the domain of the first model but also the cardinality of some chosen property (such as being a prime number). Various answers to these questions have been found, including proofs of independence (based on the ordinary axioms employed in

set theory) and proofs of conditional theorems made on the basis of certain familiar hypotheses of set theory.

Elementary logic. An area that is perhaps of more philosophical interest is that of the nature of elementary logic itself. On the one hand, the completeness discoveries seem to show in some sense that elementary logic is what the logician naturally wishes to have. On the other hand, he is still inclined to ask whether there might be some principle of uniqueness according to which elementary logic is the only solution that satisfies certain natural requirements on what a logic should be. The development of model theory has led to a more general outlook that enabled the Swedish logician Per Lindström to prove in 1969 a general theorem to the effect that, roughly speaking, within a broad class of possible logics, elementary logic is the only one that satisfies the requirements of axiomatizability and of the Löwenheim-Skolem theorem. Although Lindström's theorem does not settle satisfactorily whether or not elementary logic is the right logic, it does seem to suggest that mathematical findings can help the logician to clarify his concepts of logic and of logical truth.

Compounded models

A particularly useful tool for obtaining new models from the given models of a theory is the construction of a special combination called the "ultraproduct" of a family of structures (see below *Ultrafilters, ultraproducts, and ultrapowers*)—in particular, the ultrapower when the structures are all copies of the same structure (just as the product of $a_1, \ldots, a_n$ is the same as the power a^n, if $a_i = a$ for each i). The intuitive idea in this method is to establish that a sentence is true in the ultraproduct if and only if it is true in "almost all" of the given structures (*i.e.*, "almost everywhere"—an idea that was present in a different form in Skolem's construction of a nonstandard model of arithmetic in 1933). It follows that, if the given structures are models of a theory, then their ultraproduct is such a model also, because every sentence in the theory is true everywhere (which is a special case of "almost everywhere" in the technical sense employed). Ultraproducts have been applied, for example, to provide a foundation for what is known as "nonstandard analysis" that yields an unambiguous interpretation of the classical concept of infinitesimals—the division into units as small as one pleases. They have also been applied by two mathematicians, James Ax and Simon B. Kochen, to problems in the field of algebra (on p-adic fields).

Nonelementary logic and future developments. There are also studies, such as second-order logic and infinitary logics, that develop the model theory of nonelementary logic. Second-order logic contains, in addition to variables that range over individual objects, a second kind of variable ranging over sets of objects so that the model of a second-order sentence or theory also involves, beyond the basic domain, a larger set (called its "power set") that encompasses all the subsets of the domain. Infinitary logics may include functions or relations with infinitely many arguments, infinitely long conjunctions and disjunctions, or infinite strings of quantifiers. From studies on infinitary logics, William Hanf, an American logician, was able to define certain cardinals, some of which have been studied in connection with the large cardinals in set theory. In yet another direction, logicians are developing model theories for modal logics—those dealing with such modalities as necessity and possibility—and for the intuitionistic logic.

There is a large gap between the general theory of models and the construction of interesting particular models such as those employed in the proofs of the independence (and consistency) of special axioms and hypotheses in set theory. It is natural to look for further developments of model theory that will yield more systematic methods for constructing models of axioms with interesting particular properties, especially in deciding whether certain given sentences are derivable from the axioms. Relative to the present state of knowledge, such goals appear fairly remote. The gap is not unlike that between the abstract theory of computers and the basic properties of actual computers.

Characterizations of the first-order logic. There has been outlined above a proof of the completeness of elementary logic without including sentences asserting identity. The proof can be extended, however, to the full elementary logic in a fairly direct manner. Thus, if F is a sentence containing equality, a sentence G can be adjoined to it that embodies the special properties of identity relevant to the sentence F. The conjunction of F and G can then be treated as a sentence not containing equality (*i.e.*, "=" can be treated as an arbitrary relation symbol). Hence, the conjunction has a model in the sense of logic-without-identity if and only if F has a model in the sense of logic-with-identity; and the completeness of elementary logic (with identity) can thus be inferred.

Extension to include identity

A concept more general than validity is that of the relation of logical entailment or implication between a possibly infinite set X of sentences and a single sentence p that holds if and only if p is true in every model of X. In particular, p is valid if the empty set, defined as having no members, logically entails p—for this is just another way of saying that p is true in every model. This suggests a stronger requirement on a formal system of logic—namely, that p be derivable from X by the system whenever X logically entails p. The usual systems of logic satisfy this requirement because, besides the completeness theorem, there is also a compactness theorem:

> A theory X has a model if every finite subset of X has a model.

Roughly speaking, this theorem enables the logician to reduce an infinite set X to a finite subset X_1 in each individual case, and the case of entailment when X_1 is finite is taken care of by the completeness of the system.

These findings show that the ordinary systems of elementary logic comprise the correct formulation, provided that the actual choice of the truth functions (say negation and disjunction), of the quantifiers, and of equality as the "logical constants" is assumed to be the correct one. There remains the question, however, of justifying the particular choice of logical constants. One might ask, for example, whether "For most x" or "For finitely many x" should not also be counted as logical constants. Lindström has formulated a general concept of logic and shown that logics that apparently extend the first-order logic all end up being the same as that logic, provided that they satisfy the Löwenheim-Skolem theorem and either have the compactness property or are formally axiomatizable. There remains the question, however, of whether or why these requirements (especially that of the Löwenheim-Skolem theorem) are intrinsic to the nature of logic.

Generalizations and extensions of the Löwenheim-Skolem theorem. A generalized theorem can be proved using basically the same ideas as those employed in the more special case discussed above.

If a theory has any infinite model, then, for any infinite cardinality α, that theory has a model of cardinality α. More explicitly, this theorem contains two parts: (1) If a theory has a model of infinite cardinality β, then, for each infinite cardinal α that is greater than β, the theory has a model of cardinality α. (2) If a theory has a model of infinite cardinality β, then, for each infinite cardinal α less than β, the theory has a model of cardinality α.

It follows immediately that any theory having an infinite model has two nonisomorphic models and is, therefore, not categorical. This applies, in particular, to the aforementioned theories T_a and T_b of arithmetic (based on the language of N), the natural models of which are countable, as well as to theories dealing with real numbers and arbitrary sets, the natural models of which are uncountable; both kinds of theory have both countable and uncountable models. There is much philosophical discussion about this phenomenon.

The possibility is not excluded that a theory may be categorical in some infinite cardinality. The theory T_d, for example, of dense linear ordering (such as that of the rational numbers) is categorical in the countable cardinality. One application of the Löwenheim-Skolem theorem is: If a theory has no finite models and is categorical in some infinite cardinality α, then the theory is complete; *i.e.*, for every closed sentence in the language of the theory, either that sentence or its negation belongs to the theory. An immediate consequence of this application of the theorem is that the theory of dense linear ordering is complete.

Morley's theorem

A theorem that is generally regarded as one of the most difficult to prove in model theory is the theorem by Michael Morley, as follows:

> A theory that is categorical in one uncountable cardinality is categorical in every uncountable cardinality.

Two-cardinal theorems deal with languages having some distinguished predicate U. A theory is said to admit the pair $<\alpha, \beta>$ of cardinals if it has a model (with its domain) of cardinality α wherein the value of U is a set of cardinality β. The central two-cardinal theorem says:

> If a theory admits the pair $<\alpha, \beta>$ of infinite cardinals with β less than α, then for each regular cardinal γ the theory admits $<\gamma^+, \gamma>$, in which γ^+ is the next larger cardinal after γ.

The most interesting case is when γ is the least infinite cardinal, $\aleph_0$. (The general theorem can be established only when the "generalized continuum hypothesis" is assumed, according to which the next highest cardinality for an infinite set is that of its power set.)

Ultrafilters, ultraproducts, and ultrapowers. An ultrafilter on a nonempty set I is defined as a set D of subsets of I such that

(1) the empty set does not belong to D,
(2) if A, B are in D, so is their intersection, $A \cap B$, the set of elements common to both,
(3) if A is a subset of B, and A is in D, then B is in D, and
(4) for every subset A of I, either A is in D or I minus A is in D.

Roughly stated, each ultrafilter of a set I conveys a notion of large subsets of I so that any property applying to a member of D applies to I "almost everywhere."

The set $\{\mathfrak{A}_i\}$, where $\mathfrak{A}_i = <A_i, R_i>$ and the i are members of the set I, is taken to be a family of structures indexed by I, and D to be an ultrafilter on I. Consider now the Cartesian product B of $\{A_i\}$ (for example, if I is $\{0, 1, 2, \ldots\}$, then B is the set of all sequences f such that $f(i)$ belong to A_i). The members of B are divided into equivalence classes with the help of $D: f \equiv g$ if and only if $\{i \mid f(i) = g(i)\} \in D$—in other words, the set of indices i such that $f(i) = g(i)$ belong to D [or $f(i)$ and $g(i)$ are equal "almost everywhere"]. Let W be the set of these equivalence classes—*i.e.*, the set of all f^* such that f^* is the set of all members g of B with $g \equiv f$. Similarly, a relation S is introduced such that Sfg if and only if R_i holds between $f(i)$ and $g(i)$ for "almost all" i; *i.e.*,

$$\{i \mid R_i [f(i), g(i)]\} \in D.$$

In this way, we arrive at a new structure $U = <W, S>$, which is called the ultraproduct of the original family $\{\mathfrak{A}_i\}$ over D. In the special case when all the $\mathfrak{A}_i$ are the same, the resulting structure U is called the ultrapower of the original family over D.

The central theorems are the following:

1. If $\mathfrak{A}_i$ $(i \in I)$ are realizations of the same language, then a sentence p is true in the ultraproduct U if and only if the set of i such that p is true in $\mathfrak{A}_i$ belongs to D. In particular, if each $\mathfrak{A}_i$ is a model of a theory, then U is also a model of the theory.
2. Two realizations of the same language are said to be elementarily equivalent if they have the same set of true sentences. A necessary and sufficient condition for two realizations to be elementarily equivalent is that they admit ultrapowers that are isomorphic.

Applications to nonstandard analysis and algebra

One application of these theorems is in the introduction of nonstandard analysis, which was originally instituted by other considerations. By using a suitable ultrapower of the structure of the field $\mathfrak{R}$ of real numbers, a real closed field that is elementarily equivalent to $\mathfrak{R}$ is obtained that is non-Archimedean—*i.e.*, which permits numbers a and b such that no n can make na greater than b. This development supplies an unexpected exact foundation for the classical differential calculus using infinitesimals, which has considerable historical, pedagogical, and philosophical interest.

A widely known application to the area of algebra is that which deals with certain fields of rational numbers Q_p, called the p-adic completion of the rational numbers. The conjecture has been made that every form of degree d (in the same sense as degrees of ordinary polynomials) over Q_p, in which the number of variables exceeds d^2, has a nontrivial zero in Q_p. Using ultraproducts, it has been shown that the conjecture is true for arbitrary d with the possible exception of a finite set of primes p (depending on d). Subsequently, it was found that the original conjecture is not true when extended to full generality.

Other useful tools in model theory include the pigeonhole principles, of which the basic principle is that, if a set of large cardinality is partitioned into a small number of classes, some one class will have large cardinality. Those elements of the set that lie in the same class cannot be distinguished by the property defining that class.

A related concept is that of "indiscernibles," which also has rather extensive applications in set theory. An ordered subset of the domain of a model $\mathfrak{A}$ of a theory is a homogeneous set, or a set of indiscernibles for $\mathfrak{A}$, if $\mathfrak{A}$ cannot distinguish the members of the subset from one another. More exactly, given any $x_1 < \ldots < x_n$, $y_1 < \ldots < y_n$ in the subset, then for any sentence $F(a_1, \ldots, a_n)$ of the language of the theory, that sentence (with argument x) is satisfied by (symbolized $\Vdash$) the structure—*i.e.*,

$$\mathfrak{A} \Vdash F(x_1, \ldots, x_n)$$

—if and only if that sentence (with argument y) is also satisfied by it—*i.e.*,

$$\mathfrak{A} \Vdash F(y_1, \ldots, y_n).$$

There is also a first theorem on this notion that says that, given a theory with an infinite model and a linearly ordered set X, there is then a model $\mathfrak{A}$ of the theory such that X is a set of indiscernibles for $\mathfrak{A}$. (H.Wa./M.L.Sc.)

Applied logic

The formalism and theoretical results of pure logic can be clothed with meanings derived from a variety of sources within philosophy as well as from other sciences. This formal machinery also can be used to guide the design of computers and computer programs.

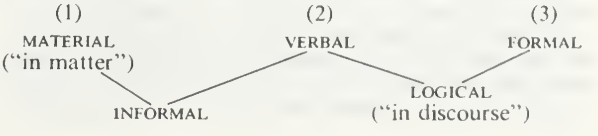
Range of applications

The applications of logic cover a vast range, relating to reasoning in the sciences and in philosophy, as well as in everyday discourse. They include (1) the various sorts of reasoning affecting the conduct of ordinary discourse as well as the theory of the logical relations that exist within special realms of discourse—between two commands, for example, or between one question and another, (2) special forms of logic designed for scientific applications, such as temporal logic (of what "was" or "will be" the case) or mereology (the logic of parts and wholes), and (3) special forms for concepts bearing upon philosophical issues, such as logics that deal with statements of the form "I know that . . . ," "I believe that . . . ," "It is permitted to . . . ," "It is obligatory to . . . ," or "It is prohibited to . . . ."

THE CRITIQUE OF FORMS OF REASONING

Correct and defective argument forms. In logic an argument consists of a set of statements, the premises, whose truth supposedly supports the truth of a single statement called the conclusion of the argument. An argument is deductively valid when the truth of the premises guarantees the truth of the conclusion; *i.e.*, the conclusion must be true, because of the form of the argument, whenever the premises are true. Some arguments that fail to be deductively valid are acceptable on grounds other than formal logic, and their conclusions are supported with less than logical necessity. In other potentially persuasive arguments, the premises give no rational grounds for accepting the conclusion. These defective forms of argument are called fallacies.

An argument may be fallacious in three ways: in its material content, through a misstatement of the facts; in its wording, through an incorrect use of terms; or in its



structure (or form), through the use of an improper process of inference. As shown in the diagram, fallacies are correspondingly classified as (1) material, (2) verbal, and (3) formal. Groups 2 and 3 are called logical fallacies, or fallacies "in discourse," in contrast to the substantive, or material, fallacies of group 1, called fallacies "in matter"; and groups 1 and 2, in contrast to group 3, are called informal fallacies.

Kinds of fallacies. *Material fallacies.* The material fallacies are also known as fallacies of presumption, because the premises "presume" too much—they either covertly assume the conclusion or avoid the issue in view.

The classification that is still widely used is that of Aristotle's *Sophistic Refutations:* (1) The fallacy of accident is committed by an argument that applies a general rule to a particular case in which some special circumstance ("accident") makes the rule inapplicable. The truth that "men are capable of seeing" is no basis for the conclusion that "blind men are capable of seeing." This is a special case of the fallacy of *secundum quid* (more fully: *a dicto simpliciter ad dictum secundum quid,* which means "from a saying [taken too] simply to a saying according to what [it really is]"—*i.e.,* according to its truth as holding only under special provisos). This fallacy is committed when a general proposition is used as the premise for an argument without attention to the (tacit) restrictions and qualifications that govern it and invalidate its application in the manner at issue. (2) The converse fallacy of accident argues improperly from a special case to a general rule. Thus, the fact that a certain drug is beneficial to some sick persons does not imply that it is beneficial to all people. (3) The fallacy of irrelevant conclusion is committed when the conclusion changes the point that is at issue in the premises. Special cases of irrelevant conclusion are presented by the so-called fallacies of relevance. These include (*a*) the argument *ad hominem* (speaking "against the man" rather than to the issue), in which the premises may only make a personal attack on a person who holds some thesis, instead of offering grounds showing why what he says is false, (*b*) the argument *ad populum* (an appeal "to the people"), which, instead of offering logical reasons, appeals to such popular attitudes as the dislike of injustice, (*c*) the argument *ad misericordiam* (an appeal "to pity"), as when a trial lawyer, rather than arguing for his client's innocence, tries to move the jury to sympathy for him, (*d*) the argument *ad verecundiam* (an appeal "to awe"), which seeks to secure acceptance of the conclusion on the grounds of its endorsement by persons whose views are held in general respect, (*e*) the argument *ad ignorantiam* (an appeal "to ignorance"), which argues that something (*e.g.,* extrasensory perception) is so since no one has shown that it is not so, and (*f*) the argument *ad baculum* (an appeal "to force"), which rests on a threatened or implied use of force to induce acceptance of its conclusion. (4) The fallacy of circular argument, known as *petitio principii* ("begging the question"), occurs when the premises presume, openly or covertly, the very conclusion that is to be demonstrated (example: "Gregory always votes wisely." "But how do you know?" "Because he always votes Libertarian."). A special form of this fallacy, called a vicious circle, or *circulus in probando* ("arguing in a circle"), occurs in a course of reasoning typified by the complex argument in which a premise p_1 is used to prove p_2; p_2 is used to prove p_3; and so on, until p_{n-1} is used to prove p_n; then p_n is subsequently used in a proof of p_1, and the whole series $p_1, p_2, \ldots, p_n$ is taken as established (example: "McKinley College's baseball team is the best in the association [$p_n = p_3$]; they are the best because of their strong batting potential [p_2]; they have this potential because of the ability of Jones, Crawford, and Randolph at the bat [p_1]." "But how do you know that Jones, Crawford, and Randolph are such good batters?" "Well, after all, these men are the backbone of the best team in the association [p_3 again]."). Strictly speaking, *petitio principii* is not a fallacy of reasoning but an ineptitude in argumentation: thus the argument from p as a premise to p as conclusion is not deductively invalid but lacks any power of conviction, since no one who questioned the conclusion could concede the premise. (5) The fallacy of false cause (*non causa pro causa*) mislocates the cause of one phenomenon in another that is only seemingly related. The most common version of this fallacy, called *post hoc ergo propter hoc* ("after which hence by which"), mistakes temporal sequence for causal connection—as when a misfortune is attributed to a "malign event," like the dropping of a mirror. Another version of this fallacy arises in using *reductio ad absurdum* reasoning: concluding that a statement is false if its addition to a set of premises leads to a contradiction. This mode of reasoning can be correct—*e.g.,* concluding that two lines do not intersect if the assumption that they do intersect leads to a contradiction. What is required to avoid the fallacy is to verify independently that each of the original premises is true. Thus, one might fallaciously infer that Williams, a philosopher, does not watch television, because adding

A: Williams, a philosopher, watches television.

to the premises

P_1: No philosopher engages in intellectually trivial activities.
P_2: Watching television is an intellectually trivial activity.

leads to a contradiction. Yet it might be that either P_1 or P_2 or both are false. It might even be the case that Williams is not a philosopher. Indeed, one might even take A as evidence for the falsity of either P_1 or P_2 or as evidence that Williams is not really a philosopher. (6) The fallacy of many questions (*plurimum interrogationum*) consists in demanding or giving a single answer to a question when this answer could either be divided (example: "Do you like the twins?" "Neither yes nor no; but Ann yes and Mary no.") or refused altogether, because a mistaken presupposition is involved (example: "Have you stopped beating your wife?"). (7) The fallacy of *non sequitur* ("it does not follow") occurs when there is not even a deceptively plausible appearance of valid reasoning, because there is an obvious lack of connection between the given premises and the conclusion drawn from them. Some authors, however, identify non sequitur with the fallacy of the consequent (see below *Formal fallacies*).

Verbal fallacies. These fallacies, called fallacies of ambiguity, arise when the conclusion is achieved through an improper use of words. The principal instances are as follows: (1) Equivocation occurs when a word or phrase is used in one sense in one premise and in another sense in some other needed premise or in the conclusion (example: "The loss made Jones mad [= angry]; mad [= insane] people should be institutionalized; so Jones should be institutionalized."). The figure-of-speech fallacy is the special case arising from confusion between the ordinary sense of a word and its metaphorical, figurative, or technical employment (example: "For the past week Joan has been living on the heights of ecstasy." "And what is her address there?"). (2) Amphiboly occurs when the grammar of a statement is such that several distinct meanings can obtain (example: "The governor says, 'Save soap and waste paper.' So soap is more valuable than paper"). (3) Accent is a counterpart of amphiboly arising when a statement can bear distinct meanings depending on which word is stressed (example: "Men are *considered* equal." "Men are considered *equal.*"). (4) Composition occurs when the premise that the parts of a whole are of a certain nature is improperly used to infer that the whole itself must also be of this nature (example: a story made up of good paragraphs is thus said to be a good story). (5) Division—the reverse of composition—occurs when the premise that a collective whole has a certain nature is improperly used to infer that a part of this whole must also be of this nature (example: in a speech that is long-winded it is presumed that every sentence is long). But this fallacy and its predecessor can be viewed as versions of equivocation, in which the distributive use of a term—*i.e.,* its application to the elements of an aggregate (example: "the crowd," viewed as individuals)—is confused with its collective use ("the crowd," as a unitary whole)—compare "The crowd were filing through the turnstile" with "The crowd was compressed into the space of a city block."

Accident, converse accident, irrelevant conclusion

Circular argument

Other material fallacies

Equivocation, amphiboly, and other verbal fallacies

Formal fallacies. Formal fallacies are deductively invalid arguments that typically commit an easily recognizable logical error. A classic case is Aristotle's fallacy of the consequent, relating to reasoning from premises of the form "If p_1, then p_2." The fallacy has two forms: (1) denial of the antecedent, in which one mistakenly argues from the premises "If p_1, then p_2" and "not-p_1" (symbolized $\sim p_1$) to the conclusion "not-p_2" (example: "If George is a man of good faith, he can be entrusted with this office; but George is not a man of good faith; therefore, George cannot be entrusted with this office"), and (2) affirmation of the consequent, in which one mistakenly argues from the premises "If p_1, then p_2" and "p_2" to the conclusion "p_1" (example: "If Amos was a prophet, then he had a social conscience; he had a social conscience; hence, Amos was a prophet"). Most of the traditionally considered formal fallacies, however, relate to the syllogism. One example may be cited, that of the fallacy of illicit major (or minor) premise, which violates the rules for "distribution." (A term is said to be distributed when reference is made to all members of the class. For example, in "Some crows are not friendly," reference is made to all friendly things but not to all crows.) The fallacy arises when a major (or minor) term that is undistributed in the premise is distributed in the conclusion (example: "All tubers are high-starch foods [undistributed]; no squashes are tubers; therefore, no squashes are high-starch foods [distributed]").

EPISTEMIC LOGIC

Epistemic logic deals with the logical issues arising within the gamut of such epistemological concepts as knowledge, belief, assertion, doubt, question-and-answer, or the like. Instead of dealing with the essentially factual issues of alethic logic (Greek: *alētheia,* "truth")—*i.e.,* with what is actually or must necessarily or can possibly be the case—it relates to what people know or believe or maintain or doubt to be the case.

The logic of belief. From the logical standpoint, a belief is generally analyzed as a relationship obtaining between the person who accepts some thesis on the one hand and the thesis that he accepts on the other. Correspondingly, given a person x, it is convenient to consider the set $\mathbf{B}_x$ of x's beliefs and represent the statement "x believes that p" as $p \in \mathbf{B}_x$. (The symbol $\in$ represents membership in a set, $\notin$ its denial.)

Theory of belief. To articulate a viable logic of belief, it is, at the very least, essential to postulate certain minimal conditions of rationality regarding the parties whose beliefs are at issue:

Conditions of rationality

1. Consistency: "If x believes that p, then x does not believe that not-p"; *i.e.,*

   $$\text{If } p \in \mathbf{B}_x, \text{ then } \sim p \notin \mathbf{B}_x.$$

   "If not-p, then x does not believe that p"; *i.e.,*

   $$\text{If } \vdash \sim p, \text{ then } p \notin \mathbf{B}_x.$$

   Example: If "Jesus was a Zealot" (p) is among ($\in$) the beliefs of Ralph ($\mathbf{B}_{\text{Ralph}}$), then "Jesus was not a Zealot" ($\sim p$) is not among ($\notin$) Ralph's beliefs. It is an accepted thesis ($\vdash$) that "Jesus was not a Zealot." Hence, "Jesus was a Zealot" is not among Ralph's beliefs. (The symbol "$\vdash$" is used to indicate that the sentence to its right is a valid deductive consequence of the sentence[s] on the left. In cases where it appears as an isolated prefix, it signifies "theoremhood"—*i.e.,* a deductive consequence from no premises.)
2. Conjunctive composition and division: "If x believes that p_1, and x believes that p_2, etc., to x believes that p_n, then x believes that p_1 and p_2, etc., and p_n"; *i.e.,*

   $$\text{If } (p_1 \in \mathbf{B}_x, p_2 \in \mathbf{B}_x, \ldots, p_n \in \mathbf{B}_x), \text{ then } (p_1 \cdot p_2 \cdot \ldots \cdot p_n) \in \mathbf{B}_x,$$

   and conversely. Example: If "cats are affectionate" (p_1), "cats are clean" (p_2), etc., to "cats are furry" (p_n) are among ($\in$) Bob's beliefs ($\mathbf{B}_{\text{Bob}}$), then "cats are affectionate and clean, etc., and furry" ($p_1 \cdot p_2 \cdot \ldots \cdot p_n$) is also a belief of Bob's.
3. Minimal inferential capacity: "If x believes that p, and q is an obvious consequence of p, then x believes that q"; *i.e.,*

   $$\text{If } p \in \mathbf{B}_x \text{ and } p \models q, \text{ then } q \in \mathbf{B}_x.$$

   Example: "If x believes that his cat is on the mat, and his cat's being on the mat has an obvious consequence that something is on the mat, then x believes that something is on the mat."

Here item 3 is a form of the entailment principle, but with $\models$ representing entailment of the simplest sort, designating obvious consequence—say, deducibility by fewer than two (or n) inferential steps, employing only those primitive rules of inference that have been classified as obvious. (In arguments about beliefs, however, all repetitions of the application of this version of the entailment principle must be avoided.) These principles endow the theory with such rules as

1. "If x believes that not-p, then x does not believe that p"; *i.e.,*

   $$\text{If } \sim p \in \mathbf{B}_x, \text{ then } p \notin \mathbf{B}_x.$$

2. "If x believes that p, and x believes that q, then x believes that both p and q taken together"; *i.e.,*

   $$\text{If } p \in \mathbf{B}_x \text{ and } q \in \mathbf{B}_x, \text{ then } p \cdot q \in \mathbf{B}_x.$$

3. "If x believes that p, then x believes that either p or q"; *i.e.,*

   $$\text{If } p \in \mathbf{B}_x, \text{ then } p \vee q \in \mathbf{B}_x,$$

   given "$p \vdash p \vee q$" as an "obvious" rule of inference (where $\vee$ means "or").

Iterative beliefs

One key question of the logical theory of belief relates to the area of iterative beliefs (example: "Andrews believes that I believe that he believes me to be untrustworthy"). Clearly, one would not want to have such theses as:

1. "If y believes that x believes that p, then x believes that p"; *i.e.,*

   $$\text{If } (p \in \mathbf{B}_x) \in \mathbf{B}_y, \text{ then } p \in \mathbf{B}_x \qquad (y \neq x)$$

2. "If y believes that x believes that p, then y believes that p"; *i.e.,*

   $$\text{If } (p \in \mathbf{B}_x) \in \mathbf{B}_y, \text{ then } p \in \mathbf{B}_y \qquad (y \neq x)$$

But when the iteration is subject-uniform rather than subject-diverse, it might be advantageous to postulate certain special theses, such as

$$\text{If } p \in \mathbf{B}_x, \text{ then } (p \in \mathbf{B}_x) \in \mathbf{B}_x,$$

which in effect limits the beliefs at issue to conscious beliefs. The plausibility of this thesis also implicates its converse—namely, whether there are circumstances under which someone's believing that he believes something would necessarily vouch for his believing of it (that is, whether it is legitimate to argue that "if x believes that he believes that p, then he believes that p"); *i.e.,*

$$\text{If } (p \in \mathbf{B}_x) \in \mathbf{B}_x, \text{ then } p \in \mathbf{B}_x.$$

According to this thesis, the belief set $\mathbf{B}_x$ is to have the feature of second-order—as opposed to direct—applicability. From $q \in \mathbf{B}_x$, it is not, in general, permissible to infer q, but one is entitled to do so when q takes the special form $p \in \mathbf{B}_x$—*i.e.,* when the belief at issue is one about the subject's own beliefs.

The theory is predicated on the view that belief is subject to logical compulsion but that the range of this compulsion is limited since people are not logically omniscient. Belief here is like sight: man has a limited range of logical vision; he can see clearly in the immediate logical neighbourhood of his beliefs but only dimly afar.

The logic of knowing. The propositional sense of knowing (*i.e.,* knowing that something or other is the case), rather than the operational sense of knowing (*i.e.,* knowing how something or other is done), is generally taken as the starting point for a logical theory of knowing. Accordingly, the logician may begin with a person x and consider a set of propositions $\mathbf{K}_x$ to represent his "body of knowledge." The aim of the theory then is to clarify and to characterize the relationship "x knows that p" or "p is among the items known to x," which is here represented as $p \in \mathbf{K}_x$.

"Knowing as" and "being" true

There can be false knowledge only in the sense that "he thought he knew that p, but he was mistaken." When the falsity of purported knowledge becomes manifest, the claim to knowledge must be withdrawn. "I know that p, but it may be false that p" is a contradiction in terms. When something is asserted or admitted as known, it follows that this must be claimed to be true. But what sort of inferential step is at issue in the thesis that "x knows p" leads to "p is true"? Is the link deductive, inductive, presuppositional, or somehow "pragmatic"? Each view has its supporters: on the deductive approach, $p \in \mathbf{K}_x$ logically implies (deductively entails) p; on the inductive approach, $p \in \mathbf{K}_x$ renders p extremely probable, though not necessarily certain; on the presuppositional approach, $p \in \mathbf{K}_x$ is improper (nonsensical) whenever p is not true; and on the pragmatic approach, the assertion of $p \in \mathbf{K}_x$ carries with it a rational commitment to the assertion of p (in a manner, however, that does not amount to deductive entailment). From the standpoint of a logic of knowing, the most usual practice is to assume the deductive approach and to lay it down as a rule that if $p \in \mathbf{K}_x$, then p is true. This approach construes knowledge in a very strong sense.

According to a common formula, knowledge is "true, justified belief." This formulation, however, seems defective. Let the expression $\mathbf{J}_x p$ be defined as meaning "x has justification for accepting p"; then

$$p \in \mathbf{K}_x = p \cdot \mathbf{J}_x p \cdot p \in \mathbf{B}_x.$$

For example, the proposition "Jane knows that ($\mathbf{K}_{\text{Jane}}$) the gown is priceless (p)" means (=) "The gown is priceless, and Jane has justification for accepting that it is priceless ($\mathbf{J}_{\text{Jane}}$ p) and Jane believes that it is priceless ($p \in \mathbf{B}_{\text{Jane}}$)." One cannot but assume that the conceptual nature of $\mathbf{J}$ is such as to underwrite the rule: "If x is justified in accepting p, then he is justified in accepting 'Either p or q' "; *i.e.*,

$$\text{If } \mathbf{J}_x p, \text{ then } \mathbf{J}_x(p \vee q), \qquad \text{(J)}$$

in which q can be any other proposition whatsoever. The components p, q, and x may be such that all of the following obtain:

1. not-p
2. q
3. x believes that p; *i.e.*, $p \in \mathbf{B}_x$
4. x does not believe that q; *i.e.*, $q \notin \mathbf{B}_x$ and, indeed, x believes that not-q; *i.e.*, $\sim q \in \mathbf{B}_x$
5. x is justified in accepting q; *i.e.*, $\mathbf{J}_x q$
6. x believes that either p or q; *i.e.*, $p \vee q \in \mathbf{B}_x$

Clearly, on any reasonable interpretation of $\mathbf{B}$ and $\mathbf{J}$, this combination of six premises is possible. But the following consequences would then obtain:

7. $p \vee q$ — by item 2 above
8. $\mathbf{J}_x(p \vee q)$ — by item 5 above and by $\mathbf{J}$
9. $(p \vee q) \in \mathbf{K}_x$ — by items 6, 7, and 8

The conclusion (9) is wrong, however; x cannot properly be said to know that either p or q when $p \vee q$ is true solely because of the truth of q (which x rejects), but $p \vee q$ is believed by x solely because he accepts p (which is false). This example shows that the proposed definition of knowledge as "true, justified belief" cannot be made to work. The best plan, therefore, seems to be to treat the logic of knowing directly, rather than through the mediation of acceptance (belief) and justification.

Overt versus tacit knowledge

Since Aristotle's day, stress has been placed on the distinction between actual, overt knowledge that requires an explicit, consciously occurring awareness of what is known and potential, tacit knowledge that requires only implicit dispositional awareness. Unless $p \in \mathbf{K}_x$ is construed in the tacit sense, the following principles will not hold:

$$\text{If } p \in \mathbf{K}_x \text{ and } p \vdash q, \text{ then } q \in \mathbf{K}_x.$$
$$\text{If } p \in \mathbf{K}_x \text{ and } q \in \mathbf{K}_x, \text{ then } (p \cdot q) \in \mathbf{K}_x.$$

These two rules, if accepted, however, suffice to guarantee the principle

$$\text{If } p_1, p_2, \ldots, p_n \vdash q, \text{ then } p_1 \in \mathbf{K}_x, p_2 \in \mathbf{K}_x, \ldots, p_n \in \mathbf{K}_x \vdash q \in \mathbf{K}_x.$$

Similar considerations regarding the potential construction of knowledge govern the answer to the question of whether, when something is known, this fact itself is known: if $p \in \mathbf{K}_x$, then $(p \in \mathbf{K}_x) \in \mathbf{K}_x$. This principle is eminently plausible, provided that the membership of $\mathbf{K}_x$ is construed in the implicit (tacit) rather than in the explicit (overt) sense.

The logic of questions. Whether a given grouping of words is functioning as a question may hinge upon intonation, accentuation, or even context, rather than upon overt form: at bottom, questions represent a functional rather than a purely grammatical category. The very concept of a question is correlative with that of an answer, and every question correspondingly delimits a range of possible answers. One way of classifying questions is in terms of the surface characteristics of this range. On this basis, the logician can distinguish (among others):

(1) yes/no questions (example: "Is today Tuesday?"),
(2) item-specification questions (example: "What is an instance of a prime number?"),
(3) instruction-seeking questions (example: "How does one bake an apple pie?"), and so on.

Propositional approach

From the logical standpoint, however, a more comprehensive policy and one leading to greater precision is to treat every answer as given in a complete proposition ("Today is not Tuesday," "Three is an example of a prime number," and so on). From this standpoint, questions can be classed in terms of the nature of the answers. There would then be factual questions (example: "What day is today?") and normative questions (example: "What ought to be done in these circumstances?").

The advantage of the propositional approach to answers is that it captures the intrinsically close relationship between question and answer. The possible answers to (1) "What is the population of A-ville?" and (2) "What is the population of B-burgh?" are seemingly the same—namely, numbers of the series 0, 1, 2, ... But once complete propositions are taken to be at issue, then an answer to 1, such as "The population of A-ville is 5,238," no longer counts as an answer to 2, since the latter must mention B-burgh. This approach has the disadvantage, on the other hand, of obscuring similarities in similar questions. One can now no longer say of two brothers that the questions "Who is Tom's father?" and "Who is John's father?" have the same answer.

With every question Q can be correlated the set of propositions $\mathbf{A}(Q)$ of possible answers to Q. Thus, "What day of the week is today?" has seven conceivable answers, of the form "The day of the week today is Monday," and the like. A possible answer to a question must be a possibly true statement. Accordingly, the question "What is an example of a prime number?" does not have "The Washington Monument is an example of a prime number" among its possible answers.

Truth-values in question theory

A question can be said to be true if it has a true answer—*i.e.*, if $(\exists p)\,[p \cdot p \in \mathbf{A}(Q)]$, which (taking the existential quantifier $\exists$ to mean "there exists . . . ") can be read "There exists a proposition p such that p is true and p is among the answers of Q." Otherwise it is false—*i.e.*, all its answers are false. If he never came at all, the question "On what day of the week did he come?" is a false question in the sense that it lacks any true answer.

A true question can be called contingent if it admits of possible answers that are false, as in "Where did Jones put his pen?" In logic and mathematics there are, presumably, no contingent questions.

Questions can have presuppositions, as in "Why does Smith dislike Jones?" Any possible answer here must take the form "Smith dislikes Jones because . . ." and so commits one to the claim that "Smith dislikes Jones." Every such question with a false presupposition must be a false question: all its possible answers (if any) are false.

Besides falsity, questions can exhibit an even more drastic sort of "impropriety." They can be illegitimate in that they have no possible answers whatsoever (example: "What is an example of an even prime number different from two?"). The logic of questions is correspondingly three-valued: a question can be true (*i.e.*, have a true answer), illegitimate (*i.e.*, have no possible answer at all), or false (*i.e.*, have possible answers but no true ones).

One question, Q_1, will entail another, Q_2, if every possible answer to the first deductively yields a possible answer to

the second, and every true answer to the first deductively yields a true answer to the second. In this sense the question "What are the dimensions of that box?" entails the question "What is the height of that box?"

PRACTICAL LOGIC

The theory of reasoning with concepts of practice—of analyzing the logical relations obtaining among statements about actions and their accompaniments in choosing, planning, commanding, permitting, and so on—constitutes the domain of practical logic.

The logic of preference. The logic of preference—also called the logic of choice, or proairetic logic (Greek *proairesis,* "a choosing")—seeks to systematize the formal rules that govern the conception "x is preferred to y." A diversity of things can be at issue here: (1) Is x preferred to y by some individual (or group), or is x preferable to y in terms of some impersonal criterion? (2) Is on-balance preferability at issue or preferability in point of some particular factor (such as economy or safety or durability)? The resolution of these questions, though vital for interpretation, does not affect the formal structure of the preference relationships.

Symbolization and approach taken in proairetic logic. The fundamental tools of the logic of preference are as follows: (1) (strong) preference: x is preferable to y, symbolically $x \gg y$, (2) indifference: x and y are indifferent, $x \cong y$, defined as "neither $x \gg y$ nor $y \gg x$," and (3) weak preference: x is no less preferred than y, $x \geqq y$, defined as "either $x \gg y$ or $x \cong y$." Since preference constitutes a relationship, its three types can be classed in terms of certain distinctions commonly drawn in the logic of relations: that of reflexivity (whether holding of itself: "John supports himself"), that of symmetry (whether holding when its terms are interchanged: "Peter is the cousin of Paul"; "Paul is the cousin of Peter"), and that of transitivity (whether transferable: $a \gg b$ and $b \gg c$; therefore $a \gg c$). Once it is established that the (strong) preference relation ($\gg$) is an ordering (*i.e.,* is irreflexive, asymmetric, and transitive), it then follows that weak preference ($\geqq$) is reflexive, nonsymmetric, and transitive and that indifference ($\cong$) is an equivalence relation (*i.e.,* reflexive, symmetric, and transitive).

The "measure of merit"

One common approach to establishing a preference relation is to begin with a "measure of merit" to evaluate the relative desirability of the items $x, y, z, \ldots$, that are at issue. Thus for any item x, a real-number quantity is obtained, symbolized $\#(x)$. (Such a measure is called a utility measure, the units are called utiles, and the comparisons or computations involved constitute a preference calculus.) In terms of such a measure, a preference ordering is readily introduced by the definitions that (1) $x \gg y$ is to be construed as $\#(x) > \#(y)$, (2) $x \geqq y$ as $\#(x) \geq \#(y)$, and (3) $x \cong y$ as $\#(x) = \#(y)$, in which $\geq$ means "is greater than or equal to." Given these definitions, the relationships enumerated above must all obtain. Thus, the step from a utility measure to a preference ordering is simple.

Construction of a logic of preference. In constructing a logic of preference, it is assumed that the items at issue are propositions $p, q, r, \ldots$ and that the logician is to introduce a preferential ordering among them, with $p \gg q$ to mean "p's being the case is preferred to q's being the case." The problem is to systematize the logical relationships among such statements in order to permit a determination of whether, for example, it is acceptable to argue that "if either p is preferable to q or p is preferable to r, then p is preferable to either q or r," symbolized

$$(p \gg q \vee p \gg r) \supset [p \gg (q \vee r)]$$

(in which $\supset$ means "implies" or "if . . . then"), or to argue similarly that

$$(p \gg q \cdot r \gg q) \supset [(p \cdot r) \gg q].$$

For example, "If eating pears (p) is preferable to eating quinces (q) and eating rhubarb (r) is preferable to eating quinces, then eating both pears and rhubarb is preferable to eating quinces." The task is one of erecting a foundation for the systematization of the formal rules governing such a propositional preference relation—a foundation that can be either axiomatic or linguistic (*i.e.,* in terms of a semantical criterion of acceptability).

Approach in terms of possible worlds

One procedure—adapted from the ideas of the Finnish philosopher Georg Henrik von Wright (b. 1916), a prolific contributor to applied logic—is as follows: beginning with a basic set of possible worlds (or states of affairs) $w_1, w_2, \ldots, w_n$, all the propositions to be dealt with are first defined with respect to these by the usual logical connectives ($\vee$, $\cdot$, $\supset$, and so on). Given two elementary propositions p and q, there are just the following possibilities: both are true, p is true and q is false, p is false and q is true, or both are false. Corresponding to each of these possibilities is a possible world; thus,

$$w_1 = p \cdot q$$
$$w_2 = p \cdot \sim q$$
$$w_3 = \sim p \cdot q$$
$$w_4 = \sim p \cdot \sim q.$$

The truth of p then amounts to the statement that one of the worlds w_1, w_2 obtains, so that p is equivalent to $w_1 \vee w_2$. Moreover, a given basic preference/indifference ordering among the w_i is assumed. On this basis the following general characterization of propositional preference is stipulated: If delta (δ) is taken to represent any (and thus every) proposition independent of p and q, then p is preferable to q ($p \gg q$), if for every such δ it is the case that every possible world in which p and not-q and δ are the case ($p \cdot \sim q \cdot \delta$) is w-preferable to every possible world in which not-p and q and δ is the case ($\sim p \cdot q \cdot \delta$)—*i.e.,* when $p \cdot \sim q$ is always preferable to $\sim p \cdot q$ provided that everything else is equal. It is readily shown that through this approach such general rules as the following are obtained:

1. If p is preferable to q, then q is not preferable to p; *i.e.,*
$$p \gg q \vdash \sim (q \gg p).$$
2. If p is preferable to q, and q is preferable to r, then p is preferable to r; *i.e.,*
$$(p \gg q \cdot q \gg r) \vdash (p \gg r).$$
3. If p is preferable to q, then not-q is preferable to not-p; *i.e.,*
$$p \gg q \vdash \sim q \gg \sim p.$$
4. If p is preferable to q, then having p and not-q is preferable to having not-p and q; *i.e.,*
$$p \gg q \vdash (p \cdot \sim q) \gg (\sim p \cdot q).$$

The preceding construction of preference requires only a preference ordering of the possible worlds. If, however, a measure for both probability and desirability (utility) of possible worlds is given, then one can define the corresponding #-value (see below) of an arbitrary proposition p as the probabilistically weighed utility value of all the possible worlds in which the proposition obtains. As an example, p may be the statement "The Franklin Club caters chiefly to business people," and q the statement "The Franklin Club is sports-oriented." It may then be supposed as given that the following values hold:

World	Probability	Desirability
$w_1 = p \cdot q$	1/6	−2
$w_2 = p \cdot \sim q$	2/6	+1
$w_3 = \sim p \cdot q$	2/6	−1
$w_4 = \sim p \cdot \sim q$	1/6	+3

The #-value of a proposition is determined by first multiplying the probability times the desirability of each world in which the proposition is true and then taking the sum of these. For example, the #-value of p is determined as follows: p is true in each of w_1 and w_2 (and only these); the probability times the desirability of w_1 is $1/6 \times (-2)$, and that of w_2 is $2/6 \times (+1)$; thus #-(p) is $1/6 \times (-2) + 2/6 \times (+1) = 0$. (The #-value corresponds to the decision theorists' notion of expected value.) By this procedure it can easily be determined that

$$\#(p) = 0 \qquad \#(\sim p) = \tfrac{1}{6}$$
$$\#(q) = -(\tfrac{4}{6}) \qquad \#(\sim q) = \tfrac{5}{6}.$$

Since both $\#(p) > \#(q)$ and $\#(\sim q) > \#(\sim p)$, one correspondingly obtains both $p \gg q$ and $\sim q \gg \sim p$ in the example at

issue—*i.e.*, "That the Franklin Club should cater chiefly to business people is preferable to its being sports-oriented" and "Its not being sports-oriented is preferable to its not catering chiefly to business people." (The result is, of course, relative to the given desirability schedule specified for the various possible-world combinations in the above tabulation.)

A more complex mode of preference results, however, if—when some basic utility measure, $\#(x)$, is given—instead of having $p \gg q$ correspond to the condition that $\#(p) > \#(q)$, it is taken to correspond to $\#(p) - \#(\sim p) > \#(q) - \#(\sim q)$. This mode will be governed by characteristic rules, specifically including all those listed above.

The logic of commands. Some scholars have maintained that there cannot be a logic of commands (instructions, orders), inasmuch as there can be no logic in which validity of inference cannot be defined. Validity, however, requires that the concept of truth be applicable (an argument being valid when its conclusion must be true if its premises are true). But, since commands—and for that matter also instructions, requests, and so on—are neither true nor false, it is argued that the concept of validity cannot be applied, so there can be no valid inference in this sphere. This line of thought, however, runs counter to clear intuitions that arise in specific cases, in which one unhesitatingly reasons from commands and sets of commands. If an examination has the instructions "Answer no fewer than three questions! Answer no more than four questions!" one would not hesitate to say that this implies the instruction, "Answer three or four questions!"

Truth involvements

This seeming impasse can be broken, in effect, by importing truth into the sphere of commands through the back door: with any command one can associate its termination statement, which, with future-tense reference, asserts it as a fact that what the command orders will be done. Thus, the command "Shut all the windows in the building!" has the termination statement "All the windows in the building will be shut." In case of a pure command argument—*i.e.*, one that infers a command conclusion from premises that are all commands—validity can be assessed in the light of the validity of the purely assertoric syllogism composed of the corresponding termination statements. Thus the validity of the command argument given above derives from the validity of the inference from the premises "No fewer than three questions will be answered and no more than four questions will be answered" to the conclusion "Three or four questions will be answered."

The logical issues of pure command inference can be handled in this manner. But what of the mixed cases in which some statement—premise or conclusion—is not a command?

Special cases

Special case 1. One mixed case is that in which the premises nontrivially include noncommands, but the inferred conclusion is a command. Some writers have endorsed the rule that there is no validity unless the command conclusion is forthcoming from the command premises alone. This, however, invalidates such seemingly acceptable arguments as "Remove all cats from the area; the shed is in the area; so, remove all cats from the shed." It is more plausible, however, to stipulate the weaker condition that an inference to a command conclusion cannot count as valid unless there is at least one command premise that is essential to the argument. Subject to this restriction, a straightforward application of the above-stated characterization of validity can again be made. This approach validates the above-mentioned command inference via the validity of the assertion inference: "All cats will be removed from the area; the shed is in the area; so, all cats will be removed from the shed." (The rule under consideration suffices to block the unacceptable argument from the factual premise "All the doors will be shut" to the command conclusion "Shut all the doors.")

Special case 2. Another mixed case is that in which the premises nontrivially include commands, but the inferred conclusion is an ordinary statement of fact. Some authorities stipulate that no indicative conclusion can be validly drawn from a set of premises which cannot validly be drawn from the indicative among them alone. This rule would seem to be acceptable, though subject to certain significant provisos: (1) It must be restricted to categorical rather than conditional commands. "If you want to see one of the world's tallest buildings, look at the Empire State Building" conveys (inter alia) the information that "The Empire State Building is one of the world's tallest buildings." (2) Exception must be made for those commands that include in their formulation—explicitly or by way of tacit presupposition—reference to a factual datum. "John, give the book to Tom's brother Jim" yields the fact that Jim is Tom's brother; and "John, drive your car home" (= "John, you own a car: drive it home") yields "John owns a car." With suitable provisos, however, the rule can be maintained to resolve the issues of the special case in view.

Deontic logic. The propositional modalities relating to normative (or valuational) classifications of actions and states of affairs, such as the permitted, the obligatory, the forbidden, or the meritorious, are characterized as deontic modalities (Greek *deontos*, "of that which is binding") and systematized in deontic logic. Though this subject was first treated as a technical discipline in 1926, its current active development dates from a paper published in 1951 by von Wright. As a highly abstracted branch of logical theory, it leaves to substantive disciplines—such as ethics and law—the concrete questions of what specific acts or states of affairs are to be forbidden, permitted, or the like (just as deductive logic does not meddle with what contingent issues are true but tells only what follows when certain facts or assumptions about the truth are given). It seeks to systematize the abstract, purely conceptual relations between propositions in this sphere, such as the following: if an act is obligatory, then its performance must be permitted and its omission forbidden. In given circumstances, either any act is permitted itself or its omission is permitted.

The systematization and relation to alethic modal logic. In the systematization of deontic logic, the symbols p, q, r, . . . may be taken to range over propositions dealing both with impersonal states of affairs and with the human acts involved in their realization. Certain special deontic operations can then be introduced: $\mathbf{P}(p)$ for "It is permitted that p be the case"; $\mathbf{F}(p)$ for "It is forbidden that p be the case"; and $\mathbf{O}(p)$ for "It is obligatory that p be the case." In a systematization of deontic logic, it is necessary to take only one of these three operations as primitive (*i.e.*, as an irreducible given), because the others can then be introduced in terms of it. For example, when $\mathbf{P}$ alone is taken as primitive (as is done here), the following can be introduced by definition: "It is obligatory that p" means "It is not permitted that not-p," and "It is forbidden that p" means "It is not permitted that p"; *i.e.*,

Reduction to permissibility terms

$$\mathbf{O}(p) = \sim\mathbf{P}(\sim p) \text{ and } \mathbf{F}(p) = \sim\mathbf{P}(p).$$

The logical grammar of $\mathbf{P}$ is presumably to be such that one wants to insist upon the rule:

$$\text{Whenever} \vdash p \supset q, \text{ then} \vdash \mathbf{P}(p \supset q).$$

Further, a basic axiom for such an operator as $\mathbf{P}$ is

$$\vdash \mathbf{P}(p \supset q) \supset (\mathbf{P}(p) \supset \mathbf{P}(q)).$$

from which it immediately follows that

$$\text{Whenever} \vdash p \supset q, \text{ then} \vdash \mathbf{P}(p) \supset \mathbf{P}(q).$$

Example: "Since one's helping Jones, who has been robbed, entails that one help someone who has been robbed, being permitted to help Jones (who has been robbed) entails that one be permitted to help someone who has been robbed." This yields such principles as "If both p and q are permitted, then p is permitted and q is permitted" and "If p is permitted, then either p or q is permitted"; *i.e.*,

$$\vdash \mathbf{P}(p \cdot q) \supset [\mathbf{P}(p) \cdot \mathbf{P}(q)] \text{ and} \vdash \mathbf{P}(p) \supset \mathbf{P}(p \vee q).$$

And, once it is postulated that "A p exists that is permitted"—*i.e.*, $\vdash (\exists p)\mathbf{P}(p)$—then the statement that "It is not permitted that both p and not-p"—*i.e.*, $\sim\mathbf{P}(p \cdot \sim p)$—is also yielded. Moreover, on any adequate theory of $\mathbf{P}$, it is necessary to have such principles as "Either p or not-p is permitted"; *i.e.*, $\vdash \mathbf{P}(p \vee \sim p)$.

On the other hand, certain principles must be rejected, such as "If p is permitted and q is permitted, then both

p and q taken together are permitted"—*i.e.*, $\dashv [\mathbf{P}(p) \cdot \mathbf{P}(q)] \supset \mathbf{P}(p \cdot q)$, in which $\dashv$ symbolizes the rejection of a thesis—and that "If either p or q is permitted, then p is permitted"—*i.e.*, $\dashv \mathbf{P}(p \vee q) \supset \mathbf{P}(p)$. The first of these, accepted unqualifiedly, would lead to the untenable result that there can be no permission-indifferent acts—*i.e.*, no acts such that both they and their omission are permitted—since this would then lead to $\mathbf{P}(p \cdot \sim p)$. The second thesis would have the unacceptable result of asserting that, when at least one member of a pair of acts is permitted, then both members are permitted.

Analogy with possibility and necessity

In all respects so far considered, deontic logic is wholly analogous to the already well-developed field of alethic modal logic, which deals with statements of the form "It is possible that . . ." (symbolized M), "It is necessary that . . ." (symbolized L), and so on (see above *Modal logic*), with **P** in the role of possibility (M) and **O** in that of necessity (L). This parallel, however, does not extend throughout. In alethic logic, the principle that "necessity implies actuality" obviously holds (*i.e.*, $\vdash Lp \supset p$). But its deontic analogue, that "obligation implies actuality" (*i.e.*, $\vdash \mathbf{O}p \supset p$), must be rejected, or rather an analogous thesis holds only in the weakened form that "obligation implies permissibility" (*i.e.*, $\vdash \mathbf{O}p \supset \mathbf{P}p$). Controversy exists about the relation of deontic to alethic modal logic, principally in the context of Immanuel Kant's thesis that "ought implies can" (*i.e.*, $\vdash \mathbf{O}p \supset Mp$), but also about the theses *ad impossibile nemo obligatur*—"no one is obliged to do the impossible" (*i.e.*, $\vdash \sim Mp \supset \sim \mathbf{O}p$)—and "necessity implies permissibility" (*i.e.*, $Lp \supset \mathbf{P}p$). Although this thesis is generally accepted, some scholars want to strengthen the thesis to "necessity implies obligation" (*i.e.*, $\vdash Lp \supset \mathbf{O}p$), or, equivalently, to "permissibility implies possibility" (*i.e.*, $\vdash \mathbf{P}p \supset Mp$), with the result that only what is possible can count as permitted, so that the impossible is forbidden. Some would deny that it is wrong (*i.e.*, impermissible) to act to realize the impossible, rather than merely unwise.

It has been proposed that deontic logic may perhaps be reduced to alethic modal logic. This approach is based on the idea of a normative code delimiting the range of the permissible. In this context, what signalizes an action as impermissible is that it involves a violation of the code: the statement that the action has occurred entails that the code has been violated and so leads to a "sanction." This line of thought leads to the definition of a modal operator $\mathbf{F}p = L(p \supset \sigma)$, "$p$ necessarily implies a sanction," in which sigma (σ) is the sanction produced by code violation. Correspondingly, one then obtains "For p to be permitted means that p does not imply by necessity a sanction"—*i.e.*, $\mathbf{P}p = \sim L(p \supset \sigma)$—and "For p to be obligatory means that not doing p implies by necessity a sanction"—*i.e.*, $\mathbf{O}p = L(\sim p \supset \sigma)$. Assuming a systematization of the alethic modal operator L, these definitions immediately produce a corresponding system of deontic logic that—if L is a normal modality—has many of the features that are desirable in a modal operator. It also yields, however—through the "paradoxes of strict implication" (see above *Alternative systems of modal logic*)—the disputed principle that "The assumption that p is not possible implies that p is not permissible"; *i.e.*, $\vdash \sim Mp \supset \sim \mathbf{P}p$. This and other similar consequences of the foregoing effort to reduce deontic logic to modal logic have been transcended by other scholars, who have resorted to a mode of implication (symbolized as $\rightarrow$) that is stronger than strict implication (as necessary material implication is called) and then defining $\mathbf{F}p$ as $p \rightarrow \sigma$ instead of as above.

Alternative deontic systems. Each of the three principal deontic systems that have been studied to date is analogous to one of the alethic modal systems that were developed in the mid-20th century.

Analogies with **M**, **S4**, and **S5**

These foundational alethic systems differ by virtue of the different axioms and rules adopted for such modalities as necessity, possibility, and contingency. In the system designated **M**, for example, developed by the aforementioned Finnish logician G.H. von Wright, the adverb "possibly," symbolized M, is taken as the fundamental undefined modality in terms of which the other modalities are constructed. "Necessarily p," symbolized Lp, for example, is defined in the system **M** as "not possibly not-p"; *i.e.*, $Lp = \sim M \sim p$. Alternatively, in an equivalent system, **T**, "necessarily p" is taken as primitive, and "possibly p" is defined as "not necessarily not-p"; *i.e.*, $Mp = \sim L \sim p$. Several nonequivalent systems have been developed by the conceptual pragmatist C.I. Lewis (1883–1964), primary author of *Symbolic Logic* (1932), the foundational work in this field. Of these systems, that known as **S4** includes all of the system **M** but adds also the axiom that " 'Necessarily p' implies 'It is necessary that necessarily p' "—*i.e.*, $Lp \supset LLp$—whereas that known as **S5** adds still another axiom, that " 'Possibly p' implies 'It is necessary that possibly p' "—*i.e.*, $Mp \supset LMp$ (see above *Alternative systems of modal logic*). The analogous deontic systems are then as follows:

1. **DM** (the deontic analogue of the system **M** of von Wright or of the system **T**). To a standard system of propositional logic the following rule is added: "Any proposition, if true, ought to be true"; that is, If $\vdash p$ then $\vdash \mathbf{O}p$. Example: Given that "to forgive is divine" (p), then "to forgive ought to be divine" ($\mathbf{O}p$). Axioms:
   - A1. "If p is obligatory, then not-p is not obligatory"; *i.e.*, $\mathbf{O}p \supset \sim \mathbf{O} \sim p$.
   - A2. "If p ought to imply q, then if p is obligatory q is obligatory"; *i.e.*, $\mathbf{O}(p \supset q) \supset (\mathbf{O}p \supset \mathbf{O}q)$.
2. **DS4** (the deontic analogue of Lewis' system **S4**). To **M** one adds the axiom:
   - A3. "If p is obligatory, then p ought to be obligatory"; *i.e.*, $\mathbf{O}p \supset \mathbf{OO}p$. Example: "If John ought to pay his debts" ($\mathbf{O}p$), then it is obligatory that John ought to pay his debts" ($\mathbf{OO}p$).
3. **DS5** (the deontic analogue of Lewis' system **S5**). To **M** one adds the axiom:
   - A4. "If p is not obligatory, then p ought to be nonobligatory"; *i.e.*, $\sim \mathbf{O}p \supset \mathbf{O} \sim \mathbf{O}p$.

Semantic systematization

A straightforward semantical systematization of systems of deontic logic can be provided as follows: given a domain of complex propositions built up from atomic propositions ($p, q, r, \ldots$) with the use of propositional connectives ($\sim$, $\cdot$, $\vee$, $\supset$) and **O**, a deontic model set Δ for this domain can be characterized as any set chosen from these propositions that meets the following conditions (in which "iff" means "if and only if"):

1. Not-p is in the set if and only if p is not in the set; *i.e.*, $\sim p \in \Delta$ iff $p \notin \Delta$.
2. "Both p and q together" is in the set if and only if p is in the set and q is in the set; *i.e.*, $(p \cdot q) \in \Delta$ iff $p \in \Delta$ and $q \in \Delta$.
3. "Either p or q" is in the set if and only if either p is in the set or q is in the set; *i.e.*, $(p \vee q) \in \Delta$ iff $p \in \Delta$ or $q \in \Delta$.
4. "That p implies q" is in the set if and only if either p is not in the set or q is in the set; *i.e.*, $(p \supset q) \in \Delta$ iff $p \notin \Delta$ or $q \in \Delta$.
5. "That p is obligatory" is in the set whenever p is posited; *i.e.*, $\mathbf{O}p \in \Delta$ whenever $\vdash p$.
6. "That not-p is not obligatory" is in the set whenever "p is obligatory" is in the set; *i.e.*, $\sim \mathbf{O} \sim p \in \Delta$ whenever $\mathbf{O}p \in \Delta$.
7. "That q is obligatory" is in the set whenever both "p is obligatory" is in the set and "That p implies q is obligatory" is in the set; *i.e.*, $\mathbf{O}q \in \Delta$ whenever both $\mathbf{O}p \in \Delta$ and $\mathbf{O}(p \supset q) \in \Delta$.

A proposition can be characterized as a deontic thesis (D-thesis) if it can be shown that, in virtue of these rules, it must belong to every deontic model set. It can be demonstrated that the D-thesis in this sense will coincide exactly with the theorems of **DM**—the first of the above three systems. Furthermore, if one adds one of the additional rules:

- 8′. "That p ought to be obligatory" is in the set whenever "p is obligatory" is in the set; *i.e.*, $\mathbf{OO}p \in \Delta$ whenever $\mathbf{O}p \in \Delta$.
- 8″. "That p ought to be non-obligatory" is in the set whenever "p is not obligatory" is in the set; *i.e.*, $\mathbf{O} \sim \mathbf{O}p \in \Delta$ whenever $\sim \mathbf{O}p \in \Delta$.

then the corresponding D′ or D″ theses will coincide exactly with the theorems of the deontic systems **DS4** and **DS5**, respectively—numbers 2 and 3 above.

LOGICS OF PHYSICAL APPLICATION

Certain systems of logic are built up specifically with particular physical applications in view. Within this range lie temporal logic; spatial, or topological, logic; mereology, or the logic of parts and wholes generally; as well as the logic of circuit analysis.

Since the field of topological logic is still relatively undeveloped, the reader is referred to the bibliography for a recent source that provides some materials and references to the literature.

Temporal logic. The object of temporal logic—variously called chronological logic or tense logic—is to systematize reasoning with time-related propositions. Such propositions generally do not involve the timeless "is" (or "are") of the mathematicians' "three is a prime," but rather envisage an explicitly temporal condition (examples: "Bob *is* sitting," "Robert *was* present," "Mary *will have been* informed"). In this area, statements are employed in which some essential reference to the before-after relationship or the past-present-future relationship is at issue; and the ideas of succession, change, and constancy enter in.

Classic historical treatments. Chronological logic originated with the Megarians of the 4th century BC, whose school (not far from Athens) reflected the influence of Socrates and of Eleaticism.

In the Megarian conception of modality, the actual is that which is realized now, the possible is that which is realized at some time or other, and the necessary is that which is realized at all times. These Megarian ideas can be found also in Aristotle, together with another temporalized sense of necessity according to which certain possibilities are possible prior to the event, actual then, and necessary thereafter, so that their modal status is not omnitemporal (as in the Megarian concept) but changes in time. The Stoic conception of temporal modality is yet another cognate development, according to which the possible is that which is realized at some time in the present or future, and the necessary that which is realized at all such times. The Diodorean concept of implication (named after the 4th-century-BC Megarian logician Diodorus Cronus) holds, for example, that the conditional "If the sun has risen, it is daytime" is to be given the temporal construction "All times after the sun has risen are times when it is daytime." The Persian logician Avicenna (980–1037), the foremost philosopher of medieval Islām, treated this chronological conception of implication in the framework of a general theory of categorical propositions (such as "All A is B") of a temporalized type and considerably advanced and developed the Megarian-Stoic theory of temporal modalities.

Fundamental concepts and relations of temporal logic.

Definite versus indefinite reference

The statements "It sometimes rains in London," "It always rains in London," and "It is raining in London on Jan. 1, AD 3000," are all termed chronologically definite, in that their truth or falsity is independent of their time assertion. By contrast, the statements "It is now raining in London," "It rained in London yesterday," and "It will rain in London sometime next week" are all chronologically indefinite, in that their truth or falsity is not independent of their time of assertion. The notation $| t \vdash p$ is here introduced to mean that the proposition p, often in itself chronologically indefinite, is represented as being asserted at the time t. For example, if p_1 is the statement "It is raining in London today" and t_1 is Jan. 1, 1900, then "$| t_1 \vdash p_1$" represents the assertion made on Jan. 1, 1900, that it is raining today—an assertion that is true if and only if the statement "It is raining in London on Jan. 1, 1900," is true. If the statement p is chronologically definite, then (by definition) the assertions "$| t \vdash p$" and "$| t' \vdash p$" are materially equivalent (*i.e.,* have the same truth value) for all values of t and t'. Otherwise, p is chronologically indefinite. The time may be measured, for example, in units of days, so that the time variable is made discrete. Then $(t + 1)$ will represent "the day after t-day," $(t - 1)$ will represent "the day before t-day," and the like. And, further, the statements p_1, q_1, and r_1 can then be as follows:

p_1: "It rains in London today."
q_1: "It will rain in London tomorrow."
r_1: "It rained in London yesterday."

The following assertions can now be made:

$$\begin{aligned} &\text{P:}| \ t \vdash p_1 \\ &\text{Q:}| \ t - 1 \vdash q_1 \\ &\text{R:}| \ t + 1 \vdash r_1. \end{aligned}$$

Clearly, for any value of t whatsoever, the assertions P, Q, and R must (logically) be materially equivalent (*i.e.,* have the same truth value). This illustration establishes the basic point—that the theory of chronological propositions must be prepared to exhibit the existence of logical relationships among propositions of such a kind that the truth of the assertion of one statement at one time may be bound up essentially with the truth (or falsity) of the assertion of some very different statement at another time.

Dated versus pseudo-dated statements

A (genuine) date is a time specification that is chronologically stable (such as "Jan. 1, 3000," or "the day of Lincoln's assassination"); a pseudodate is a time specification that is chronologically unstable (such as "today" or "six weeks ago"). These lead to very different results depending on the nature of the fundamental reference point—the "origin" in mathematical terms. If the origin is a pseudodate—say, "today"—the style of dating will be such that its chronological specifiers are pseudodates—tomorrow, the day before yesterday, four days ago, and so on. If, on the other hand, the origin is a genuine date, say that of the founding of Rome or the accession of Alexander, the style of dating will be such that all its dates are of the type: two hundred and fifty years *ab urbe condita* ("since the founding of the city"). Clearly, a chronology of genuine dates will then be chronologically definite, and one of pseudodates will be chronologically indefinite.

Let p be some chronologically indefinite statement. Then, in general, another statement can be formed, asserting that p holds (obtains) at the time t. Correspondingly, let the statement-forming operation $\mathbf{R}_t$ be introduced. The statement $\mathbf{R}_t(p)$, which is to be read "p is realized at the time t," will then represent the statement stating explicitly that p holds (obtains) specifically at the time t. Thus, if t_1 is 3:00 PM Greenwich Mean Time on Jan. 1, 2000, and p_1 is the (chronologically indefinite) statement "All men are (*i.e.,* are now) playing chess," then "$\mathbf{R}_{t_1}(p_1)$" is the statement "It is the case at 3:00 PM Greenwich Mean Time on Jan. 1, 2000, that all men are playing chess."

Systematization of temporal reasoning. On the basis of these ideas, the logical theory of chronological propositions can be developed in a systematic, formal way. It may be postulated that the operator $\mathbf{R}$ is to be governed by the following rules:

> The negation of a statement p is realized at a given time if and only if it is not the case that the statement is realized at that time; *i.e.,* $\mathbf{R}_t(\sim p) \equiv \sim \mathbf{R}_t(p)$, in which $\equiv$ signifies equivalence and is read "if and only if." (T1)

> A conjunction of two statements is realized at a given time if and only if each of these two statements is realized at that time: $\mathbf{R}_t(p \cdot q) \equiv [\mathbf{R}_t(p) \cdot \mathbf{R}_t(q)]$. Example: "John and Jane are at the railroad station at 10:00 AM—$\mathbf{R}_t(p \cdot q)$—if and only if John is at the station at 10:00 AM—$\mathbf{R}_t(p)$—and Jane is at the station at 10:00 AM—$\mathbf{R}_t(q)$." (T2)

If a statement is realized universally—*i.e.,* at any and every time whatsoever—it can then be expressed more simply as being true without any temporal qualifications; hence the rule:

> If for every time t the statement p is realized, then p obtains unqualifiedly; *i.e.,* $(\forall t)\mathbf{R}_t(p) \supset p$, in which $\forall$ is the universal quantifier.

If two times are involved, however, then the left-hand term in rule (T3) can be expressed within the second time frame as "It will be the case τ from now that, for every time t, it will be the case t from the first now that p"; *i.e.,* $\mathbf{R}_\tau[(\forall t)\mathbf{R}_t(p)]$. It is an algebraic rule, however, that an $\mathbf{R}_t$ operator can be moved to the right past an irrelevant quantifier; hence

$$\mathbf{R}_\tau[(\forall_t)\mathbf{R}_t(p)] \equiv (\forall_t)(\mathbf{R}_\tau[\mathbf{R}_t(p)]);$$

and, correspondingly, with the existential quantifier ∃: "It will be the case τ from now that there exists a time t such that p will be realized at t" is equivalent to saying "There exists a time t such that it will be the case τ from now that p will be realized t from the first now" (in which τ is a second time); *i.e.*,

$$\mathbf{R}_\tau[(\exists_t)\mathbf{R}_t(p)] \equiv (\exists_t)(\mathbf{R}_\tau[\mathbf{R}_t(p)]). \qquad \text{(T4)}$$

It is notable that the left-hand side of this equivalence is itself equivalent with $(\exists t)\mathbf{R}_t(p)$ since what follows the initial $\mathbf{R}_\tau$ is a chronologically definite statement.

Finally, there are two distinct ways of construing iterations of the $\mathbf{R}_t$ operator, depending on the choice of origin of the second time scale. Thus a choice is required between two possible rules:

$$\mathbf{R}_\tau[\mathbf{R}_t(p)] \equiv \mathbf{R}_t(p) \qquad \text{(T5-I)}$$

$$\mathbf{R}_\tau[\mathbf{R}_t(p)] \equiv \mathbf{R}_{\tau+t}(p). \qquad \text{(T5-II)}$$

Taking these rules as a starting point, two alternative axiomatic theories are generated for the logic of the operation of chronological realization.

Rules and modalities

Apart from strictly technical results establishing the formal relationships between the various systems of chronological logic, the most interesting findings about the systems of tense logic relate to the theory of temporal modalities. The most striking finding concerns the logical structure of the system of modalities, be it Megarian or Stoic:

Megarian	possibly p:	$(\exists t)\mathbf{R}_t(p)$
	necessarily p:	$(\forall t)\mathbf{R}_t(p)$
Stoic	possibly p:	$(\exists t)[\mathbf{F}(t) \cdot \mathbf{R}_t(p)]$
	necessarily p:	$(\forall t)[\mathbf{F}(t) \supset \mathbf{R}_t(p)]$

in which $\mathbf{F}(t)$ signifies "t is future." It has been shown that the forms, or structures, of both of these systems of temporal modalities are given by the aforementioned system **S5** of C.I. Lewis. Exactly parallel results are obtained for modalities of past times, $\mathbf{P}_t(p)$: p was realized at some (past) time t; and $\sim\mathbf{P}_t(\sim p)$: p has been realized at all (past) times.

Mereology. The founder of mereology was the Polish logician Stanisław Leśniewski. Leśniewski was much exercised about Russell's paradox of the class of all classes not elements of themselves—if this class is a member of itself, then it is not; and if it is not, then it is (example: "This barber shaves everyone in town who does not shave himself." Does the barber then shave himself? If he does, he does not; if he does not, he does.).

Basic concepts and definitions. The paradox results, Leśniewski argued, from a failure to distinguish the distributive and the collective interpretations of class expressions. The statement "x is an element of the class of X's" is correspondingly equivocal. When its key terms (element of, class of) are used distributively, it means simply that x is an X. But, if these terms are used collectively, it means that x is a part (proper or improper) of the whole consisting of the X's—*i.e.*, that x is a part of the object that meets the following two conditions: (1) that every x is a part of it and (2) that every part of it has a common part with some x. On either construction of class membership, one of the inferences essential to the derivation of Russell's paradox is blocked.

Leśniewski presented his theory of the collective interpretation of class expressions in a paper published in 1916. Eschewing symbolization, he formulated his theorems and their proofs in ordinary language. Later he sought to formalize the theory by embedding it within a broader body of logical theory. This theory comprised two parts: protothetic, a logic of propositions (not analyzed into their parts); and ontology, which contains counterparts to the predicational logic (of subjects and predicates), including the calculus of relations and the theory of identity. On his own approach, mereology was developed as an extension of ontology and protothetic, but the practice of most later writers has been to develop as a counterpart to mereology a theory of parts and wholes that is simply an extension of the more familiar machinery of quantificational logic employing ∃ and ∀. This is the course adopted here.

An undefined relation **Pt** serves as the basis for an axiomatic theory of the part relation. This relation is operative with respect to the items of some domain **D**, over which the variables α, β, γ, ... (alpha, beta, gamma, and so on) are assumed to range. Thus, $\alpha\mathbf{Pt}\beta$ is to be read "alpha is a part of beta"—with "part" taken in the wider sense in which the whole counts as part of itself. Two definitions are basic:

Disjointness and summation

1. "α is disjoint from β"; *i.e.*, $\alpha \mid \beta$ is defined as obtaining when "there exists no item γ such that γ is a part of α and γ is a part of β"; *i.e.*, $\sim(\exists\gamma)(\gamma\mathbf{Pt}\alpha \cdot \gamma\mathbf{Pt}\beta)$. Example: "The transmission (α) is disjoint from the motor (β) if there exists no machine part (γ) such that it is a part of the transmission and also a part of the motor."
2. "S has the sum of (or sums to) α"; *i.e.*, $S\,\Sigma\alpha$ is defined as obtaining when "for every γ, this γ is disjoint from α if and only if, for every β, to be a member of S is to be disjoint from γ"; *i.e.*,

$$(\forall\gamma)[\gamma \mid \alpha \equiv (\forall\beta)(\beta \in S \supset \beta \mid \gamma)].$$

$S\Sigma\alpha$ thus obtains whenever everything disjoint from α is disjoint from every S-element (β) as well, and conversely. Example: "A given group of buildings (S) comprises (Σ) the University of Oxford (α) when, for every room in the world (γ)—office, classroom, etc.—this room is disjoint from the university if and only if, in the case of each building (β), for it to be a member ($\in$) of the group that comprises the university (S) it must not have this room as a part ($\beta \mid \gamma$)."

Axiomatization of mereology. A comprehensive theory of parts and wholes can now be built up from three axioms: The first axiom expresses the fact that "for every α and every β, if α is a part of β and β is a part of α, then α and β must be one and the same item"; *i.e.*,

$$(\forall\alpha)(\forall\beta)(\alpha\mathbf{Pt}\beta \cdot \beta\mathbf{Pt}\alpha \supset \alpha = \beta);$$

hence, the axiom:

Items that are parts of one another are identical. (A1)

The second axiom expresses the fact that "for every α and every β, α is a part of β if and only if, for every γ, if this γ is disjoint from β it is then disjoint from α as well"; *i.e.*,

$$(\forall\alpha)(\forall\beta)[\alpha\mathbf{Pt}\beta \equiv (\forall\gamma)(\gamma \mid \beta \supset \gamma \mid \alpha)];$$

hence, the axiom:

One item is part of another only if every item disjoint from the second is also disjoint from the first. (A2)

The third axiom expresses the fact that "if there exists an α that is a member of a nonempty set of items S, then there also exists a β that is the sum of this set"; *i.e.*,

$$(\exists\alpha)(\alpha \in S) \supset (\exists\beta)S\Sigma\beta;$$

hence, the axiom:

Every nonempty set has a sum. (A3)

Several theorems follow from these axioms: Deduced theorems

The first states that "for every α, α is a part of α"; *i.e.*,

$$(\forall\alpha)\alpha\mathbf{Pt}\alpha;$$

hence, the theorem:

Every item is part of itself. (T1)

The second theorem states that "for every α, for every β, and for every γ, if α is a part of β, and β is a part of γ, then α is a part of γ"; *i.e.*,

$$(\forall\alpha)(\forall\beta)(\forall\gamma)[(\alpha\mathbf{Pt}\beta \cdot \beta\mathbf{Pt}\gamma) \supset \alpha\mathbf{Pt}\gamma];$$

hence, the theorem:

The **Pt**-relation is transitive. (T2)

The third theorem states that "for every α, for every β, and for every γ, if γ is a part of α only when it is also a part of β, then α is identical with β"; *i.e.*,

$$(\forall\alpha)(\forall\beta)(\forall\gamma)[(\gamma\mathbf{Pt}\alpha \equiv \gamma\mathbf{Pt}\beta) \supset \alpha = \beta];$$

hence, the theorem:

Any item is completely determined by its parts; items are identical when they have the same parts in common. (T3)

The fourth theorem states that "for every α and every β, there exists a γ that is the sum of α and β"; *i.e.*,

$$(\forall\alpha)(\forall\beta)(\exists\gamma)(\{\alpha, \beta\}\Sigma\gamma);$$

hence, the theorem:

Any two items whatsoever may be summed up. (T4)

In this form as a formal theory of the part relation, the history of mereology can be dated from some drafts and essays of Leibniz prepared in the late 1690s.

COMPUTER DESIGN AND PROGRAMMING

In the most general terms a computer is a device that calculates a result ("output") from one or more initial items of information ("input"). Inputs and outputs are usually represented in binary terms—*i.e.*, in strings of 0s and 1s—and the values of 0 and 1 are realized in the machine by the presence or absence of a current (of electricity, water, light, and so on). When the output is a completely determined function of the input, the connection between a computer and the two-valued logic of propositions is immediate, for a valid argument can be construed as a partial function of the truth values of the premises such that when the premises each have the value true, so does the conclusion.

One of the simplest computers has one input, either 0 or 1 (*i.e.*, a current either off or on), and one output, namely, the reverse of the input. That is, when 0 is input, 1 is output, and, conversely, when 1 is input, 0 is output. This is also the behaviour of the truth function negation ($\sim p$) when applied to the truth values true and false. Thus a circuit elements that behaves in such a way is called a NOT gate:

Symbol for the NOT gate

When no current is input from the left, a current flows out on the right, and, conversely, when a current flows in from the left, none is output to the right.

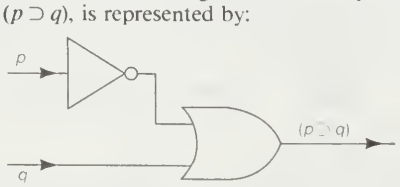
Similarly, devices with two inputs and one output correspond in behaviour to the truth functions conjunction ($p \cdot q$) and disjunction ($p \vee q$). Specifically, in an AND gate,

Symbol for the AND gate

current flows out to the right only when current is present in both inputs; otherwise there is no output. In an OR gate, current is output when a current is present in either or both of the inputs on the left.

Symbol for the OR gate

Other truth functional connectives are easily constructed using combinations of these gates. For example, the conditional, ($p \supset q$), is represented by:



There is no output if there is input from p ("p" is true) and none from q ("q" is false).

It is also possible to connect these gates to memory devices that store intermediate results in order to construct circuits that perform elementary binary arithmetic: addition, subtraction, multiplication, and division. These simple circuits, and others like them, can be connected together in order to perform various computations such as determining the implications of a set of premises or determining the numerical value of a mathematical function for specific argument values.

The details of computer design and architecture depend less on logical theory and more on the mathematical theory of lattices (see ALGEBRA: *Lattice theory*) and are outside the scope of this article. In computer programming, however, logic has a significant role.

Some modern computers, such as the ones in automobiles or washing machines, are dedicated; that is, they are constructed to perform only certain sorts of computations. Others are general-purpose computers, which require a set of instructions about what to do and when to do it. A set of such instructions is called a program. A general-purpose computer operating under a program begins in an initial state with a given input, passes through intermediate states, and should eventually stop in a final state with a definite output. For a given program, the various momentary states of the machine are characterized by the momentary values of all the variables in the program.

In 1974 the British computer scientist Rod M. Burstall first remarked on the connection between machine states and the possible worlds used in the semantics of modal logic (see above *Modal logic*). The use of concepts and results from modal logic to investigate the properties and behaviour of computer programs (*e.g.*, does this program stop after a finite number of steps?) was soon taken up by others, notably Vaughan R. Pratt (dynamic logic), Amir Pnueli (temporal logic), and David Harel (process logic).

The connection between the possible worlds of the logician and the internal states of a computer is easily described. In possible world semantics, p is possible in some world w if and only if p is true in some world w' accessible to w. Depending on the properties of the accessibility relation (reflexive, symmetric, and so on), there will be different theorems about possibility and necessity ("p is necessary" = "$\sim M\sim p$"). The accessibility relation of modal logic semantics can thus be understood as the relation between states of a computer under the control of a program such that, beginning in one state, the machine will (in a finite time) be in one of the accessible states. In some programs, for instance, one cannot return from one state to an earlier state; hence state accessibility here is not symmetric. (For detailed treatments of this subject, refer to the *Bibliography*.)

HYPOTHETICAL REASONING AND COUNTERFACTUAL CONDITIONALS

A simple conditional, or "if," statement asserts a strictly formal relationship between antecedent ("if" clause) and consequent ("then" clause): "If p, then q," without any reference to the status of the antecedent. The knowledge status of this antecedent, however, may be problematic (unknown), or known-to-be-true, or known-to-be-false. In these three cases, one obtains, respectively, the problematic conditional ("Should it be the case that p—which it may or may not be—then q"), the factual conditional ("Since p, then q"), and the counterfactual conditional ("If it were the case that p—which it is not—then q"). Counterfactual conditionals have a special importance in the area of thought experiments in history as well as elsewhere.

Material implication, $p \supset q$, construed simply as the truth-functional "either not-p or q," is clearly not suited to represent counterfactual conditionals, because any material implication with a false antecedent is true: when p is false, then $p \supset q$ and $p \supset \sim q$ are both true, regardless of what one may choose to put in place of q. But even when a stronger mode of implication is invoked, such as strict implication or its cognates, the problem of auxiliary hypotheses (soon to be explained) would still remain.

It seems most natural to view a counterfactual conditional in the light of an inference to be drawn from the contrary-to-fact thesis represented by its antecedent. Thus, "If this rubber band were made of copper, then it would conduct electricity" would be construed as an incomplete presentation of the argument resulting from its expansion into:

Assumption: "This rubber band is made of copper."
Known fact: "Everything made of copper conducts electricity."
Conclusion: "This rubber band conducts electricity."

On the analysis, the conclusion (= the consequent of the counterfactual) appears as a deductive consequence of the assumption (= the antecedent of the counterfactual). This truncated-argument analysis of counterfactuals is a contribution, in essence, of a Polish linguistic theorist, Henry Hiż (b. 1917). On Hiż's analysis, counterfactual conditionals are properly to be understood as metalinguistic—*i.e.,* as making statements about statements. Specifically, "If *A* were so, then *B* would be so" is to be construed in the context of a given system of statements *S,* saying that when *A* is adjoined as a supplemental premise to *S,* then *B* follows. This approach has been endorsed by the American Roderick Chisholm, an important writer in applied logic, and has been put forward by many logicians, most of whom incline to take *S,* as above, to include all or part of the corpus of scientific laws.

Hiż's analysis

The approach warrants a closer scrutiny. On fuller analysis, the following situation, with a considerably enlarged group of auxiliary hypotheses, comes into focus:

Evaluation through hypotheses, facts, and laws

Known facts:
1. "This band is made of rubber."
2. "This band is not made of copper."
3. "This band does not conduct electricity."
4. "Things made of rubber do not conduct electricity."
5. "Things made of copper do conduct electricity."

Assumption: Not-2; *i.e.,* "This band is made of copper."

When this assumption is introduced within the framework of known facts, a contradiction obviously ensues. How can this situation be repaired? Clearly, the logician must begin by dropping items 1 and 2 and replacing them with their negations—the assumption itself so instructs him. But a contradiction still remains. The following alternatives are open:

Alternative 1: Retain: 3, 4. Reject: 1, 2, 5.
Alternative 2: Retain: 4, 5. Reject: 1, 2, 3.

That is, the analyst actually has a choice between rejecting 3 in favour of 5 or 5 in favour of 3, resulting in the following conditionals:

1. "If this rubber band were made of copper, then it would conduct electricity" (since copper conducts electricity).
2. "If this rubber band were made of copper, then copper would not (always) conduct electricity" (since this band does not conduct electricity).

If the first conditional seems more natural than the second, this is owing to the fact that, in the face of the counterfactual hypothesis at issue, the first invites the sacrifice of a particular fact (that the band does not conduct electricity) in favour of a general law (that copper conducts electricity), whereas the second counterfactual would have sacrificed a law to a purely hypothetical fact. On this view, there is a fundamental epistemological difference between actual and hypothetical situations: in actual cases one makes laws give way to facts, but in hypothetical cases one makes the facts yield to laws.

But in more complex cases the fact/law distinction may not help matters. For example, assume a group of three laws L_1, L_2, L_3, where $\sim L_1$ is inconsistent with the conjunction of L_2 and L_3. If asked to hypothesize the denial of L_1—so that the "fact" that one is opposing is itself a law—then what remains is a choice between laws; the distinction between facts and laws does not resolve the issue, and some more sophisticated mechanism for a preferential choice among laws is necessary. (N.R./M.L.Sc.)

THE HISTORY OF LOGIC

Origins of logic in the West

PRECURSORS OF ANCIENT LOGIC

There was a medieval tradition according to which the Greek philosopher Parmenides (5th century BC) invented logic while living on a rock in Egypt. The story is pure legend, but it does reflect the fact that Parmenides was the first philosopher to use an extended argument for his views, rather than merely proposing a vision of reality. But using arguments is not the same as studying them, and Parmenides never systematically formulated or studied principles of argumentation in their own right. Indeed, there is no evidence that he was even aware of the implicit rules of inference used in presenting his doctrine.

Perhaps Parmenides' use of argument was inspired by the practice of early Greek mathematics among the Pythagoreans. Thus it is significant that Parmenides is reported to have had a Pythagorean teacher. But the history of Pythagoreanism in this early period is shrouded in mystery, and it is hard to separate fact from legend.

If Parmenides was not aware of general rules underlying his arguments, the same perhaps is not true for his disciple Zeno of Elea (5th century BC). Zeno was the author of many arguments, known collectively as "Zeno's Paradoxes," purporting to infer impossible consequences from a non-Parmenidean view of things and so to refute such a view and indirectly to establish Parmenides' monist position. The logical strategy of establishing a claim by showing that its opposite leads to absurd consequences is known as reductio ad absurdum. The fact that Zeno's arguments were all of this form suggests that he recognized and reflected on the general pattern.

Zeno's Paradoxes

Other authors too contributed to a growing Greek interest in inference and proof. Early rhetoricians and sophists—*e.g.,* Gorgias, Hippias, Prodicus, and Protagoras (all 5th-century BC)—cultivated the art of defending or attacking a thesis by means of argument. This concern for the techniques of argument on occasion merely led to verbal displays of debating skills, what Plato called "eristic." But it is also true that the sophists were instrumental in bringing argumentation to the central position it came uniquely to hold in Greek thought. The sophists were, for example, among the first people anywhere to demand that moral claims be justified by reasons.

Certain particular teachings of the sophists and rhetoricians are significant for the early history of logic. For example, Protagoras is reported to have been the first to distinguish different kinds of sentences: questions, answers, prayers, and injunctions. Prodicus appears to have maintained that no two words can mean exactly the same thing. Accordingly, he devoted much attention to carefully distinguishing and defining the meanings of apparent synonyms, including many ethical terms.

Socrates (*c.* 470–399 BC) is said to have attended Prodicus' lectures. Like Prodicus, he pursued the definitions of things, particularly in the realm of ethics and values. These investigations, conducted by means of debate and argument as portrayed in the writings of Plato (428/427–348/347 BC), reinforced Greek interest in argumentation and emphasized the importance of care and rigour in the use of language.

Plato continued the work begun by the sophists and by Socrates. In the *Sophist,* he distinguished affirmation from negation and made the important distinction between verbs and names (including both nouns and adjectives). He remarked that a complete statement (*logos*) cannot consist of either a name or a verb alone but requires at least one of each. This observation indicates that the analysis of language had developed to the point of investigating the internal structures of statements, in addition to the relations of statements as a whole to one another. This new development would be raised to a high art by Plato's pupil Aristotle (384–322 BC).

There are passages in Plato's writings where he suggests

that the practice of argument in the form of dialogue (Platonic "dialectic") has a larger significance beyond its occasional use to investigate a particular problem. The suggestion is that dialectic is a science in its own right, or perhaps a general method for arriving at scientific conclusions in other fields. These seminal but inconclusive remarks indicate a new level of generality in Greek speculation about reasoning.

ARISTOTLE

The logical work of all these men, important as it was, must be regarded as piecemeal and fragmentary. None of them was engaged in the systematic, sustained investigation of inference in its own right. That seems to have been done first by Aristotle. At the end of his *Sophistic Refutations,* Aristotle acknowledges that in most cases new discoveries rely on previous labours by others, so that, while those others' achievements may be small, they are seminal. But then he adds:

> Of the present inquiry, on the other hand, it was not the case that part of the work had been thoroughly done before, while part had not. Nothing existed at all. . . . [O]n the subject of deduction we had absolutely nothing else of an earlier date to mention, but were kept at work for a long time in experimental researches.
>
> (From *The Complete Works of Aristotle: The Revised Oxford Translation*, ed. Jonathan Barnes, 1984, by permission of Oxford University Press.)

The *Organon*

Aristotle's logical writings comprise six works, known collectively as the *Organon* ("Tool"). The significance of the name is that logic, for Aristotle, was not one of the theoretical sciences. These were physics, mathematics, and metaphysics. Instead, logic was a tool used by all the sciences. (To say that logic is not a science in this sense is in no way to deny it is a rigorous discipline. The notion of a science was a very special one for Aristotle, most fully developed in his *Posterior Analytics.*)

Aristotle's logical works, in their traditional but not chronological order, are:

1. *Categories,* which discusses Aristotle's 10 basic kinds of entities: substance, quantity, quality, relation, place, time, position, state, action, and passion. Although the *Categories* is always included in the *Organon,* it has little to do with logic in the modern sense.
2. *De interpretatione* (*On Interpretation*), which includes a statement of Aristotle's semantics, along with a study of the structure of certain basic kinds of propositions and their interrelations.
3. *Prior Analytics* (two books), containing the theory of syllogistic (described below).
4. *Posterior Analytics* (two books), presenting Aristotle's theory of "scientific demonstration" in his special sense. This is Aristotle's account of the philosophy of science or scientific methodology.
5. *Topics* (eight books), an early work, which contains a study of nondemonstrative reasoning. It is a miscellany of how to conduct a good argument.
6. *Sophistic Refutations,* a discussion of various kinds of fallacies. It was originally intended as a ninth book of the *Topics.*

Aristotle's logic was a term logic, in the following sense. Consider the schema: "If every β is an α and every γ is a β, then every γ is an α." The "α," "β," and "γ" are variables—*i.e.,* placeholders. Any argument that fits this pattern is a valid syllogism and, in fact, a syllogism in the form known as Barbara. (On this terminology, see below.)

The variables here serve as placeholders for terms or names. Thus, replacing "α" by "substance," "β" by "animal," and "γ" by "dog" in the schema yields: "If every animal is a substance and every dog is an animal, then every dog is a substance," a syllogism in Barbara. Aristotle's logic was a term logic in the sense that it focused on logical relations among such terms in valid inferences.

Aristotle was the first logician to use variables. This innovation was tremendously important, since without them it would have been impossible for him to reach the level of generality and abstraction that he did.

Most of Aristotle's logic was concerned with certain kinds of propositions that can be analyzed as consisting of (1) usually a quantifier ("every," "some," or the universal negative quantifier "no"), (2) a subject, (3) a copula, (4) perhaps a negation ("not"), (5) a predicate. Propositions analyzable in this way were later called categorical propositions and fall into one or another of the following forms:

Categorical forms

1. Universal affirmative: "Every β is an α."
2. Universal negative: "Every β is not an α," or equivalently "No β is an α."
3. Particular affirmative: "Some β is an α."
4. Particular negative: "Some β is not an α."
5. Indefinite affirmative: "β is an α."
6. Indefinite negative: "β is not an α."
7. Singular affirmative: "x is an α," where "x" refers to only one individual (*e.g.,* "Socrates is an animal").
8. Singular negative: "x is not an α," with "x" as before.

Sometimes, and very often in the *Prior Analytics,* Aristotle adopted alternative but equivalent formulations. Instead of saying, for example, "Every β is an α," he would say, "α belongs to every β" or "α is predicated of every β."

In syllogistic, singular propositions (affirmative or negative) were generally ignored, and indefinite affirmatives and negatives were treated as equivalent to the corresponding particular affirmatives and negatives. In the Middle Ages, propositions of types 1–4 were said to be of forms A, E, I, and O, respectively. This notation will be used below.

In the *De interpretatione* Aristotle discussed ways in which affirmative and negative propositions with the same subjects and predicates can be opposed to one another. He observed that when two such propositions are related as forms A and E, they cannot be true together but can be false together. Such pairs Aristotle called contraries. When the two propositions are related as forms A and O or as forms E and I or as affirmative and negative singular propositions, then it must be that one is true and the other false. These Aristotle called contradictories. He had no special term for pairs related as forms I and O, although they were later called subcontraries. Subcontraries cannot be false together, although, as Aristotle remarked, they may be true together. The same holds for indefinite affirmatives and negatives, construed as equivalent to the corresponding particular forms. Note that if a universal proposition (affirmative or negative) is true, its contradictory is false, and so the subcontrary of that contradictory is true. Thus propositions of form A imply the corresponding propositions of form I, and those of form E imply those of form O. These last relations were later called subalternation, and the particular propositions (affirmative or negative) were said to be subalternate to the corresponding universal propositions.

Theory of conversion

Near the beginning of the *Prior Analytics,* Aristotle formulated several rules later known collectively as the theory of conversion. To "convert" a proposition in this sense is to interchange its subject and predicate. Aristotle observed that propositions of forms E and I can be validly converted in this way: if no β is an α, then so too no α is a β, and if some β is an α, then so too some α is a β. In later terminology, such propositions were said to be converted "simply" (*simpliciter*). But propositions of form A cannot be converted in this way: if every β is an α, it does not follow that every α is a β. It does follow, however, that some α is a β. Such propositions, which can be converted provided that not only are their subjects and predicates interchanged but also the universal quantifier is weakened to a particular quantifier "some," were later said to be converted "accidentally" (*per accidens*). Propositions of form O cannot be converted at all: from the fact that some animal is not a dog, it does not follow that some dog is not an animal. Aristotle used these laws of conversion in later chapters of the *Prior Analytics* to reduce other syllogisms to syllogisms in the first figure, as described below.

Aristotle defined a syllogism as "discourse in which, certain things being stated something other than what is stated follows of necessity from their being so." (From *The Complete Works of Aristotle: The Revised Oxford Translation,* ed. Jonathan Barnes, 1984, by permission of Oxford University Press.) But in practice he confined the term to arguments containing two premises and a conclusion, each of which is a categorical proposition. The

subject and predicate of the conclusion each occur in one of the premises, together with a third term (the middle) that is found in both premises but not in the conclusion. A syllogism thus argues that because α and γ are related in certain ways to β (the middle) in the premises, they are related in a certain way to one another in the conclusion.

The predicate of the conclusion is called the major term, and the premise in which it occurs is called the major premise. The subject of the conclusion is called the minor term and the premise in which it occurs is called the minor premise. This way of describing major and minor terms conforms to Aristotle's actual practice and was proposed as a definition by the 6th-century Greek commentator John Philoponus. But in one passage Aristotle put it differently: the minor term is said to be "included" in the middle and the middle "included" in the major term. This remark, which appears to have been intended to apply only to the first figure (see below), has caused much confusion among some of Aristotle's commentators, who interpreted it as applying to all three figures.

Aristotle distinguished three different figures of syllogisms, according to how the middle is related to the other two terms in the premises. In one passage, he says that if one wants to prove α of γ syllogistically, one finds a middle β such that either α is predicated of β and β of γ (first figure), or β is predicated of both α and γ (second figure), or else both α and γ are predicated of β (third figure). All syllogisms must fall into one or another of these figures.

The fourth figure

But there is plainly a fourth possibility, that β is predicated of α and γ of β. Many later logicians recognized such syllogisms as belonging to a separate, fourth figure. Aristotle explicitly mentioned such syllogisms but did not group them under a separate figure; his failure to do so has prompted much speculation among commentators and historians. Other logicians included these syllogisms under the first figure. The earliest to do this was Theophrastus (see below), who reinterpreted the first figure in so doing.

Four figures, each with three propositions in one of four forms (A, E, I, O), yield a total of 256 possible syllogistic patterns. Each pattern is called a mood. Only 24 moods are valid, 6 in each figure. Some valid moods may be derived from others by subalternation—that is, if premises validly yield a conclusion of form A, the same premises will yield the corresponding conclusion of form I. So too with forms E and O. Such derived moods were not discussed by Aristotle; they seem to have been first recognized by Ariston of Alexandria (*c.* 50 BC). In the Middle Ages they were called "subalternate" moods. Disregarding them, there are 4 valid moods in each of the first two figures, 6 in the third figure, and 5 in the fourth. Aristotle recognized all 19 of them.

Here are the valid moods, including subalternate ones, under their medieval mnemonic names (subalternate moods are marked with an asterisk):

First figure:	Barbara, Celarent, Darii, Ferio, *Barbari, *Celaront.
Second figure:	Cesare, Camestres, Festino, Baroco, *Cesaro, *Camestrop.
Third figure:	Darapti, Disamis, Datisi, Felapton, Bocardo, Ferison.
Fourth figure:	Bramantip, Camenes, Dimaris, Fesapo, Fresison, *Camenop.

The sequence of vowels in each name indicates the sequence of categorical propositions in the mood in the order: major, minor, conclusion. Thus, for example, Celarent is a first figure syllogism with an E-form major, A-form minor, and E-form conclusion.

Reduction

If one assumes the nonsubalternate moods of the first figure, then, with two exceptions, all valid moods in the other figures can be proved by "reducing" them to one of those "axiomatic" first-figure moods. This reduction shows that, if the premises of the reducible mood are true, then it follows, by rules of conversion and one of the axiomatic moods, that the conclusion is true. The procedure is encoded in the medieval names:

1. The initial letter is the initial letter of the first-figure mood to which the given mood is reducible. Thus Felapton is reducible to Ferio.
2. When it is not the final letter, "s" after a vowel means "Convert the sentence simply," and "p" there means "Convert the sentence *per accidens*."
3. When "s" or "p" is the final letter, the conclusion of the first-figure syllogism to which the mood is reduced must be converted simply or *per accidens,* respectively.
4. The letter "m" means "Change the order of the premises."
5. When it is not the first letter, "c" means that the syllogism cannot be directly reduced to the first figure but must be proved by reductio ad absurdum. (There are two such moods; see below.)
6. The letters "b" and "d" (except as initial letters) and "l," "n," "t," and "r" serve only to facilitate pronunciation.

Thus the premises of Felapton (third figure) are "No β is an α" and "Every β is a γ." Convert the minor premise *per accidens* to "Some γ is a β," as instructed by the "p" after the second vowel. This new proposition and the major premise of Felapton form the premises of a syllogism in Ferio (first figure), the conclusion of which is "Some γ is not an α," which is also the conclusion of Felapton. Hence, given Ferio and the rule of *per accidens* conversion, the premises of Felapton validly imply its conclusion. In this sense, Felapton has been "reduced" to Ferio.

The two exceptional cases, which must be proven indirectly by reductio ad absurdum, are Baroco and Bocardo. Both are reducible indirectly to Barbara in the first figure as follows: Assume the A-form premise (the major in Baroco, the minor in Bocardo). Assume the contradictory of the conclusion. These yield a syllogism in Barbara, the conclusion of which contradicts the O-form premise of the syllogism to be reduced. Thus, given Barbara as axiomatic, and given the premises of the reducible syllogism, the contradictory of its conclusion is false, so that the original conclusion is true.

Reduction and indirect proof together suffice to prove all moods not in the first figure. This fact, which Aristotle himself showed, makes his syllogistic the first deductive system in the history of logic.

While the medieval names of the moods contain a great deal of information, they provide no way by themselves to determine to which figure a mood belongs, and so no way to reconstruct the actual form of the syllogism. Mnemonic verses were developed in the Middle Ages for this purpose.

Assertoric and modal syllogisms

Categorical propositions in which α is merely said to belong (or not) to some or every β are called assertoric categorical propositions; syllogisms composed solely of such categoricals are called assertoric syllogisms. Aristotle was also interested in categoricals in which α is said to belong (or not) necessarily or possibly to some or every β. Such categoricals are called modal categoricals, and syllogisms in which the component categoricals are modal are called modal syllogisms (they are sometimes called "mixed" if only one of the premises is modal).

Aristotle discussed two notions of the "possible": (1) as what is not impossible (*i.e.,* the opposite of which is not necessary) and (2) as what is neither necessary nor impossible (*i.e.,* the contingent). In his modal syllogistic, the term "possible" (or "contingent") is always used in sense 2 in syllogistic premises, but it is sometimes used in sense 1 in syllogistic conclusions if a conclusion in sense 2 would be incorrect.

Aristotle's procedure in his modal syllogistic is to survey each valid mood of the assertoric syllogistic and then to test the several modal syllogisms that can be formed from an assertoric mood by changing one or more of its component categoricals into a modal categorical. The interpretation of this part of Aristotle's logic, and the correctness of his arguments, have been disputed since antiquity.

Although Aristotle did not develop a full theory of propositions in tenses other than the present, there is a famous passage in the *De interpretatione* that was influential in later developments in this area. In chapter 9 of that work, Aristotle discussed the assertion "There will be a sea battle tomorrow." The discussion assumes that as of now the question is still unsettled. Although there are different interpretations of the passage, Aristotle seems there to have been maintaining that although now, before

the fact, it is neither true nor false that there will be a sea battle tomorrow, nevertheless it is true even now, before the fact, that there either will or will not be a sea battle tomorrow. In short, Aristotle appears to have affirmed the law of excluded middle (for any proposition replacing "*p*," it is true that either *p* or not-*p*), but to have denied the principle of bivalence (that every proposition is either true or false) in the case of future contingent propositions.

Aristotle's logic presupposes several principles that he did not explicitly formulate about logical relations among any propositions whatever, independent of the propositions' internal analyses into categorical or any other form. For example, it presupposes that the principle "If *p* then *q*; but *p*; therefore *q*" (where *p* and *q* are replaced by any propositions) is valid. Such patterns of inference belong to what is called the logic of propositions. Aristotle's logic is, by contrast, a logic of terms in the sense described above. A sustained study of the logic of propositions came only after Aristotle.

THEOPHRASTUS OF ERESUS

Aristotle's successor as head of his school at Athens was Theophrastus of Eresus (*c.* 371–*c.* 286 BC). All Theophrastus' logical writings are now lost, and much of what was said about his logical views by late ancient authors was attributed to both Theophrastus and his colleague Eudemus, so that it is difficult to isolate their respective contributions.

Theophrastus is reported to have added to the first figure of the syllogism the five moods that others later classified under a fourth figure. These moods were then called indirect moods of the first figure. In order to accommodate them, he had in effect to redefine the first figure as that in which the middle is the subject in one premise and the predicate in the other, not necessarily the subject in the major premise and the predicate in the minor, as Aristotle had it.

Contributions to modal syllogistic

Theophrastus' most significant departure from Aristotle's doctrine occurred in modal syllogistic. He abandoned Aristotle's notion of the possible as neither necessary nor impossible and adopted Aristotle's alternative notion of the possible as simply what is not impossible. This allowed him to effect a considerable simplification in Aristotle's modal theory. Thus, his conversion laws for modal categoricals were exact parallels to the corresponding laws for assertoric categoricals. In particular, for Theophrastus "problematic" universal negatives ("No β is possibly an α") can be simply converted. Aristotle had denied this.

In addition, Theophrastus adopted a rule that the conclusion of a valid modal syllogism can be no stronger than its weakest premise. (Necessity is stronger than possibility, and an assertoric claim without any modal qualification is intermediate between the two). This rule simplifies modal syllogistic and eliminates several moods that Aristotle had accepted. Yet Theophrastus himself allowed certain modal moods that, combined with the principle of indirect proof (which he likewise accepted), yield results that perhaps violate this rule.

Theophrastus also developed a theory of inferences involving premises of the form "α is universally predicated of everything of which γ is universally predicated" and of related forms. Such propositions he called prosleptic propositions, and inferences involving them were termed prosleptic syllogisms. Greek *proslepsis* can mean "something taken in addition," and Theophrastus claimed that propositions like these implicitly contain a third, indefinite term, in addition to the two definite terms ("α" and "γ" in the example).

The term prosleptic proposition appears to have originated with Theophrastus, although Aristotle discussed such propositions briefly in his *Prior Analytics* without exploring their logic in detail. The implicit third term in a prosleptic proposition Theophrastus called the middle. After an analogy with syllogistic for categorical propositions, he distinguished three "figures" for prosleptic propositions and syllogisms, based on the position of the implicit middle. The prosleptic proposition "α is universally predicated of everything that is universally predicated of γ" belongs to the first figure and can be a premise in a first-figure prosleptic syllogism. "Everything predicated universally of α is predicated universally of γ" belongs to the second figure and can be a premise in a second-figure syllogism, and so too "α is universally predicated of everything of which γ is universally predicated" for the third figure. Thus, for example, the following is a prosleptic syllogism in the third figure: "α is universally affirmed of everything of which γ is universally affirmed; γ is universally affirmed of β; therefore, α is universally affirmed of β."

Theophrastus observed that certain prosleptic propositions are equivalent to categoricals and differ from them only "potentially" or "verbally." Some late ancient authors claimed that this made prosleptic syllogisms superfluous. But in fact not all prosleptic propositions are equivalent to categoricals.

Hypothetical syllogisms

Theophrastus is also credited with investigations into hypothetical syllogisms. A hypothetical proposition, for Theophrastus, is a proposition made up of two or more component propositions (*e.g.*, "*p* or *q*," or "if *p* then *q*"), and a hypothetical syllogism is an inference containing at least one hypothetical proposition as a premise. The extent of Theophrastus' work in this area is uncertain, but it appears that he investigated a class of inferences called totally hypothetical syllogisms, in which both premises and the conclusion are conditionals. This class would include, for example, syllogisms such as "If α then β; if β than γ; therefore, if α then γ," or "if α then β; if not α then γ; therefore, if not β then γ." As with his prosleptic syllogisms, Theophrastus divided these totally hypothetical syllogisms into three "figures," after an analogy with categorical syllogistic.

Theophrastus was the first person in the history of logic known to have examined the logic of propositions seriously. Still, there was no sustained investigation in this area until the period of the Stoics.

THE MEGARIANS AND STOICS

Throughout the ancient world, the logic of Aristotle and his followers was one main stream. But there was also a second tradition of logic, that of the Megarians and Stoics.

The Megarians were followers of Euclid (or Euclides) of Megara (*c.* 430–*c.* 360 BC), a pupil of Socrates. In logic the most important Megarians were Diodorus Cronus (4th century BC) and his pupil Philo of Megara. The Stoics were followers of Zeno of Citium (*c.* 336–*c.* 265 BC). By far the most important Stoic logician was Chrysippus (*c.* 279–206 BC). The influence of Megarian on Stoic logic is indisputable, but many details are uncertain, since all but fragments of the writings of both groups are lost.

The Megarians were interested in logical puzzles. Many paradoxes have been attributed to them, including the "liar paradox" (someone says that he is lying; is his statement true or false?), the discovery of which has sometimes been credited to Eubulides of Miletus, a pupil of Euclid of Megara. The Megarians also discussed how to define various modal notions and debated the interpretation of conditional propositions.

The Master Argument

Diodorus Cronus originated a mysterious argument called the Master Argument. It claimed that the following three propositions are jointly inconsistent, so that at least one of them is false:

1. Everything true about the past is now necessary. (That is, the past is now settled, and there is nothing to be done about it.)
2. The impossible does not follow from the possible.
3. There is something that is possible, and yet neither is nor will be true. (That is, there are possibilities that will never be realized.)

It is unclear exactly what inconsistency Diodorus saw among these propositions. Whatever it was, Diodorus was unwilling to give up 1 or 2, and so rejected 3. That is, he accepted the opposite of 3, namely: Whatever is possible either is or will be true. In short, there are no possibilities that are not realized now or in the future. It has been suggested that the Master Argument was directed against Aristotle's discussion of the sea battle tomorrow in the *De interpretatione*.

Diodorus also proposed an interpretation of conditional propositions. He held that the proposition "If *p*, then *q*"

is true if and only if it neither is nor ever was possible for the antecedent p to be true and the consequent q to be false simultaneously. Given Diodorus' notion of possibility, this means that a true conditional is one that at no time (past, present, or future) has a true antecedent and a false consequent. Thus, for Diodorus a conditional does not change its truth value; if it is ever true, it is always true. But Philo of Megara had a different interpretation. For him, a conditional is true if and only if it does not now have a true antecedent and a false consequent. This is exactly the modern notion of material implication. In Philo's view, unlike Diodorus', conditionals may change their truth value over time.

These and other theories of modality and conditionals were discussed not only by the Megarians but by the Stoics as well. Stoic logicians, like the Megarians, were not especially interested in scientific demonstration in Aristotle's special sense. They were more concerned with logical issues arising from debate and disputation: fallacies, paradoxes, forms of refutation. Aristotle had also written about such things, but his interests gradually shifted to his special notion of science. The Stoics kept their interest focused on disputation and developed their studies in this area to a high degree.

Unlike the Aristotelians, the Stoics developed propositional logic to the neglect of term logic. They did not produce a system of logical laws arising from the internal structure of simple propositions, as Aristotle had done with his account of opposition, conversion, and syllogistic for categorical propositions. Instead, they concentrated on inferences from hypothetical propositions as premises. Theophrastus had already taken some steps in this area, but his work had little influence on the Stoics.

Disjunction and conjunction

Stoic logicians studied the logical properties and defining features of words used to combine simpler propositions into more complex ones. In addition to the conditional, which had already been explored by the Megarians, they investigated disjunction ("or") and conjunction ("and"), along with words like "since" and "because." Some of these they defined truth-functionally (*i.e.,* solely in terms of the truth or falsehood of the propositions they combined). For example, they defined a disjunction as true if and only if exactly one disjunct is true (the modern "exclusive" disjunction). They also knew "inclusive" disjunction (defined as true when at least one disjunct is true), but this was not widely used. More important, the Stoics seem to have been the first to show how some of these truth-functional words may be defined in terms of others.

Unlike Aristotle, who typically formulated his syllogisms as conditional propositions, the Stoics regularly presented principles of logical inference in the form of schematic arguments. While Aristotle had used Greek letters as variables replacing terms, the Stoics used ordinal numerals as variables replacing whole propositions. Thus: "Either the first or the second; but not the second; therefore, the first." Here the expressions "the first" and "the second" are variables or placeholders for propositions, not terms.

Chrysippus regarded five valid inference schemata as basic or indemonstrable.They are:

1. If the first, then the second; but the first; therefore, the second.
2. If the first, then the second; but not the second; therefore not the first.
3. Not both the first and the second; but the first; therefore, not the second.
4. Either the first or the second; but the first; therefore, not the second.
5. Either the first or the second; but not the second; therefore, the first.

Using these five "indemonstrables," Chrysippus proved the validity of many further inference schemata. Indeed, the Stoics claimed (falsely, it seems) that all valid inference schemata could be derived from the five indemonstrables.

The differences between Aristotelian and Stoic logic were ones of emphasis, not substantive theoretical disagreements. At the time, however, it appeared otherwise. Perhaps because of their real disputes in other areas, Aristotelians and Stoics at first saw themselves as holding incompatible theories in logic as well. But by the late 1st century BC, an eclectic movement had begun to weaken these hostilities. Thereafter the two traditions were combined in commentaries and handbooks for general education.

LATE REPRESENTATIVES OF ANCIENT GREEK LOGIC

After Chrysippus, little important logical work was done in Greek. But the commentaries and handbooks that were written did serve to consolidate the previous traditions and in some cases are the only extant sources for the doctrines of earlier writers. Among late authors, Galen the physician (AD 129–*c.* 199) wrote several commentaries, now lost, and an extant *Introduction to Dialectic.* Galen observed that the study of mathematics and logic was important to a medical education, a view that had considerable influence in the later history of logic, particularly in the Arab world. Tradition has credited Galen with "discovering" the fourth figure of the Aristotelian syllogism, although in fact he explicitly rejected it.

Aristotle's commentators

Alexander of Aphrodisias (fl. *c.* AD 200) wrote extremely important commentaries on Aristotle's writings, including the logical works. Other important commentators include Porphyry of Tyre (*c.* 232–before 306), Ammonius Hermeiou (5th century), Simplicius (6th century), and John Philoponus (6th century). Sextus Empiricus (late 2nd–early 3rd centuries) and Diogenes Laërtius (probably early 3rd century) are also important sources for earlier writers. Significant contributions to logic were not made again in Europe until the 12th century.

Medieval logic

TRANSMISSION OF GREEK LOGIC TO THE LATIN WEST

As the Greco-Roman world disintegrated and gave way to the Middle Ages, knowledge of Greek declined in the West. Nevertheless, several authors served as transmitters of Greek learning to the Latin world. Among the earliest of them, Cicero (106–43 BC) introduced Latin translations for technical Greek terms. Although his translations were not always finally adopted by later authors, he did make it possible to discuss logic in a language that had not previously had any precise vocabulary for it. In addition, he preserved much information about the Stoics. In the 2nd century AD Lucius Apuleius passed on some knowledge of Greek logic in his *De philosophia rationali* ("On Rational Philosophy").

In the 4th century Marius Victorinus produced Latin translations of Aristotle's *Categories* and *De interpretatione* and of Porphyry of Tyre's *Isagoge* ("Introduction," on Aristotle's *Categories*), although these translations were not very influential. He also wrote logical treatises of his own. A short *De dialectica* ("On Dialectic"), doubtfully attributed to St. Augustine (354–430), shows evidence of Stoic influence, although it had little influence of its own. The pseudo-Augustinian *Decem categoriae* ("Ten Categories") is a late 4th-century Latin paraphrase of a Greek compendium of the *Categories.* In the late 5th century Martianus Capella's allegorical *De nuptiis Philologiae et Mercurii* (*The Marriage of Philology and Mercury*) contains "On the Art of Dialectic" as book IV.

Boethius

The first truly important figure in medieval logic was Boethius (480–524/525). Like Victorinus, he translated Aristotle's *Categories* and *De interpretatione* and Porphyry's *Isagoge,* but his translations were much more influential. He also seems to have translated the rest of Aristotle's *Organon,* except for the *Posterior Analytics,* but the history of those translations and their circulation in Europe is much more complicated; they did not come into widespread use until the first half of the 12th century. In addition, Boethius wrote commentaries and other logical works that were of tremendous importance throughout the Latin Middle Ages. Until the 12th century his writings and translations were the main sources for medieval Europe's knowledge of logic. In the 12th century they were known collectively as the *Logica vetus* ("Old Logic").

ARABIC LOGIC

Between the time of the Stoics and the revival of logic in 12th-century Europe, the most important logical work

was done in the Arab world. Arabic interest in logic lasted from the 9th to the 16th century, although the most important writings were done well before 1300.

Syrian Christian authors in the late 8th century were among the first to introduce Alexandrian scholarship to the Arab world. Through Galen's influence, these authors regarded logic as important to the study of medicine. (This link with medicine continued throughout the history of Arabic logic and, to some extent, later in medieval Europe.) By about 850, at least Porphyry's *Isagoge* and Aristotle's *Categories, De interpretatione,* and *Prior Analytics* had been translated via Syriac into Arabic. Between 830 and 870 the philosopher and scientist al-Kindī (*c.* 805–873) produced in Baghdad what seem to have been the first Arabic writings on logic that were not translations. But these writings, now lost, were probably mere summaries of others' work.

By the late 9th century, the school of Baghdad was the focus of logic studies in the Arab world. Most of the members of this school were Nestorian or Jacobite Christians, but the Muslim al-Fārābī (*c.* 873–950) wrote important commentaries and other logical works there that influenced all later Arabic logicians. Many of these writings are now lost, but among the topics al-Fārābī discussed were future contingents (in the context of Aristotle's *De interpretatione,* chapter 9), the number and relation of the categories, the relation between logic and grammar, and non-Aristotelian forms of inference. This last topic showed the influence of the Stoics. Al-Fārābī, along with Avicenna and Averroës (see below), was among the best logicians the Arab world produced.

By 1050 the school of Baghdad had declined. The 11th century saw very few Arabic logicians, with one distinguished exception: the Persian Ibn Sīnā, or Avicenna (980–1037), perhaps the most original and important of all Arabic logicians. Avicenna abandoned the practice of writing on logic in commentaries on the works of Aristotle and instead produced independent treatises. He sharply criticized the school of Baghdad for what he regarded as their slavish devotion to Aristotle. Among the topics Avicenna investigated were quantification of the predicates of categorical propositions, the theory of definition and classification, and an original theory of "temporally modalized" syllogistic, in which premises include such modifiers as "at all times," "at most times," and "at some time."

Avicenna

The Persian mystic and theologian al-Ghazālī, or Algazel, (1058–1111), followed Avicenna's logic, although he differed sharply from Avicenna in other areas. Al-Ghazālī was not a significant logician but is important nonetheless because of his influential defense of the use of logic in theology.

In the 12th century the most important Arab logician was Ibn Rushd, or Averroës (1126–98). Unlike the Persian followers of Avicenna, Averröes worked in Moorish Spain, where he revived the tradition of al-Fārābī and the school of Baghdad by writing penetrating commentaries on Aristotle's works, including the logical ones. Such was the stature of these excellent commentaries that, when they were translated into Latin in the 1220s or 1230s, Averroës was often referred to simply as "the Commentator."

After Averroës, logic declined in western Islām because of the antagonism felt to exist between logic and philosophy on the one hand and Muslim orthodoxy on the other. But in eastern Islām, owing in part to the work of al-Ghazālī, logic was not regarded as being so closely linked with philosophy. Instead, it was viewed as a tool that could be profitably used in any field of study, even (as al-Ghazālī had done) on behalf of theology against the philosophers. Thus the logical tradition continued in Persia long after it died out in Spain. The 13th century produced a large number of logical writings, but these were mostly unoriginal textbooks and handbooks. After about 1300, logical study was reduced to producing commentaries on these earlier, already derivative handbooks.

THE REVIVAL OF LOGIC IN EUROPE

St. Anselm and Peter Abelard. Except in the Arabic world, there was little activity in logic between the time of Boethius and the 12th century. Certainly Byzantium produced nothing of note. In Latin Europe there were a few authors, including Alcuin of York (*c.* 730–804) and Garland the Computist (*fl. c.* 1040). But it was not until late in the 11th century that serious interest in logic revived. St. Anselm of Canterbury (1033–1109) discussed semantical questions in his *De grammatico,* and investigated the notions of possibility and necessity in surviving fragments, but these texts did not have much influence. More important was Anselm's general method of using logical techniques in theology. His example set the tone for much that was to follow.

The first important Latin logician after Boethius was Peter Abelard (1079–1142). He wrote three sets of commentaries and glosses on Porphyry's *Isagoge* and Aristotle's *Categories* and *De interpretatione;* these were the *Introductiones parvulorum* (also containing glosses on some writings of Boethius), *Logica "Ingredientibus,"* and *Logica "Nostrorum petitioni sociorum"* (on the *Isagoge* only), together with the independent treatise *Dialectica* (extant in part). These works show a familiarity with Boethius but go far beyond him. Among the topics discussed insightfully by Abelard are the role of the copula in categorical propositions, the effects of different positions of the negation sign in categorical propositions, modal notions like "possibility," future contingents (as treated, for example, in chapter 9 of Aristotle's *De interpretatione*), and conditional propositions or "consequences."

Peter Abelard

Abelard's fertile investigations raised logical study in medieval Europe to a new level. His achievement is all the more remarkable since the sources at his disposal were the same ones that had been available in Europe for the preceding 600 years: Aristotle's *Categories* and *De interpretatione* and Porphyry's *Isagoge,* together with the commentaries and independent treatises by Boethius.

The "properties of terms" and discussions of fallacies. Even in Abelard's lifetime, however, things were changing. After about 1120, Boethius' translations of Aristotle's *Prior Analytics, Topics,* and *Sophistic Refutations* began to circulate. Sometime in the second quarter of the 12th century, James of Venice translated the *Posterior Analytics* from Greek, thus making the whole of the *Organon* available in Latin. These newly available Aristotelian works were known collectively as the *Logica nova* ("New Logic"). In a flurry of activity, others in the 12th and 13th centuries produced additional translations of these works and of Greek and Arabic commentaries on them, along with many other philosophical writings and other works from Greek and Arabic sources.

The *Sophistic Refutations* proved an important catalyst in the development of medieval logic. It is a little catalog of fallacies, how to avoid them, and how to trap others into committing them. The work is very sketchy. Many kinds of fallacies are not discussed, and those that are could have been treated differently. Unlike the *Posterior Analytics,* the *Sophistic Refutations* was relatively easy to understand. And unlike the *Prior Analytics*—where, except for modal syllogistic, Aristotle had left little to be done—there was obviously still much to be investigated about fallacies. Moreover, the discovery of fallacies was especially important in theology, particularly in the doctrines of the Trinity and the Incarnation. In short, the *Sophistic Refutations* was tailor-made to exercise the logical ingenuity of the 12th century. And that is exactly what happened.

The *Sophistic Refutations,* and the study of fallacy it generated, produced an entirely new logical literature. A genre of *sophismata* ("sophistical") treatises developed that investigated fallacies in theology, physics, and logic. The theory of "supposition" (see below) also developed out of the study of fallacies. Whole new kinds of treatises were written on what were called "the properties of terms," semantic properties important in the study of fallacy. In addition, a new genre of logical writings developed on the topic of "syncategoremata"—expressions such as "only", "inasmuch as," "besides," "except," "lest," and so on, which posed quite different logical problems than did the terms and logical particles in traditional categorical propositions or in the simpler kind of "hypothetical" propositions inherited from the Stoics. The study of valid

Sophismata treatises

inference generated a literature on "consequences" that went into far more detail than any previous studies. By the late 12th or early 13th century, special treatises were devoted to *insolubilia* (semantic paradoxes such as the liar paradox, "This sentence is false") and to a kind of disputation called "obligationes," the exact purpose of which is still in question.

All these treatises, and the logic contained in them, constitute the peculiarly medieval contribution to logic. It is primarily on these topics that medieval logicians exercised their best ingenuity. Such treatises, and their logic, were called the *Logica moderna* ("Modern Logic"), or "terminist" logic, because they laid so much emphasis on the "properties of terms." These developments began in the mid-12th century, and continued to the end of the Middle Ages.

DEVELOPMENTS IN THE 13TH AND EARLY 14TH CENTURIES

In the 13th century the *sophismata* literature continued and deepened. In addition several authors produced summary works that surveyed the whole field of logic, including the "Old" and "New" logic as well as the new developments in the *Logica moderna.* These compendia are often called "*summulae*" ("little summaries"), and their authors "summulists." Among the most important of the summulists are: (1) Peter of Spain (also known as Petrus Hispanus; later Pope John XXI), who wrote a *Tractatus* more commonly known as *Summulae logicales* ("Little Summaries of Logic") probably in the early 1230s; it was used as a textbook in some late medieval universities; (2) Lambert of Auxerre, who wrote a *Logica* sometime between 1253 and 1257; and (3) William of Sherwood, who produced *Introductiones in logicam* (*Introduction to Logic*) and other logical works sometime about the mid-century.

Despite his significance in other fields, Thomas Aquinas is of little importance in the history of logic. He did write a treatise on modal propositions and another one on fallacies. But there is nothing especially original in these works; they are early writings and are confined to passing on received doctrine. He also wrote an incomplete commentary on the *De interpretatione,* but it is of no great logical significance.

About the end of the 13th century John Duns Scotus (*c.* 1266–1308) composed several works on logic. There also are some very interesting logical texts from the same period that have been falsely attributed to Scotus and were published in the 17th century among his authentic works. These are now referred to as the works of "the Pseudo-Scotus," although they may not all be by the same author.

English logicians

The first half of the 14th century saw the high point of medieval logic. Much of the best work was done by people associated with the University of Oxford. Among them were William of Ockham (*c.* 1285–1347), the author of an important *Summa logicae* ("Summary of Logic") and other logical writings. Perhaps because of his importance in other areas of medieval thought, Ockham's originality in logic has sometimes been exaggerated. But there is no doubt that he was one of the most important logicians of the century. Another Oxford logician was Walter Burley (or Burleigh), an older contemporary of Ockham. Burley was a bitter opponent of Ockham in metaphysics. He wrote a work *De puritate artis logicae* ("On the Purity of the Art of Logic"; in two versions), apparently in response and opposition to Ockham's views, although on some points Ockham simply copied Burley almost verbatim.

Slightly later, on the Continent, Jean Buridan was a very important logician at the University of Paris. He wrote mainly during the 1330s and '40s. In many areas of logic and philosophy his views were close to Ockham's, although the extent of Ockham's influence on Buridan is not clear. Buridan's *Summulae de dialectica* ("Little Summaries of Dialectic"), intended for instructional use at Paris, was largely an adaptation of Peter of Spain's *Summulae logicales.* He appears to have been the first to use Peter of Spain's text in this way. Originally meant as the last treatise of his *Summulae de dialectica,* Buridan's extremely interesting *Sophismata* (published separately in early editions) discusses many issues in semantics and philosophy of logic. Among Buridan's pupils was Albert of Saxony (d. 1390), the author of a *Perutilis logica* ("A Very Useful Logic") and later first rector of the University of Vienna. Albert was not an especially original logician, although his influence was by no means negligible.

The theory of supposition. Many of the characteristically medieval logical doctrines in the *Logica moderna* centred around the notion of "supposition" (*suppositio*). Already by the late 12th century the theory of supposition had begun to form. In the 13th century, special treatises on the topic multiplied. The summulists all discussed it at length. Then, after about 1270, relatively little was heard about it. In France, supposition theory was replaced by a theory of "speculative grammar" or "modism" (so called because it appealed to "modes of signifying"). Modism was not so popular in England, but there too the theory of supposition was largely neglected in the late 13th century. In the early 14th century the theory reemerged both in England and on the Continent. Burley wrote a treatise on the topic in about 1302, and Buridan revived the theory in France in the 1320s. Thereafter the theory remained the main vehicle for semantic analysis until the end of the Middle Ages.

Supposition theory, at least in its 14th-century form, is best viewed as two theories under one name. The first, sometimes called the theory of "supposition proper," is a theory of reference and answers the question "To what does a given occurrence of a term refer in a given proposition?" In general (the details depend on the author) three main types of supposition were distinguished: (1) personal supposition (which, despite the name, need not have anything to do with persons), (2) simple supposition, and (3) material supposition. These types are illustrated, respectively, by the occurrences of the term *horse* in the statements "Every horse is an animal" (in which the term *horse* refers to individual horses), "Horse is a species" (in which the term refers to a universal), and "Horse is a monosyllable" (in which it refers to the spoken or written word). The theory was elaborated and refined by considering how reference may be broadened by tense and modal factors (for example, the term *horse* in "Every horse will die," which may refer to future as well as present horses) or narrowed by adjectives or other factors (for example, *horse* in "Every horse in the race is less than two years old").

The theory of "supposition proper"

The second part of supposition theory applies only to terms in personal supposition. It divides personal supposition into several types, including (again the details vary according to the author): (1) determinate (*e.g., horse* in "Some horse is running"), (2) confused and distributive (*e.g., horse* in "Every horse is an animal"), and (3) merely confused (*e.g., animal* in "Every horse is an animal"). These types were described in terms of a notion of "descent to (or ascent from) singulars." For example, in the statement "Every horse is an animal," one can "descend" under the term "horse" to: "This horse is an animal, and that horse is an animal, and so on," but one cannot validly "ascend" from "This horse is an animal" to the original proposition. There are many refinements and complications.

The purpose of this second part of the theory of supposition has been disputed. Since the question of what it is to which a given occurrence of a term refers is already answered in the first part of supposition theory, the purpose of this second part must have been different. The main suggestions are (1) that it was devised to help detect and diagnose fallacies, (2) that it was intended as a theory of truth conditions for propositions or as a theory of analyzing the senses of propositions, and (3) that, like the first half of supposition theory, it originated as part of an account of reference, but, once its theoretical insufficiency for that task was recognized, it was gradually divorced from that first part of supposition theory and by the early 14th century was left as a conservative vestige that continued to be disputed but no longer had any question of its own to answer. There are difficulties with all of these suggestions. The theory of supposition survived beyond the Middle Ages and was frequently applied not only in logical discussions but also in theology and in the natural sciences.

Connotation

In addition to supposition and its satellite theories, several logicians during the 14th century developed a sophisticated theory of "connotation" (*connotatio* or *appellatio;* in which the term *black*, for instance, not only refers to black things but also "connotes" the quality, blackness, that they possess) and a subtle theory of "mental language," in which tools of semantic analysis were applied to epistemology and the philosophy of mind. Important treatises on *insolubilia* and *obligationes*, as well as on the theory of consequence or inference, continued to be produced in the 14th century, although the main developments there were completed by mid-century.

Developments in modal logic. Medieval logicians continued the tradition of modal syllogistic inherited from Aristotle. In addition, modal factors were incorporated into the theory of supposition. But the most important developments in modal logic occurred in three other contexts: (1) whether propositions about future contingent events are now true or false (Aristotle had raised this question in *De interpretatione*, chapter 9), (2) whether a future contingent event can be known in advance, and (3) whether God (who, the tradition says, cannot be acted upon causally) can know future contingent events. All these issues link logical modality with time. Thus, Peter Aureoli (*c.* 1280–1322) held that if something is in fact φ ('φ' is some predicate) but can be not-φ, then it is capable of changing from being φ to being not-φ.

Duns Scotus in the late 13th century was the first to sever the link between time and modality. He proposed a notion of possibility that was not linked with time but based purely on the notion of semantic consistency. This radically new conception had a tremendous influence on later generations down to the 20th century. Shortly afterward, Ockham developed an influential theory of modality and time that reconciles the claim that every proposition is either true or false with the claim that certain propositions about the future are genuinely contingent.

LATE MEDIEVAL LOGIC

Most of the main developments in medieval logic were in place by the mid-14th century. On the Continent, the disciples of Jean Buridan—Albert of Saxony (*c.* 1316–90), Marsilius of Inghen (d. 1399), and others—continued and developed the work of their predecessors. In 1372 Pierre d'Ailly wrote an important work, *Conceptus et insolubilia* (*Concepts and Insolubles*), which appealed to a sophisticated theory of mental language in order to solve semantic paradoxes such as the liar paradox.

In England the second half of the 14th century produced several logicians who consolidated and elaborated earlier developments. Their work was not very original, although it was often extremely subtle. Many authors during this period compiled brief summaries of logical topics intended as textbooks. The doctrine in these little summaries is remarkably uniform, making it difficult to determine who their authors were. By the early 15th century, informal collections of these treatises had been gathered under the title *Libelli sophistarum* ("Little Books for Arguers")—one collection for Oxford and a second for Cambridge; both were printed in early editions. Among the notable logicians of this period are Henry Hopton (fl. 1357), John Wycliffe (*c.* 1330–84), Richard Lavenham (d. after 1399), Ralph Strode (fl. *c.* 1360), Richard Ferrybridge (or Feribrigge; fl. *c.* 1360s), and John Venator (also known as John Huntman or Hunter; fl. 1373).

Libelli sophistarum

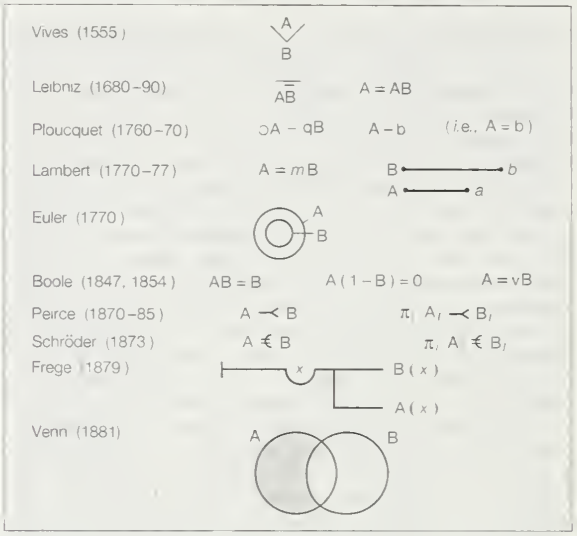
Beginning in 1390, the Italian Paul of Venice studied for at least three years at Oxford and then returned to teach at Padua and elsewhere in Italy. Although English logic was studied in Italy even before Paul's return, his own writings advanced this study greatly. Among Paul's logical works were the very popular *Logica parva* ("Little Logic"), printed in several early editions, and possibly the huge *Logica magna* ("Big Logic") that has sometimes been regarded as a kind of encyclopaedia of the whole of medieval logic.

After about 1400, serious logical study was dead in England. However, it continued to be pursued on the Continent until the end of the Middle Ages and afterward.

(P.V.S.)

Modern logic

It is customary to speak of logic since the Renaissance as "modern logic." This is not to suggest that there was a smooth development of a unified conception of reasoning, or that the logic of this period is "modern" in the usual sense. Logic in the modern era has exhibited an extreme diversity, and its chaotic development has reflected all too clearly the surrounding political and intellectual turmoil. These upheavals include the Renaissance itself, the diminishing role of the Roman Catholic church and of Latin, the Reformation and subsequent religious wars, the scientific revolution and the growth of modern mathematics, the rise and fall of empires and nation-states, and the waxing influence of the New World and the former Soviet Union.



Representations of the universal affirmative, "All A's are B's" in modern logic.

THE 16TH CENTURY

Renaissance writers sometimes denounced all of scholastic logic. The humanism of the Renaissance is often seen as promoting the study of Greek and Roman classics, but Aristotle's logic was frequently regarded as being so hopelessly bound together with "sterile" medieval logic as to constitute an exception to this spirit of rebirth. Some, such as Martin Luther (1483–1546), were repelled by any hint of Aristotelianism. Others, such as the great humanist essayist Desiderius Erasmus (1466–1536), occasionally praised Aristotle but never his logical theory; like many writers in the Renaissance, Erasmus found in the theory of the syllogism only "subtlety and arid ingenuity" (Johan Huizinga, *Erasmus* [1924]). The German Lutheran humanist Philipp Melanchthon (1497–1560) had a more balanced appreciation of Aristotle's logic. Melanchthon's *Compendaria dialectices ratio* ("Brief Outline of Dialects") of 1520, built upon his *Institutiones Rhetoricae* of the previous year, became a popular Lutheran text. There he described his purpose as presenting "a true, pure and uncomplicated logic, just as we have received it from Aristotle and some of his judicious commentators." Elsewhere, influential writers such as Rabalais, Petrarch, and Montaigne had few kind words for logic as they knew it.

Petrus Ramus

The French reformer and pamphleteer Petrus Ramus (Pierre de la Ramée) was also the author of extremely influential "Reform" logical texts. His *Dialectique* (Dialectics) of 1555 (translated into English in 1574) was the first major logical work in a modern language. In this work and in his *Dialecticae libri duo* ("Two Books of Dialectics") of 1556 he combined attacks on scholastic logic, an emphasis on the use of logic in actual arguments ("dialectics"), and a presentation of a much simplified approach to categorical syllogism (without an attempt to follow Aristotle). Elsewhere, he proposed that reasoning should be taught by using Euclid's *Elements* rather than by the study of the syllogism. He devoted special attention to valid syllogisms with singular premises, such as "Octavius is the

heir of Caesar. I am Octavius. Therefore, I am the heir of Caesar." Singular terms (such as proper names) had been treated by earlier logicians: Pseudo-Scotus, among others, had proposed assimilating them to universal propositions by understanding "Julius Caesar is mortal" as "All Julius Caesars are mortal." Although Ramus' proposals for singular terms were not widely accepted, his concern for explicitly addressing them and his refusal to use artificial techniques to convert them to standard forms prefigured more recent interests. Although it had its precursors in medieval semantic thought, Ramus' division of thought into a hierarchy composed of concepts, judgments, arguments, and method was influential in the 17th and 18th centuries.

Scholastic logic remained alive, especially in predominantly Roman Catholic universities and countries, such as Italy and Spain. Some of this work had considerable value, even though it was outside of the mainstream logical tradition, from which it diverged in the 16th century. If the Reform tradition of Melanchthon and Ramus represents one major tradition in modern logic, and the neo-scholastic tradition another, then (here following the historian of logic Nicholai Ivanovich Styazhkin) a third tradition is found in the followers of the Spanish (Majorcan) soldier, priest, missionary, and mystic Ramón Lull (1235–1315). His *Ars magna, generalis et ultima* (1501; "Great, General and Ultimate Art") represents an attempt to symbolize concepts and derive propositions that form various combinations of possibilities. These notions, associated with lore of the Kabbala, later influenced Pascal and Leibniz and the rise of probability theory. Lull's influence can be seen more directly in the work of his fellow Spaniard Juan Luis Vives (1492–1540), who used a V-shaped symbol to indicate the inclusion of one term in another. Other work inspired by Lull includes the logic and notational system of the German logician Johann Heinrich Alsted (1588–1638). The work of Vives and Alsted represents perhaps the first systematic effort at a logical symbolism.

Interest in the systematic symbolization of logic

With the 17th century came increasing interest in symbolizing logic. These symbolizations sometimes took graphic or pictorial forms but more often used letters in the manner of algebra to stand for propositions, concepts, classes, properties, and relations, as well as special symbols for logical notions. Inspired by the triumphs achieved in mathematics after it had turned to the systematic use of special symbols, logicians hoped to imitate this success. The systematic application of symbols and abbreviations and the conscious hope that through this application great progress could be made have been a distinguishing characteristic of modern logic into the 20th century.

The modern era saw major changes not only in the external appearance of logical writings but also in the purposes of logic. Logic for Aristotle was a theory of ideal human reasoning and inference that also had clear pedagogical value. Early modern logicians stressed what they called "dialectics" (or "rhetoric"), because "logic" had come to mean an elaborate scholastic theory of reasoning that was not always directed toward improving reasoning. A related goal was to extend the scope of human reasoning beyond textbook syllogistic theory and to acknowledge that there were important kinds of valid inference that could not be formulated in traditional Aristotelian syllogistic. But another part of the rejection of Aristotelian logic (broadly conceived to include scholastic logic) is best explained by the changing and quite new goals that logic took on in the modern era. One such goal was the development of an ideal logical language that naturally expressed ideal thought and was more precise than natural languages. Another goal was to develop methods of thinking and discovery that would accelerate or improve human thought or would allow its replacement by mechanical devices. Whereas Aristotelian logic had seen itself as a tool for training "natural" abilities at reasoning, later logics proposed vastly improving meagre and wavering human tendencies and abilities. The linking of logic with mathematics was an especially characteristic theme in the modern era. Finally, in the modern era came an intense consciousness of the importance of logical form (forms of sentences, as well as forms or patterns of arguments). Although the medievals made many distinctions among patterns of sentences and arguments, the modern logical notion of "form" perhaps first crystallized in the work of Sir William Rowan Hamilton and the English mathematician and logician Augustus De Morgan (De Morgan's *Formal Logic* of 1847). The now standard discussions of validity, invalidity, and the self-conscious separation of "formal" from nonformal aspects of sentences and arguments all trace their roots to this work.

THE 17TH CENTURY

The *Logica Hamburgensis* (1638) of Joachim Jung (also called Jungius or Junge) was one replacement for the "Protestant" logic of Melanchthon. Its chief virtue was the care with which late medieval theories and techniques were gathered and presented. Jung devoted considerable attention to valid arguments that do not fit into simpler, standard conceptions of the syllogism and immediate inference. Of special interest is his treatment of quantified relational arguments, then called "oblique" syllogisms because of the oblique (non-nominative) case that is used to express them in Latin. An example is: "The square of an even number is even; 6 is even; therefore, the square of 6 is even." The technique of dealing with such inferences involved rewriting a premise so that the term in the oblique case (for example, "of an even number") would occur in the subject position and thus be amenable to standard syllogistic manipulation. Such arguments had in fact been noticed by Aristotle and were also treated in late medieval logic.

"Oblique" syllogisms

An especially widely used text of the 17th century is usually termed simply the *Port-Royal Logic* after the seat of the anticlerical Jansenist movement outside Paris. It was written by Antoine Arnauld and Pierre Nicole, possibly with others, and was published in French in 1662 with the title *La Logique ou l'art de penser* "Logic or the Art of Thinking". It was promptly translated into Latin and English and underwent many reprintings in the late 17th and 18th centuries. In its outline, it followed Ramus' outline of concept, judgment, argument, and method; it also briefly mentioned oblique syllogisms. The *Port-Royal Logic* followed the general Reform program of simplifying syllogistic theory, reducing the number of syllogistic figures from four, and minimizing distinctions thought to be useless. In addition, the work contained an important contribution to semantics in the form of the distinction between comprehension and extension. Although medieval semantic theory had used similar notions, the Port-Royal notions found their way into numerous 18th- and 19th-century discussions of the meanings and reference of terms; they appeared, for example, in John Stuart Mill's influential text *A System of Logic* (1843). The "comprehension" of a term consisted of all the essential attributes in it (those that cannot be removed without "destroying" the concept), and the extension consisted of all those objects to which the concept applies. Thus the comprehension of the term "triangle" might include the attributes of being a polygon, three-sided, three-angled, and so on. Its extension would include all kinds of triangles. The *Port-Royal Logic* also contained an influential discussion of definitions that was inspired by the work of the French mathematician and philosopher Blaise Pascal. According to this discussion, some terms could not be defined ("primitive" terms), and definitions were divided between nominal and real ones. Real definitions were descriptive and stated the essential properties in a concept, while nominal definitions were creative and stipulated the conventions by which a linguistic term was to be used.

Nominal and real definitions

Discussions of "nominal" and "real" definitions go back at least to the nominalist/realist debates of the 14th century; Pascal's application of the distinction is interesting for the emphasis that it laid on mathematical definitions being nominal and on the usefulness of nominal definitions. Although the Port-Royal logic itself contained no symbolism, the philosophical foundation for using symbols by nominal definitions was nevertheless laid.

One intriguing 17th-century treatment of logic in terms of demonstrations, postulates, and definitions in a Euclidean fashion occurs in the otherwise quite traditional *Logica Demonstrativa* (1697; "Demonstrative Logic") of the Ital-

ian Jesuit Gerolamo Saccheri. Saccheri is better known for his suggestion of the possibility of a non-Euclidean geometry in *Euclides ab Omni Naevo Vindicatus* (1733; "Euclid Cleared of Every Flaw"). Another incisive traditional logic was that of the Dutch philosopher Arnold Geulincx, *Logica fundamentis suis restituta* (1662; "Logic Restored to its Fundamentals"). This work attempted to resurrect the rich detail of scholastic logic, including the theory of *suppositio* and issues of existential import.

LEIBNIZ

With the logical work of the German mathematician, philosopher, and diplomat Gottfried Wilhelm Leibniz, we encounter one of the great triumphs, and tragedies, in the history of logic. He created in the 1680s a symbolic logic that is remarkably similar to George Boole's system of 1847—and Boole is widely regarded as the initiator of mathematical or symbolic logic. But nothing other than vague generalities about Leibniz' goals for logic was published until 1903—well after symbolic logic was in full blossom. Thus one could say that, great though Leibniz' discoveries were, they were virtually without influence in the history of logic. (There remains some slight possibility that Lambert or Boole may have been directly or indirectly influenced by Leibniz' logical system.)

Leibniz' logical research was not entirely symbolic, however, nor was he without influence in the history of (nonsymbolic) logic. Early in his life, Leibniz was strongly interested in the program of Lull, and he wrote the *De arte combinatoria* (1666); this work followed the general Lullian goal of discovering truths by combining concepts into judgments in exhaustive ways and then methodically assessing their truth. Leibniz later developed a goal of devising what he called a "universally characteristic language" (*lingua characteristica universalis*) that would, first, notationally represent concepts by displaying the more basic concepts of which they were composed, and second, naturally represent (in the manner of graphs or pictures, "iconically") the concept in a way that could be easily grasped by readers, no matter what their native tongue. Leibniz studied and was impressed by the method of the Egyptians and Chinese in using picturelike expressions for concepts. The goal of a universal language had already been suggested by Descartes for mathematics as a "universal mathematics"; it had also been discussed extensively by the English philologist George Dalgarno (*c.* 1626–87) and, for mathematical language and communication, by the French algebraist François Viète (1540–1603). The search for a universal language to replace Latin was seriously taken up again in the late 19th century, first by Giuseppe Peano—whose work on Interlingua, an uninflected form of Latin, was directly inspired by Leibniz' conception—and then with Esperanto. The goal of a logical language also inspired Gottlob Frege, and in the 20th century it prompted the development of the logical language LOGLAN and the computer language PROLOG.

The goal of a universal language

Another and distinct goal Leibniz proposed for logic was a "calculus of reason" (*calculus ratiocinator*). This would naturally first require a symbolism but would then involve explicit manipulations of the symbols according to established rules by which either new truths could be discovered or proposed conclusions could be checked to see if they could indeed be derived from the premises. Reasoning could then take place in the way large sums are done—that is, mechanically or algorithmically—and thus not be subject to individual mistakes and failures of ingenuity. Such derivations could be checked by others or performed by machines, a possibility that Leibniz seriously contemplated. Leibniz' suggestion that machines could be constructed to draw valid inferences or to check the deductions of others was followed up by Charles Babbage, William Stanley Jevons, and Charles Sanders Peirce and his student Allan Marquand in the 19th century, and with wide success on modern computers after World War II.

The symbolic calculus that Leibniz devised seems to have been more of a calculus of reason than a "characteristic" language. It was motivated by his view that most concepts were "composite": they were collections or conjunctions of other more basic concepts. Symbols (letters, lines, or circles) were then used to stand for concepts and their relationships. This resulted in what is called an "intensional" rather than an "extensional" logic—one whose terms stand for properties or concepts rather than for the things having these properties. Leibniz' basic notion of the truth of a judgment was that the concepts making up the predicate were "included in" the concept of the subject. What Leibniz symbolized as "$A \propto B$," or what we might write as "$A = B$" was that all the concepts making up concept A also are contained in concept B, and vice versa.

Intensional logic

Leibniz used two further notions to expand the basic logical calculus. In his notation, "$A \oplus B \propto C$" indicates that the concepts in A and those in B wholly constitute those in C. We might write this as "$A + B = C$" or "$A \cup B = C$"—if we keep in mind that A, B, and C stand for concepts or properties, not for individual things. Leibniz also used the juxtaposition of terms in the following way: "$AB \propto C$," which we might write as "$A \times B = C$" or "$A \cap B = C$," signifies in his system that all the concepts in both A and B wholly constitute the concept C.

A universal affirmative judgment, such as "All A's are B's," becomes in Leibniz' notation "$A \propto AB$." This equation states that the concepts included in the concepts of both A and B are the same as those in A. A syllogism, "All A's are B's; all B's are C's; therefore all A's are C's," becomes the sequence of equations "$A = AB$; $B = BC$; therefore $A = AC$." This conclusion can be derived from the premises by two simple algebraic substitutions and the associativity of logical multiplication. Leibniz' interpretation of particular and negative statements was more problematic. Although he later seemed to prefer an algebraic, equational symbolic logic, he experimented with many alternative techniques, including graphs.

As with many early symbolic logics, including many developed in the 19th century, Leibniz' system had difficulties with particular and negative statements, and it included little discussion of propositional logic and no formal treatment of quantified relational statements. (Leibniz later became keenly aware of the importance of relations and relational inferences.) Although Leibniz might seem to deserve to be credited with great originality in his symbolic logic—especially in his equational, algebraic logic—it turns out that such insights were relatively common to mathematicians of the 17th and 18th centuries who had a knowledge of traditional syllogistic logic. In 1685 Jakob Bernoulli published a pamphlet on the parallels of logic and algebra and gave some algebraic renderings of categorical statements. Later the symbolic work of Lambert, Ploucquet, Euler, and even Boole—all apparently uninfluenced by Leibniz' or even Bernoulli's work—seems to show the extent to which these ideas were apparent to the best mathematical minds of the day.

THE 18TH AND 19TH CENTURIES

In the 18th century there were three major contributors to the development of formal logic: Ploucquet, Lambert, and Euler, although none went far beyond Leibniz and none influenced subsequent developments in the way that Boole and Frege later did. Leibniz' major goals for logic, such as the development of a "characteristic" language; the parallels among arithmetic, algebra, and syllogistic; and his notion of the truth of a judgment as the concept of the predicate being "included in" the concept of the subject, were carried forward by Christian Wolff but without any significant development of a logic, symbolic or otherwise. The prolific Wolff publicized Leibniz' general views widely and spawned two minor symbolic formulations of logic; that of J.A. Segner in 1740 and that of Joachim Georg Darjes (1714–91) in 1747. Segner used the notation "$B < A$" to signify, intensionally in the manner of Leibniz, that the concept of B is included in the concept of A (*i.e.*, "All A's are B's").

The work of Gottfried Ploucquet (1716–90) was based on the ideas of Leibniz, although the symbolic calculus Ploucquet developed does not resemble that of Leibniz. The basis of Ploucquet's symbolic logic was the sign ">," which he unfortunately used to indicate that two concepts are disjoint—*i.e.*, having no basic concepts in common; in its propositional interpretation, it is equivalent to what

Gottfried Ploucquet

became known in the 20th century as the "Sheffer stroke" function (also known to Peirce) meaning "neither . . . nor." The universal negative proposition, "No A's are B's," would become "A > B" (or, convertibly, "B > A"). The equality sign was used to denote conceptual identity, as in Leibniz. Capital letters were used for distributed terms, lowercase ones for undistributed terms. The intersection of concepts was represented by "+"; the multiplication sign (or juxtaposition) stood for the inclusive union of concepts; and a bar over a letter stood for complementation (in the manner of Leibniz). Thus "Ā" represented all non-A's, while "ā" meant the same as "some non-A." Rules of inference were the standard algebraic substitution of identicals along with more complicated implicit rules for manipulating the nonidentities using ">." Ploucquet was interested in graphic representations of logical relations—using lines, for example. He was also one of the first symbolic logicians to have worried extensively about representing quantification—although his own contrast of distributed and undistributed terms is a clumsy and limited device. Not a mathematician, Ploucquet did not pursue the logical interpretation of inverse operations (*e.g.,* division, square root, and so on) and of binomial expansions; the interpretation of these operations was to plague some algebras of logic and sidetrack substantive development—first in the work of Leibniz and the Bernoullis, then in that of Lambert, Boole, and Schröder. Ploucquet published and promoted his views widely (his publications included an essay on Leibniz' logic); he influenced his contemporary Lambert and had a still greater influence upon Georg Jonathan von Holland and Christian August Semler.

Johann Heinrich Lambert

The greatest 18th-century logician was undoubtedly Johann Heinrich Lambert. Lambert was the first to demonstrate the irrationality of π, and, when asked by Frederick the Great in what field he was most capable, is said to have curtly answered "All." His own highly articulated philosophy was a more thorough and creative reworking of rationalist ideas from Leibniz and Wolff. His symbolic and formal logic, developed especially in his *Sechs Versuche einer Zeichenkunst in der Vernunftlehre* (1777; "Six Attempts at a Symbolic Method in the Theory of Reason"), was an elegant and notationally efficient calculus, extensively duplicating, apparently unwittingly, sections of Leibniz' calculus of a century earlier. Like the systems of Leibniz, Ploucquet, and most Germans, it was intensional, using terms to stand for concepts, not individual things. It used an identity sign and the plus sign in the natural algebraic way that one sees in Leibniz and Boole. Five features distinguish it from other systems. First, Lambert was concerned to separate the simpler concepts constituting a more complex concept into the genus and differentia—the broader and narrowing concepts—typical of standard definitions: the symbols for the genus and differentia of a concept were operations on terms, extracting the genus or differentia of a concept. Second, Lambert carefully differentiated among letters for known, undetermined, and genuinely unknown concepts, using different letters from the Latin alphabet; the lack of such distinctions in algebra instruction has probably caused extensive confusion. Third, his disjunction or union operation, " + ," was taken in the exclusive sense—excluding the overlap of two concepts, in distinction to Ploucquet's inclusive operation, for example. Fourth, Lambert accomplished the expression of quantification such as that in "Every A is B" by writing "$a = mb$"—that is, the known concept a is identical to the concepts in both the known concept b and an indeterminate concept m; this device is similar enough to Boole's later use of the letter "y" to suggest some possible influence. Finally, Lambert considered briefly the symbolic theorems that would not hold if the concepts were relations, such as "is the father of." He also introduced a notation for expressing relational notions in terms of single-placed functions: in his system, "$i = \alpha :: c$" indicates that the individual (concept) i is the result of applying a function α to the individual concept c. Although it is not known whether Frege had read Lambert, it is possible that Lambert's analysis influenced Frege's analysis of quantified relations, which depends on the notion of a function.

Lambert also developed a method of pictorially displaying the overlap of the content of concepts with overlapping line segments. Leibniz had experimented with similar techniques. Two-dimensional techniques were popularized by the Swiss mathematician Leonhard Euler in his *Lettres à une princesse d'Allemagne* (1768–74; "Letters to a German Princess"). These techniques and the related Venn diagrams have been especially popular in logic education. In Euler's method the interior areas of circles represented (intensionally) the more basic concepts making up a concept or property. To display "All A's are B's," Euler drew a circle labeled "A" that was entirely contained within another circle, "B." Such circles could be manipulated to discover the validity of syllogisms. Euler did not develop this method very far, and it did not constitute a significant logical advance. Leibniz himself had occasionally drawn such illustrations, and they apparently first entered the literature in the *Universalia Euclidea* (1661) of Johann C. Sturm and were more frequently used by Johann C. Lange in 1712. (Vives had employed triangles for similar purposes in 1555.) Euler's methods were systematically developed by the French mathematician Joseph-Diez Gergonne in 1816–17, although Gergonne retreated from two-dimensional graphs to linear formulas that could be more easily printed and manipulated. For complicated reasons, almost all German formal logic came from the Protestant areas of the German-speaking world.

Leonhard Euler

The German philosophers Immanuel Kant and Georg Wilhelm Friedrich Hegel made enormous contributions to philosophy, but their contributions to formal logic can only be described as minimal or even harmful. Kant refers to logic as a virtually completed artifice in his important *Critique of Pure Reason* (1781). He showed no interest in Leibniz' goal of a natural, universal, and efficient logical language and no appreciation of symbolic or mathematical formulations. His own lectures on logic, published in 1800 as *Immanuel Kants Logik: ein Handbuch zu Vorlesungen,* and his earlier *The Mistaken Subtlety of the Four Syllogistic Figures* (1762) were minor contributions to the history of logic. Hegel refers early in his massive *Science of Logic* (1812–16) to the centuries of work in logic since Aristotle as a mere preoccupation with "technical manipulations." He took issue with the claim that one could separate the "logical form" of a judgment from its substance—and thus with the very possibility of logic based on a theory of logical form. When the study of logic blossomed again on German-speaking soil, contributors came from mathematics and the natural sciences.

In the English-speaking world, logic had always been more easily and continuously tolerated, even if it did not so early reach the heights of mathematical sophistication that it had in the German- and French-speaking worlds. Logic textbooks in English appeared in considerable numbers in the 17th and 18th centuries: some were translations, while others were handy, simplified handbooks with some interesting and developed positions, such as John Wallis' *Institutio Logicae* (1687) and works by Henry Aldrich, Isaac Watts, and the founder of Methodism, John Wesley. Out of this tradition arose Richard Whately's *Elements of Logic* (1826) and, in the same tradition, John Stuart Mill's enormously popular *A System of Logic* (1843). Although now largely relegated to a footnote, Whately's nonsymbolic textbook reformulated many concepts in such a thoughtful and clear way that it is generally (and first by De Morgan) credited with single-handedly bringing about the "rebirth" of English-language logic.

Boole and De Morgan

The two most important contributors to British logic in the first half of the 19th century were undoubtedly George Boole and Augustus De Morgan. Their work took place against a more general background of logical work in English by figures such as Whately, George Bentham, Sir William Hamilton, and others. Although Boole cannot be credited with the very first symbolic logic, he was the first major formulator of a symbolic extensional logic that is familiar today as a logic or algebra of classes. (A correspondent of Lambert, Georg von Holland, had experimented with an extensional theory, and in 1839 the English writer Thomas Solly presented an extensional logic in *A Syllabus of Logic,* though not an algebraic one.)

Boole published two major works, *The Mathematical*

Analysis of Logic in 1847 and *An Investigation of the Laws of Thought* in 1854. It was the first of these two works that had the deeper impact on his contemporaries and on the history of logic. *The Mathematical Analysis of Logic* arose as the result of two broad streams of influence. The first was the English logic-textbook tradition. The second was the rapid growth in the early 19th century of sophisticated discussions of algebra and anticipations of nonstandard algebras. The British mathematicians D.F. Gregory and George Peacock were major figures in this theoretical appreciation of algebra. Such conceptions gradually evolved into "nonstandard" abstract algebras such as quaternions, vectors, linear algebra, and Boolean algebra itself.

Boole used capital letters to stand for the extensions of terms; they are referred to (in 1854) as classes of "things" but should not be understood as modern sets. The universal class or term—which he called simply "the Universe"—was represented by the numeral "1," and the null class by "0." The juxtaposition of terms (for example, "AB") created a term referring to the intersection of two classes or terms. The addition sign signified the non-overlapping union; that is, "$A + B$" referred to the entities in A or in B; in cases where the extensions of terms A and B overlapped, the expression was held to be "undefined." For designating a proper subclass of a class, Boole used the notation "v," writing for example "vA" to indicate some of the A's. Finally, he used subtraction to indicate the removing of terms from classes. For example, "$1 - x$" would indicate what one would obtain by removing the elements of x from the universal class—that is, obtaining the complement of x (relative to the universe, 1).

Basic equations included: $1A = A$, $0A = 0$, $A + 0 = 0$, $A + 1 = 1$ (but only where $A = 0$), $A + B = B + A$, $AB = BA$, $AA = A$ (but not $A + A = A$), $(AB)C = A(BC)$, and the distribution laws, $A(B + C) = AB + AC$ and $A + (BC) = (A + B)(A + C)$. Boole offered a relatively systematic, but not rigorously axiomatic, presentation. For a universal affirmative statement such as "All A's are B's," Boole used three alternative notations: $AB = B$ (somewhat in the manner of Leibniz), $A(1 - B) = 0$, or $A = vB$ (the class of A's is equal to some proper subclass of the B's). The first and second interpretations allowed one to derive syllogisms by algebraic substitution: the latter required manipulation of subclass ("v") symbols.

In contrast to earlier symbolisms, Boole's was extensively developed, with a thorough exploration of a large number of equations (including binomial-like expansions) and techniques. The formal logic was separately applied to the interpretation of propositional logic, which became an interpretation of the class or term logic—with terms standing for occasions or times rather than for concrete individual things. Following the English textbook tradition, deductive logic is but one half of the subject matter of the book, with inductive logic and probability theory constituting the other half of both his 1847 and 1854 works.

Seen in historical perspective, Boole's logic was a remarkably smooth bend of the new "algebraic" perspective and the English-logic textbook tradition. His 1847 work begins with a slogan that could have served as the motto of abstract algebra: ". . . the validity of the processes of analysis does not depend upon the interpretation of the symbols which are employed, but solely upon the laws of combination."

Modifications to Boole's system were swift in coming: in the 1860s Peirce and Jevons both proposed replacing Boole's " + " with a simple inclusive union or summation: the expression "A + B" was to be interpreted as designating the class of things in A, in B, or in both. This results in accepting the equation "1 + 1 =1," which is certainly not true of the ordinary numerical algebra and at which Boole apparently balked.

Relational inferences

Interestingly, one defect in Boole's theory, its failure to detail relational inferences, was dealt with almost simultaneously with the publication of his first major work. In 1847 Augustus De Morgan published his *Formal Logic; or, the Calculus of Inference, Necessary and Probable.* Unlike Boole and most other logicians in the United Kingdom, De Morgan knew the medieval theory of logic and semantics and also knew the Continental, Leibnizian symbolic tradition of Lambert, Ploucquet, and Gergonne. The symbolic system that De Morgan introduced in his work and used in subsequent publications is, however, clumsy and does not show the appreciation of abstract algebras that Boole's did. De Morgan did introduce the enormously influential notion of a possibly arbitrary and stipulated "universe of discourse" that was used by later Booleans. (Boole's original universe referred simply to "all things.") This view influenced 20th-century logical semantics. De Morgan contrasted uppercase and lowercase letters: a capital letter represented a class of individuals, while a lowercase letter represented its complement relative to the universe of discourse, a convention Boole might have expressed by writing "$x = (1 - X)$"; this stipulation results in the general principle: $xX = 0$. A period indicated a (propositional) negation, and the parentheses "(" and ")" indicated, respectively, distributed (if the parenthesis faces toward the nearby term) and undistributed terms. Thus De Morgan would write "All A's are B's" as "$A))B$" and "Some A's are B's" as "$A(\ )B$." These distinctions parallel Boole's account of distribution (quantification) in "$A = vB$" (where A is distributed but B is not) and "$vA = B$" (where both terms are distributed). Although his entire system was developed with wit, consistency, and brilliance, it is remarkable that De Morgan never saw the inferiority of his notation to almost all available symbolisms.

De Morgan's other essays on logic were published in a series of papers from 1846 to 1862 (and an unpublished essay of 1868) entitled simply "On the Syllogism." The first series of four papers found its way into the middle of the *Formal Logic* of 1847. The second series, published in 1850, is of considerable significance in the history of logic, for it marks the first extensive discussion of quantified relations since late medieval logic and Jung's massive *Logica hamburgensis* of 1638. In fact, De Morgan made the point, later to be exhaustively repeated by Peirce and implicitly endorsed by Frege, that relational inferences are the core of mathematical inference and scientific reasoning of all sorts; relational inferences are thus not just one type of reasoning but rather are the most important type of deductive reasoning. Often attributed to De Morgan—not precisely correctly but in the right spirit—was the observation that all of Aristotelian logic was helpless to show the validity of the inference, "All horses are animals; therefore, every head of a horse is the head of an animal." The title of this series of papers, De Morgan's devotion to the history of logic, his reluctance to mathematize logic in any serious way, and even his clumsy notation—apparently designed to represent as well as possible the traditional theory of the syllogism—show De Morgan to be a deeply traditional logician.

Charles Sanders Peirce

Charles Sanders Peirce, the son of the Harvard mathematics professor and discoverer of linear algebra Benjamin Peirce, was the first significant American figure in logic. Peirce had read the work of Aristotle, Whately, Kant, and Boole as well as medieval works and was influenced by his father's sophisticated conceptions of algebra and mathematics. Peirce's first published contribution to logic was his improvement in 1867 of Boole's system. Although Peirce never published a book on logic (he did edit a collection of papers by himself and his students, the *Studies in Logic* of 1883), he was the author of an important article in 1870, whose abbreviated title was "On the Notation of Relatives," and of a series of articles in the 1880s on logic and mathematics; these were all published in American mathematics journals.

It is relatively easy to describe Peirce's main approach to logic, at least in his earlier work: it was a refinement of Boole's algebra of logic and, especially, the development of techniques for handling relations within that algebra. In a phrase, Peirce sought a blend of Boole (on the algebra of logic) and De Morgan (on quantified relational inferences). Described in this way, however, it is easy to underestimate the originality and creativity (even idiosyncrasy) of Peirce. Although committed to the broadly "algebraic" tradition of Boole and his father, Peirce quickly moved away from the equational style of Boole and from efforts to mimic numerical algebra. In particular, he argued that

a transitive and asymmetric logical relation of inclusion, for which he used the symbol "$-\prec$," was more useful than equations; the importance of such a basic, transitive relation was first stressed by De Morgan, and much of Peirce's work can be seen as an exploration of the formal, abstract properties of this distinctively logical relation. He used it to express class inclusion, the "if . . . then" connective of propositional logic, and even the relation between the premises and conclusion of an argument ("illation"). Furthermore, Peirce slowly abandoned the strictly substitutional character of algebraic terms and increasingly used notation that resembled modern quantifiers (see above *Formal logic: The predicate calculus*). Quantifiers were briefly introduced in 1870 and were used extensively in the papers of the 1880s. They were borrowed by Schröder for his extremely influential treatise on the algebra of logic and were later adopted by Peano from Schröder; thus in all probability they are the source of the notation for quantifiers now widely used. In his earlier works, Peirce might have written "$A - \prec B$" to express the universal statement "All A's are B's"; however, he often wrote this as "$\Pi_i A_i - \prec \Pi_i B_i$" (the class of all the i's that are A is included in the class of all the i's that are B) or, still later and interpreted in the modern way, as "For all i's, if i is A, then i is B." Peirce and Schröder were never clear about whether they thought these quantifiers and variables were necessary for the expression of certain statements (as opposed to using strictly algebraic formulas), and Frege did not address this vital issue either; the Boolean algebra without quantifiers, even with extensions for relations that Peirce introduced, was demonstrated to be inadequate only in the mid-20th century by Alfred Tarski and others.

Algebra of relations and existential graphs

Peirce developed this symbolism extensively for relations. His earlier work was based on versions of multiplication and addition for relations—called relative multiplication and addition—so that Boolean laws still held. Both Peirce's conception of the purposes of logic and the details of his symbolism and logical rules were enormously complicated by highly developed and unusual philosophical views, by elaborate theories of mind and thought, and by his theory of mental and visual signs (semiotics). He argued that all reasoning was "diagrammatic" but that some diagrams were better (more iconic) than others if they more accurately represented the structure of our thoughts. His earlier works seems to be more in the tradition of developing a calculus of reason that would make reasoning quicker and better and permit one to validate others' reasoning more accurately and efficiently. His later views, however, seem to be more in the direction of developing a "characteristic" language. In the late 1880s and 1890s Peirce developed a far more extensively iconic system of logical representation, his existential graphs. This work was, however, not published in his lifetime and was little recognized until the 1960s.

Peirce did not play a major role in the important debates at the end of the 19th century on the relationship of logic and mathematics and on set theory. In fact, in responding to an obviously quick reading of Russell's restatements of Frege's position that mathematics could be derived from logic, Peirce countered that logic was properly seen as a branch of mathematics, not vice versa. He had no influential students: the brilliant O.H. Mitchell died at an early age, and Christine Ladd Franklin never adapted to the newer symbolic tradition of Peano, Frege, and Russell. On the other hand, Peano and especially Schröder had read Peirce's work carefully and adopted much of his notation and his doctrine of the importance of relations (although they were less fervent than De Morgan and Peirce). Peano and Schröder, using much of Peirce's notation, had an enormous influence into the 20th century.

In Germany, the older formal and symbolic logical tradition was barely kept alive by figures such as Salomon Maimon, Semler, August Detlev Twesten, and Moritz Wilhelm Drobisch. The German mathematician and philologist Hermann Günther Grassmann published in 1844 his *Ausdehnungslehre* ("The Theory of Extension"), in which he used a novel and difficult notation to explore quantities ("extensions") of all sorts—logical extension and intension, numerical, spatial, temporal, and so on. Grassmann's notion of extension is very similar to the use of the broad term "quantity" (and the phrase "logic of quantity") that is seen in the works of George Bentham and Sir William Hamilton from the same period in the United Kingdom; it is from this English-language tradition that the terms, still in use, of logical "quantification" and "quantifiers" derive. Grassmann's work influenced Robert Grassmann's *Die Begriffslehre oder Logik* (1872; "The Theory of Concepts or Logic"), Schröder, and Peano. The stage for a rebirth of German formal logic was further set by Friedrich Adolf Trendelenburg's works, published in the 1860s and '70s, on Aristotle's and Leibniz' logic and on the relationship of mathematics and philosophy. Alois Riehl's much-read article "Die englische Logik der Gegenwart (1876; "Contemporary English Logic") introduced German speakers to the works of Boole, De Morgan, and Jevons.

Gottlob Frege

In 1879 the young German mathematician Gottlob Frege—whose mathematical specialty, like Boole's, had actually been calculus—published perhaps the finest single book on symbolic logic in the 19th century, *Begriffsschrift* ("Conceptual Notation"). The title was taken from Trendelenburg's translation of Leibniz' notion of a characteristic language. Frege's small volume is a rigorous presentation of what would now be called the first-order predicate logic. It contains a careful use of quantifiers and predicates (although predicates are described as functions, suggestive of the technique of Lambert). It shows no trace of the influence of Boole and little trace of the older German tradition of symbolic logic. One might surmise that Frege was familiar with Trendelenburg's discussion of Leibniz, had probably encountered works by Drobisch and Hermann Grassmann, and possibly had a passing familiarity with the works of Boole and Lambert, but was otherwise ignorant of the history of logic. He later characterized his system as inspired by Leibniz' goal of a characteristic language but not of a calculus of reason. Frege's notation was unique and problematically two-dimensional; this alone caused it to be little read.

Frege was well aware of the importance of functions in mathematics, and these form the basis of his notation for predicates; he never showed an awareness of the work of De Morgan and Peirce on relations or of older medieval treatments. The work was reviewed (by Schröder, among others), but never very positively, and the reviews always chided him for his failure to acknowledge the Boolean and older German symbolic tradition; reviews written by philosophers chided him for various sins against reigning idealist dogmas. Frege stubbornly ignored the critiques of his notation and persisted in publishing all his later works using it, including his little-read magnum opus, *Grundgesetze der Arithmetik* (1893–1903; *The Basic Laws of Arithmetic*).

His first writings after the *Begriffsschrift* were bitter attacks on Boolean methods (showing no awareness of the improvements by Peirce, Jevons, Schröder, and others) and a defense of his own system. His main complaint against Boole was the artificiality of mimicking notation better suited for numerical analysis rather than developing a notation for logical analysis alone. This work was followed by the *Die Grundlagen der Arithmetik* (1884; *The Foundations of Arithmetic*) and then by a series of extremely important papers on precise mathematical and logical topics. After 1879 Frege carefully developed his position that all of mathematics could be derived from, or reduced to, basic "logical" laws—a position later to be known as logicism in the philosophy of mathematics. His view paralleled similar ideas about the reducibility of mathematics to set theory from roughly the same time—although Frege always stressed that his was an intensional logic of concepts, not of extensions and classes. His views are often marked by hostility to British extensional logic and to the general English-speaking tendencies toward nominalism and empiricism that he found in authors such as J.S. Mill. Frege's work was much admired in the period 1900–10 by Bertrand Russell who promoted Frege's logicist research program—first in the *Introduction to Mathematical Logic* (1903), and then with Alfred North Whitehead, in *Principia Mathematica* (1910–13)—but who used a Peirce-Schröder-Peano system of notation rather than

The logicist position

Frege's; Russell's development of relations and functions was very similar to Schröder's and Peirce's. Nevertheless, Russell's formulation of what is now called the "set-theoretic" paradoxes was taken by Frege himself, perhaps too readily, as a shattering blow to his goal of founding mathematics and science in an intensional, "conceptual" logic. Almost all progress in symbolic logic in the first half of the 20th century was accomplished using set theories and extensional logics and thus mainly relied upon work by Peirce, Schröder, Peano, and Georg Cantor. Frege's care and rigour were, however, admired by many German logicians and mathematicians, including David Hilbert and Ludwig Wittgenstein. Although he did not formulate his theories in an axiomatic form, Frege's derivations were so careful and painstaking that he is sometimes regarded as a founder of this axiomatic tradition in logic. Since the 1960s Frege's works have been translated extensively into English and reprinted in German, and they have had an enormous impact on a new generation of mathematical and philosophical logicians.

German symbolic logic (in a broad sense) was cultivated by two other major figures in the 19th century. The tradition of Hermann Grassmann was continued by the German mathematician and algebraist Ernst Schröder. His first work, *Der Operations-kreis des Logikkalkuls* (1877; "The Circle of Operations of the Logical Calculus"), was an equational algebraic logic influenced by Boole and Grassmann but presented in an especially clear, concise, and careful manner; it was, however, intensional in that letters stand for concepts, not classes or things. Although Jevons and Frege complained of what they saw as the "mysterious" relationship between numerical algebra and logic in Boole, Schröder announced with great clarity: "There is certainly a contrast of the objects of the two operations. They are totally different. In arithmetic, letters are numbers, but here, they are arbitrary concepts." He also used the phrase "mathematical logic." Schröder's main work was his three-volume *Vorlesungen über die Algebra der Logik* (1890–1905; "Lectures on the Algebra of Logic"). This is an extensive and sometimes original presentation of all that was known about the algebra of logic circa 1890, together with derivations of thousands of theorems and an extensive bibliography of the history of logic. It is an extensional logic with a special sign for inclusion " (" (paralleling Peirce's "—<"), an inclusive notion of class union, and the usual Boolean operations and rules.

Ernst Schröder

The first volume is devoted to the basic theory of an extensional theory of classes (which Schröder called *Gebiete*, logical "domains," a term that is somewhat suggestive of Grassmann's "extensions"). Schröder was especially interested in formal features of the resulting calculus, such as the property he called "dualism" (carried over from his 1877 work): any theorem remains valid if the addition and multiplication, as well as 0 and 1, are switched—for example, $A\bar{A} = 0$, $A + \bar{A} = 1$, and the pair of De Morgan laws. The second volume is a discussion of propositional logic, with propositions taken to refer to domains of times in the manner of Boole's *Laws of Thought* but using the same calculus. Schröder, unlike Boole and Peirce, distinguished between the universes for the separate cases of the class and propositional logics, using respectively 1 and 1. The third volume contains Schröder's masterful but leisurely development of the logic of relations, borrowing heavily from Peirce's work. In the first decades of the 20th century, Schröder's volumes were the only major works in German on symbolic logic other than Frege's, and they had an enormous influence on important figures writing in German, such as Thoralf Albert Skolem, Leopold Löwenheim, Julius König, Hilbert, and Tarski. (Frege's influence was felt mainly through Russell and Whitehead's *Principia Mathematica*, but this tradition had a rather minor impact on 20th-century German logic.) Although it was an extensional logic more in the English tradition, Schröder's logic exhibited the German tendency of focusing exclusively upon deductive logic; it was a legacy of the English textbook tradition always to cover inductive logic in addition, and this trait survived in (and often cluttered) the works of Boole, De Morgan, Venn, and Peirce.

A development in Germany originally completely distinct from logic but later to merge with it was Georg Cantor's development of set theory. In work originating from discussions on the foundations of the infinitesimal and derivative calculus by Baron Augustin-Louis Cauchy and Karl Weierstrauss, Cantor and Richard Dedekind developed methods of dealing with the large, and in fact infinite, sets of the integers and points on the real number line. Although the Booleans had used the notion of a class, they rarely developed tools for dealing with infinite classes, and no one systematically considered the possibility of classes whose elements were themselves classes, which is a crucial feature of Cantorian set theory. The conception of "real" or "closed" infinities of things, as opposed to infinite possibilities, was a medieval problem that had also troubled 19th-century German mathematicians, especially the great Carl Friedrich Gauss. The Bohemian mathematician and priest Bernhard Bolzano emphasized the difficulties posed by infinities in his *Paradoxien des Unendlichen* (1851; "Paradoxes of the Infinite"); in 1837 he had written an anti-Kantian and pro-Leibnizian nonsymbolic logic that was later widely studied. First Dedekind, then Cantor used Bolzano's tool of measuring sets by one-to-one mappings; using this technique, Dedekind gave in *Was sind und was sollen die Zahlen?* (1888; "What Are and Should Be the Numbers?") a precise definition of an infinite set. A set is infinite if and only if the whole set can be put into one-to-one correspondence with a proper part of the set. (De Morgan and Peirce had earlier given quite different but technically correct characterizations of infinite domains; these were not especially useful in set theory and went unnoticed in the German mathematical world.)

Cantorian set theory

Although Cantor developed the basic outlines of a set theory, especially in his treatment of infinite sets and the real number line, he did not worry about rigorous foundations for such a theory—thus, for example, he did not give axioms of set theory—nor about the precise conditions governing the concept of a set and the formation of sets. Although there are some hints in Cantor's writing of an awareness of problems in this area (such as hints of what later came to be known as the class/set distinction), these difficulties were forcefully posed by the paradoxes of Russell and the Italian mathematician Cesare Burali-Forti and were first overcome in what has come to be known as Zermelo-Fraenkel set theory.

French logic was ably, though not originally, represented in this period by Louis Liard and Louis Couturat. Couturat's *L'Algèbre de la logique* (1905; *The Algebra of Logic*) and *De l'Infini mathematique* (1896; "On Mathematical Infinity") were important summaries of German and English research on symbolic logic, while his book on Leibniz' logic (1901) and an edition of Leibniz' previously unpublished writings on logic (1903) were very important events in the study of the history of logic. In Russia V.V. Bobyin (1886) and Platon Sergeevich Poretsky (1884) initiated a school of algebraic logic. In the United Kingdom a vast amount of work on formal and symbolic logic was published in the best philosophical journals from 1870 until 1910. This includes work by William Stanley Jevons, whose intensional logic is unusual in the English-language tradition; John Venn, who was notable for his (extensional) diagrams of class relationships but who retained Boole's noninclusive class union operator; Hugh MacColl; Alexander Bain; Sophie Bryant; Emily Elizabeth Constance Jones; Arthur Thomas Shearman; Lewis Carroll (Charles Lutwidge Dodgson); and Whitehead, whose *A Treatise on Universal Algebra* (1898) was the last major English logical work in the algebraic tradition. Little of this work influenced Russell's conception, which was soon to sweep through English-language logic; Russell was more influenced by Frege, Peano, and Schröder. The older nonsymbolic syllogistic tradition was represented in major English universities well into the 20th century by John Cook Wilson, William Ernest Johnson, Lizzie Susan Stebbing, and Horace William Brindley Joseph and in the United States by Ralph Eaton, James Edwin Creighton, Charles West Churchman, and Daniel Sommer Robinson.

British logicians

The Italian mathematician Giuseppe Peano's contributions represent a more extensive impetus to the new, nonalgebraic logic. He had a direct influence on the no-

tation of later symbolic logic that exceeded that of Frege and Peirce. His early works (such as the logical section of the *Calcolo geometrico secondo l'Ausdehnungslehre di H. Grassman* [1888; "Calculus of Geometry According to the Theory of Extension of H. Grassmann"]) were squarely in the algebraic tradition of Boole, Grassmann, Peirce, and Schröder. Writing in the 1890s in his own journal, *Revista di mathematica,* with a growing appreciation of the use of quantifiers in the first and third volumes of Schröder's *Vorlesungen,* Peano evolved a notation for quantifiers. This notation, along with Peano's use of the Greek letter epsilon, ε, to denote membership in a set, was adopted by Russell and Whitehead and used in later logic and set theory. Although Peano himself was not interested in the logicist program of Frege and Russell, his five postulates governing the structure of the natural numbers (now known as the Peano Postulates), with similar ideas in the work of Peirce and Dedekind, came to be regarded as the crucial link between logic and mathematics. It was widely thought that all mathematics could be derived from the theory for the natural numbers; if the Peano postulates could be derived from logic, or from logic including set theory, its feasibility would have been demonstrated. Simultaneously with his work in logic, Peano wrote many articles on universal languages and on the features of an ideal notation in mathematics and logic—all explicitly inspired by Leibniz.

The Paris international congresses

Logic in the 19th century culminated grandly with the First International Congress of Philosophy and the Second International Congress of Mathematics held consecutively in Paris in August 1900. The overlap between the two congresses was extensive and fortunate for the future of logic and philosophy. Peano, Alessandro Padoa, Burali-Forti, Schröder, Cantor, Dedekind, Frege, Felix Klein, Ladd Franklin (Peirce's student), Coutourat, and Henri Poincaré were on the organizing committee of the Philosophical Congress; for the subsequent development of logic, Bertrand Russell was perhaps its most important attendee. The influence of algebraic logic was already ebbing, and the importance of nonalgebraic symbolic logics, of axiomatizations, and of logic (and set theory) as a foundation for mathematics were ascendant. Until the congresses of 1900 and the work of Russell and Hilbert, mathematical logic lacked full academic legitimacy. None of the 19th-century logicians had achieved major positions at first-rank universities: Peirce never obtained a permanent university position, Dedekind was a high-school teacher, and Frege and Cantor remained at provincial universities. The mathematicians stayed for the Congress of Mathematics, and it was here that David Hilbert gave his presentation of the 23 most significant unsolved problems of mathematics—several of which were foundational issues in mathematics and logic that were to dominate logical research during the first half of the 20th century.

20th-century logic

In 1900 logic was poised on the brink of the most active period in its history. The late 19th-century work of Frege, Peano, and Cantor, as well as Peirce's and Schröder's extensions of Boole's insights, had broken new ground, raised considerable interest, established international lines of communication, and formed a new alliance between logic and mathematics. Five projects internal to late 19th-century logic coalesced in the early 20th century; especially in works such as Russell and Whitehead's *Principia Mathematica.* These were the development of a consistent set or property theory (originating in the work of Cantor and Frege), the application of the axiomatic method (including non-symbolically), the development of quantificational logic, and the use of logic to understand mathematical objects and the nature of mathematical proof. The five projects were unified by a general effort to use symbolic techniques, sometimes called mathematical, or formal, techniques. Logic became increasingly "mathematical," then, in two senses. First, it attempted to use symbolic methods like those that had come to dominate mathematics. Second, an often dominant purpose of logic came to be its use as a tool for understanding the nature of mathematics—such as in defining mathematical concepts, precisely characterizing mathematical systems, or describing the nature of ideal mathematical proof. (See MATHEMATICS, THE HISTORY OF: *Mathematics in the 19th and 20th centuries,* and MATHEMATICS, THE FOUNDATIONS OF.)

RUSSELL AND WHITEHEAD'S PRINCIPIA MATHEMATICA

The three-volume *Principia Mathematica* (1910–13) was optimistically named after the *Philosophiae naturalis principia mathematica* of another hugely important Cambridge thinker, Isaac Newton. Like Newton's *Principia,* it was imbued with an optimism about the application of mathematical techniques, this time not to physics but to logic and to mathematics itself—what the first sentence of their preface calls "the mathematical treatment of the principles of mathematics." It was intended by Russell and Whitehead both as a summary of then-recent work in logic (especially by Frege, Cantor and Peano) and as a ground-breaking, large-scale treatise systematically developing mathematical logic and deriving basic mathematical principles from the principles of logic alone.

The *Principia* was the natural outcome of Russell's earlier polemical book, *The Principles of Mathematics* (published in 1903 but largely written in 1900), and his views were later summarized in *Introduction to Mathematical Philosophy* (1919). Whitehead's *A Treatise on Universal Algebra* (1898) was more in the algebraic tradition of Boole, Peirce, and Schröder, but there is a sense in which *Principia Mathematica* became the second volume both of it and of Russell's *Principles.*

The main idea in the *Principia* is the view, taken from Frege, that all of mathematics could be derived from the principles of logic alone. This view later came to be known as logicism and was one of the principal philosophies of mathematics in the early 20th century. Number theory, the core of mathematics, was organized around the Peano postulates, stated in works by Peano of 1889 and 1895 (and anticipated by similar but less influential theories of Peirce and Dedekind). These postulates state and organize the fundamental laws of "natural" (integral, positive) numbers, and thus of all of mathematics:

The Peano postulates

1. 0 is a number.
2. The successor of any number is also a number.
3. No two distinct numbers have the same successor.
4. 0 is not the successor of any number.
5. If any property is possessed by 0 and also by the successor of any number having the property, then all numbers have that property.

If some entities satisfying these conditions could be derived or constructed in logic, it would have been shown that mathematics was (or at least could be) founded in pure logic, requiring no additional assumptions.

Although his language actually used the intensional and second-order language of functions and properties, Frege had claimed to have accomplished precisely this, identifying 0 with the empty set, 1 with the set of all single-membered sets (singletons), 2 with the set of all dual-membered sets (doubletons), and so on. These sets of equinumerous sets were then what numbers really were. Unfortunately, Russell showed through his famous paradox that the theory is inconsistent and, hence, that any statement at all can be derived in Frege's system, not merely desired logical truths, the Peano postulates, and what follows from them. Russell, in a famous letter to Frege, asked him to consider "the set of all those sets not members of themselves." Paradox follows if one assumes such a set is empty, or is not empty. After meditating on this paradox and a great many other paradoxes devised by Burali-Forti, George Godfrey Berry, and others, Russell and Whitehead concluded that the main difficulty lies in allowing the construction of entities that contain a "vicious circle"—*i.e.,* entities that are used in the construction or definition of themselves.

Russell and Whitehead sought to rule out this possibility while at the same time allowing a great many of the operations that Frege had deemed desirable. The result was the theory of types: all sets and other entities have a logical "type," and sets are always constructed from spec-

ifying members with lower types. (F.P. Ramsay offered a criticism that was subsequently accommodated in later editions of *Principia Mathematica;* as modified, the theory came to be known as the "ramified" theory of types.) Consequently, to speak of sets that are, or are not, "members of themselves" is simply to violate this rule governing the specification of sets. There is some evidence that Cantor had been aware of the difficulties created when there is no such restriction (he permitted large collective entities that do not obey the usual rules for sets), and a parallel intuition concerning the pitfalls of certain operations was independently followed by Ernst Zermelo in the development of his set theory.

In addition to its notation (much of it borrowed from Peano), its masterful development of logical systems for propositional and predicate logic, and its overcoming of difficulties that had beset earlier logical theories and logistic conceptions, the *Principia* offered discussions of functions, definite descriptions, truth, and logical laws that had a deep influence on discussions in analytical philosophy and logic throughout the 20th century. What is perhaps missing is any hesitation or perplexity about the limits of logic: whether this logic is, for example, provably consistent, complete, or decidable, or whether there are concepts expressible in natural languages but not in this logical notation. This is somewhat odd, given the well-known list of problems posed by Hilbert in 1900 that came to animate 20th-century logic, especially German logic. The *Principia* is a work of confidence and mastery and not of open problems and possible difficulties and shortcomings; it is a work closer to the naive progressive elements of the *Jahrhundertwende* than to the agonizing fin de siècle.

20TH-CENTURY SET THEORY

Zermelo's axioms of set theory

Independently of Russell and Whitehead's work, and more narrowly in the German mathematical tradition of Dedekind and Cantor, in 1908 Ernst Zermelo described axioms of set theory that, slightly modified, came to be standard in the 20th century. The type theory of the *Principia Mathematica* has, by contrast, gradually faded in influence. Like that of Russell and Whitehead, Zermelo's system avoids the paradoxes inherent in Frege's and Cantor's systems by imposing certain restrictions on what may be a set.

Zermelo's axioms are:

1. Axiom of extensionality. If two sets have the same members, then they are identical.
2. Axiom of elementary sets. There exists a set with no members, the null or empty set. For any two members of a set, there exist (singleton) sets containing only those members, as well as a (doubleton) set containing only those members.
3. Axiom of separation. For any well-formed property and any set S, there is a set, S′, containing all and only the members of S having this property. That is, already-existing sets can be partitioned or separated into parts by certain properties.
4. Power set axiom. If S is a set, then there exists a set, S′, which contains all and only the subsets of S.
5. Union axiom. If S is a set, then there is a set containing all and only the members of the sets in S.
6. Axiom of choice. (Discussed below.)
7. Axiom of infinity. There exists at least one set that contains an infinite number of members.

With the exception of axiom 2, all these axioms allow new sets to be constructed from already-constructed sets by carefully constrained operations. This method embodies what has come to be known as the "iterative" conception of a set. This list of axioms was eventually modified by Zermelo, and by Abraham Fraenkel, and the result is widely known as Zermelo-Fraenkel set theory, or ZF for short. (See the article SET THEORY.)

Axiomatized Zermelo-Frankel set theory is almost always what mathematicians and logicians now mean by "set theory." The system was later modified by John von Neumann and others with the addition of a "foundation axiom" explicitly prohibiting (among others) sets that contain themselves as members. The system was further modified for technical reasons by von Neumann, Paul Bernays, and Kurt Gödel in the 1920s and '30s, and the result is called von Neumann-Bernays-Gödel set theory, or NBG. A more distinct alternative was proposed by the American logician Willard Van Orman Quine and is called New Foundations (NF; from 1936–37). Quine's system is not widely used, however, and there have been recurrent suspicions that it is inconsistent. Other set theories have been proposed, but most of them, such as relevant, fuzzy, or multivalued set theories, differ from ZF in having different underlying logics. ZF was soon shown to be capable of deriving the Peano postulates by several alternative methods—for example, by identifying the natural numbers with certain sets, such as 0 with the empty set, Λ, 1 with the singleton empty set $\{\Lambda\}$, and so on. The crucial mathematical notions of relation and function were defined as certain sets of ordered pairs, and ordered pairs were defined strictly within set theory using suggestions first by the American mathematician and cyberneticist Norbert Wiener, and then by the Polish logician Kasimierz Kuratowski and the Norwegian logician Thoralf Skolem. With these proposals, the need for basic notions of function or relation (and generally, of order) that had been proposed by Frege, Peirce, and Schröder, disappeared. Zermelo and other early set theorists (obviously influenced by Hilbert's list of open problems) were concerned with a number of issues about the properties of the whole system: Was ZF consistent? Was its consistency provable? Were the axioms independent of one another? Were there other desirable axioms that should be added? Particularly problematic was the status of the axiom of choice.

The axiom of choice

The axiom of choice states (in Zermelo's first version) that, given any set of disjoint (nonoverlapping) sets, a set can be formed with one and only one element from each of these disjoint sets. The issue is whether elements can be "chosen" or selected from sets; the problem is acute only when infinite sets are permitted or when numerous nonidentical memberless sets (similar to the empty set), which Zermelo called *Urelementen* (literally "primitive" or "original" elements), are permitted. The axiom of choice has a large number of formulations that are logically equivalent to it, some quite surprisingly so: these include a well-ordering axiom (that the elements of any set can be put in a certain order). Early perplexity in set theory centred on whether the axiom of choice is consistent with the other axioms and whether or not it is independent of them. While clearly desirable, the axiom of choice has the nonintuitive character of a postulate, rather than being self-evident. The first question is whether the addition of the axiom of choice to a system of axiomatic set theory makes the resulting system inconsistent if it was not so previously. The second question is whether the axiom of choice can be derived from the other axioms or whether its inclusion really adds anything to the system—*i.e.*, whether every useful implication of it could be derived without it. The consistency of the axiom of choice with the other axioms of set theory (specifically in NBG set theory) was shown by Kurt Gödel in 1940. The independence of the axiom of choice from the other axioms was shown, trivially, for set theories with *Urelementen* very early; the independence of the axiom of choice in NBG or ZF set theories was one of the major outstanding problems in 20th-century mathematical logic until Paul Cohen showed in 1963 that the axiom of choice was indeed independent of the other standard axioms for set theory.

Another early outstanding issue in axiomatic set theory was whether what came to be known as the "continuum hypothesis" was consistent with the other axioms of ZF, and whether it was independent of them. The continuum hypothesis states that between $\aleph_0$ (aleph-null; the "smallest" infinite cardinality, on the order of the integers) and its power set, $\aleph_1$ (a cardinality usually identified with the continuum of points on a real number line), as well as between other integral alephs, there is no intermediate cardinality—no $\aleph_{1/2}$, so to speak. This is the first of Hilbert's 1900 list of 23 open problems in mathematics and its foundations. The second problem is the consistency and independence of the Peano postulates and any alternative general axioms for mathematics. In his work

of 1938–40, Kurt Gödel had shown that the continuum hypothesis—that there are no intermediate cardinalities—was consistent with the other axioms of set theory. In 1963, employing techniques similar to those that he used for showing the independence of the axiom of choice, Paul Cohen showed the independence of the continuum hypothesis. Since 1963 a number of alternative and less difficult methods of showing these independence results have emerged.

A third, but less conceptually vital, area of research in set theory has been in the precise form of axioms of infinity. It became evident that there are a variety of "stronger" axioms of infinity that can be added to ZF: these declare the existence of infinite sets with cardinalities beyond all the integral $\aleph$ cardinalities. With the results of Gödel from 1931, which have implications for the completeness and consistency of set theory (and are discussed below), and with the independence results of Cohen from 1963, basic questions concerning standard set theories (ZF and NBG) are considered to have been answered, even if the answers are somewhat unsatisfactory. The questions that have lingered about set theory, now a very well understood formal system, have centred on philosophical issues of whether numbers and mathematical operations are really "just" sets and set-theoretic operations, or whether one can usefully understand mathematics and the world in other than set-theoretic terms.

Alternatives to set theory

Various substantive alternatives to set theory have been proposed. One is the part-whole calculus, or "calculus of individuals," also called mereology, of Stanisław Lésniewski (1916, 1927–31). This theory rejects the hierarchy of sets, sets of sets, and so on, that emerge in set theory through the member-of relation (as defined by the power set axiom) and instead proposes a part-whole relationship. It obeys rules like those for the subset relationship in set theory. Its inspiration seems to have been the earlier Boolean theory of classes (especially as described by Schröder), as well as the work of the German philosopher Edmund Husserl and his followers on conceptualization in everyday thought ("Phenomenology") of collections. This work was developed by Henry Leonard and Nelson Goodman in the United States in the mid-20th century. It has continued to attract philosophers of logic and mathematics who are nominalists, who suspect set theory of being inherently Platonistic, or who are otherwise suspicious of the complex entities proposed by, and the complicated assumptions needed for, set theory. Although some interesting proposals have been made, it does not appear that the part-whole calculus is capable of grounding mathematics, or at least of doing so in as straightforward a manner as does ZF. A much different approach to logical foundations for mathematics is to be seen in the category theory of Saunders MacLane and others. The category theory proposes that mathematics is based on highly abstract formal objects: categories ("topoi," singular: "topos") that are neither sets nor properties. In set theory there is a distinction between the objects of the theory—sets—and what one does to them: intersecting them, unioning them, and so forth. In category theory, this distinction between objects and operations on them (transformations, or morphisms) disappears. In the latter part of the 20th century, interest has also arisen in the logic of collective entities other than sets, classes, or classes of individuals: this includes theories of heaps and aggregates and theories for mass terms—such as water or butter—that are not conceptualized as formed from distinct individuals. The goal has been to give formal theories for collective or quantitative terms used in natural language.

LOGIC AND PHILOSOPHIES OF MATHEMATICS

Philosophies of mathematics are more extensively discussed in the article MATHEMATICS, THE FOUNDATIONS OF; the major schools are mentioned here briefly. An outgrowth of the theory of Russell and Whitehead, and of most modern set theories, was a better articulation of a philosophy of mathematics known as logicism: that operations and objects spoken about in mathematics are really purely logical constructions. This has focused increased attention on what exactly "pure" logic is and whether, for example, set theory is really logic in a narrow sense. There seems little doubt that set theory is not "just" logic in the way in which, for example, Frege viewed logic—*i.e.*, as a formal theory of functions and properties. Because set theory engenders a large number of interestingly distinct kinds of nonphysical, nonperceived abstract objects, it has also been regarded by some philosophers and logicians as suspiciously (or endearingly) Platonistic. Others, such as Quine, have "pragmatically" endorsed set theory as a convenient way—perhaps the only such way—of organizing the whole world around us, especially if this world contains the richness of transfinite mathematics.

Relationship between set theory and logic

For most of the first half of the 20th century, new work in logic saw logic's goal as being primarily to provide a foundation for, or at least to play an organizing role in, mathematics. Even for those researchers who did not endorse the logicist program, logic's goal was closely allied with techniques and goals in mathematics, such as giving an account of formal systems (formalism) or of the ideal nature of nonempirical proof and demonstration. (Interest in the logicist and formalist program waned after Gödel's demonstration that logic could not provide exactly the sort of foundation for mathematics or account of its formal systems that had been sought. Namely, mathematics could not be reduced to a provably complete and consistent logical theory, but logic has still remained closely allied with mathematical foundations and principles.)

Traditionally, logic had set itself the task of understanding valid arguments of all sorts, not just mathematical ones. It had developed the concepts and operations needed for describing concepts, propositions, and arguments—especially in terms of "logical form"—insofar as such tools could conceivably affect the assessment of any argument's quality or ideal persuasiveness. It is this general ideal that many logicians have developed and endorsed, and that some, such as Hegel, have rejected as impossible or useless. For the first decades of the 20th century, logic threatened to become exclusively preoccupied with a new and historically somewhat foreign role of serving in the analysis of arguments in only one field of study, mathematics. The philosophical-linguistic task of developing tools for analyzing statements and arguments that can be expressed in some natural language about some field of inquiry, or even for analyzing propositions as they are actually (and perhaps necessarily) thought or conceived by human beings, was almost completely lost. There were scattered efforts to eliminate this gap by reducing basic principles in all disciplines—including physics, biology, and even music—to axioms, particularly axioms in set theory or first-order logic. But these attempts, beyond showing that it could be done, did not seem especially enlightening. Thus, such efforts, at their zenith in the 1950s and '60s, had all but disappeared in the '70s: one did not better and more usefully understand an atom or a plant by being told it was a certain kind of set.

LOGIC NARROWLY CONSTRUED

Although set theory and the type theory of Russell and Whitehead were considered to be "logic" for the purposes of the logicist program, a narrower sense of logic reemerged in the mid-20th century as what is usually called the "underlying logic" of these systems: whatever concerns only rules for propositional connectives, quantifiers, and nonspecific terms for individuals and predicates. (An interesting issue is whether the privileged relation of identity, typically denoted by the symbol "=," is a part of logic: most researchers have assumed that it is.) In the early 20th century and especially after Tarski's work in the 1920s and '30s, a formal logical system was regarded as being composed of three parts, all of which could be rigorously described. First, there was the notation: the rules of formation for terms and for well-formed formulas (wffs) in the logical system. This theory of notation itself became subject to exacting treatment in the concatenation theory, or theory of strings, of Tarski, and in the work of the American Alonzo Church. Previously, notation was often a haphazard affair in which it was unclear what could be formulated or asserted in a logical theory and whether expressions were finite or were schemata standing

The theory of notation

for infinitely long wffs. Issues that arose out of notational questions include definability of one wff by another (addressed in Beth's and Craig's theorems, and in other results), creativity, and replaceability, as well as the expressive power and complexity of different logical languages.

The second part of a logical system consisted of the axioms, rules of inference, or other ways of identifying what counts as a theorem. This is what is usually meant by the logical "theory" proper: a (typically recursive) description of the theorems of the theory, including axioms and every wff derivable from axioms by admitted rules. Although the axiomatic method of characterizing such theories with axioms or postulates or both and a small number of rules of inference had a very old history (going back to Euclid or further), two new methods arose in the 1930s and '40s. First, in 1934, there was the German mathematician Gerhard Gentzen's method of succinct *Sequenzen* (rules of consequents), which were especially useful for deriving metalogical decidability results. This method originated with Paul Hertz in 1932, and a related method was described by Stanisław Jaśkowski in 1934. Next to appear was the similarly axiomless method of "natural deduction," which used only rules of inference; it originated in a suggestion by Russell in 1925 but was developed by Quine and the American logicians Frederick Fitch and George David Wharton Berry. The natural deduction technique is widely used in the teaching of logic, although it makes the demonstration of metalogical results somewhat difficult, partly because historically these arose in axiomatic and consequent formulations.

A formal description of a language, together with a specification of a theory's theorems (derivable propositions), are often called the "syntax" of the theory. (This is somewhat misleading when one compares the practice in linguistics, which would limit syntax to the narrower issue of grammaticality.) The term "calculus" is sometimes chosen to emphasize the purely syntactic, uninterpreted nature of a formal theory.

Finally, the third component of a logical system was the semantics for such a theory and language: a declaration of what the terms of a theory refer to, and how the basic operations and connectives are to be interpreted in a domain of discourse, including truth conditions for wffs in this domain. A specification of a domain of objects (De Morgan's "universe of discourse"), and of rules for interpreting the symbols of a logical language in this domain such that all the theorems of the logical theory are true is then said to be a "model" of the theory (or sometimes, less carefully, an "interpretation" of the theory).

The notion of a rigorous logical theory, in the sense of a specification, often axiomatic, of theorems of a theory, was fairly well understood by Euclid, Aristotle, and others in ancient times. With the crises in geometry of the 19th century, the need developed for very careful presentations of these theories. Hilbert's work, as well that of a group of American mathematicians that included Edward Vermilye Huntington, Oswald Veblen, and Benjamin Abram Bernstein (the postulate theorists, working shortly after 1900), reestablished this tradition with even higher standards. Frege and, in his footsteps, Russell and Whitehead, had separate claims to emphasizing standards of precision and care in the statement of logical theories. Cantor, Zermelo, and most other early set theorists did not often state the content of their axioms and theorems in symbolic form, or restrict themselves to certain symbols. Zermelo, in fact, did not often use the formal language for quantifiers and binding variables that was then available; instead, he used ordinary expressions such as "for any," "all," or "there exists." Through the 1920s, logical axioms and rules of inference were typically not all explicitly and precisely stated, especially various principles of substitution that mimicked widely understood algebraic practices.

Syntax and semantics

What is known as formal semantics, or model theory, has a more complicated history than does logical syntax; indeed, one could say that the history of the emergence of semantic conceptions of logic in the late 19th and early 20th centuries is poorly understood even today. Certainly, Frege's notion that propositions refer to (German: *bedeuten*) "The True" or "The False"—and this for complex propositions as a function of the truth values of simple propositions—counts as semantics. Earlier medieval theories of supposition incorporated useful semantic observations. So, too, do Boolean techniques of letters taking or referring to the values 1 and 0 that are seen from Boole through Peirce and Schröder. Both Peirce and Schröder occasionally gave brief demonstrations of the independence of certain logical postulates using models in which some postulates were true, but not others. (The first explicit use of such techniques seems to have arisen earlier in the 19th century, and in geometry.) The first clear and significant general result in model theory is usually accepted to be a result discovered by Löwenheim in 1915 and strengthened in work by Skolem from the 1920s. This is the Löwenheim-Skolem theorem, which states that a theory that has a model at all has a countable model. That is to say, if there exists some model of a theory (*i.e.,* an application of it to some domain of objects), then there is sure to be one with a domain no larger than the natural numbers (see above *Metalogic: Discoveries about logical calculi*). Although Löwenheim and Skolem understood their results perfectly well, they did not explicitly use the modern language of "theories" being true in "models." The Löwenheim-Skolem theorem is in some ways a shocking result, since it implies that any consistent formal theory of anything—no matter how hard it tries to address the phenomena unique to a field such as biology, physics, or even sets—can just as well be understood from its formalisms alone as being about natural numbers.

The second major result in formal semantics, Gödel's completeness theorem of 1930, required even for its description, let alone its proof, more careful development of precise concepts about logical systems—metalogical concepts—than existed in earlier decades. One question for all logicians since Boole, and certainly since Frege, had been: Was the theory consistent? In its purely syntactic analysis, this amounts to the question: Was a contradictory sentence (of the form A & ~A) a theorem? In its semantic analysis, it is equivalent to the question: Does the theory have a model at all? For a logical theory, consistency means that a contradictory theorem cannot be derived in the theory. But since logic was intended to be a theory of necessarily true statements, the goal was stronger: a theory is Post-consistent (named for the Polish-American logician Emil Post) if every theorem is valid—that is, if no theorem is a contradictory or a contingent statement. (In nonclassical logical systems, one may define many other interestingly distinct notions of consistency; these notions were not distinguished until the 1930s.) Consistency was quickly acknowledged as a desired feature of formal systems: it was widely and correctly assumed that various earlier theories of propositional and first-order logic were consistent. Zermelo was, as has been observed, concerned with demonstrating that ZF was consistent; Hilbert had even observed that there was no proof that the Peano postulates were consistent. These questions received an answer that was not what was hoped for in a later result of Gödel (discussed below). A clear proof of the consistency of propositional logic was first given by Post in 1921. Its tardiness in the history of symbolic logic is a commentary not so much on the difficulty of the problem as it is on the slow emergence of the semantic and syntactic notions necessary to characterize consistency precisely. The first clear proof of the consistency of the first-order predicate logic is found in the work of Hilbert and Wilhelm Ackermann from 1928. Here the problem was not only the precise awareness of consistency as a property of formal theories but also of a rigorous statement of first-order predicate logic as a formal theory.

The question of consistency

In 1928 Hilbert and Ackermann also posed the question of whether a logical system, and, in particular, first-order predicate logic, was (as it is now expressed) "complete." This is the question of whether every valid proposition—that is, every proposition that is true in all intended models—is provable in the theory. In other words, does the formal theory describe all the noncontingent truths of a subject matter? Although some sort of completeness had clearly been a guiding principle of formal logical theories dating back to Boole, and even to Aristotle (and

The question of completeness

to Euclid in geometry)—otherwise they would not have sought numerous axioms or postulates, risking nonindependence and even inconsistency—earlier writers seemed to have lacked the semantic terminology to specify what their theory was about and wherein "aboutness" consists. Specifically, they lacked a precise notion of a proposition being "valid,"—that is, "true in all (intended) models"—and hence lacked a way of precisely characterizing completeness. Even the language of Hilbert and Ackermann from 1928 is not perfectly clear by modern standards.

Gödel proved the completeness of first-order predicate logic in his doctoral dissertation of 1930; Post had shown the completeness of propositional logic in 1921. In many ways, however, explicit consideration of issues in semantics, along with the development of many of the concepts now widely used in formal semantics and model theory (including the term metalanguage), first appeared in a paper by Alfred Tarski, "The Concept of Truth in Formalized Languages," published in Polish in 1933; it became widely known through a German translation of 1936. Although the theory of truth Tarski advocated has had a complex and debated legacy (see the article LINGUISTICS: *Philosophical views on meaning*), there is little doubt that the concepts there (and in later papers from the 1930s) developed for discussing what it is for a sentence to be "true in" a model marked the beginning of model theory in its modern phase. Although the outlines of how to model propositional logic had been clear to the Booleans and to Frege, one of Tarski's most important contributions was an application of his general theory of semantics in a proposal for the semantics of the first-order predicate logic (now termed the set-theoretic, or Tarskian, interpretation).

Tarski's techniques and language for precisely discussing semantic concepts, as well as properties of formal systems described using his concepts—such as consistency, completeness, and independence—rapidly and almost imperceptibly entered the literature in the late 1930s and after. This influence accelerated with the publication of many of his works in German and then in English, and with his move to the United States in 1939.

The incompleteness theorem

Gödel's first incompleteness theorem, from 1931, stands as a major turning point of 20th-century logic. It states that no finitely axiomatizable theory sufficient to derive the Peano postulates is both consistent and complete. (How Gödel proved this fascinating result is discussed more extensively in the article MATHEMATICS, THE FOUNDATIONS OF; see also above *Metalogic: Discoveries about formal mathematical systems.*) In other words, if we try to build a theory sufficient for a foundation for mathematics, stating the axioms and rules of inference so that we have stipulated precisely what is and what is not an axiom (as opposed to open-ended axiom schemata), then the resulting theory will either (1) not be sufficient for mathematics (*i.e.,* not allow the derivation of the Peano postulates for number theory) or (2) not be complete (*i.e.,* there will be some valid proposition that is not derivable in the theory) or (3) be inconsistent. (Gödel actually distinguished between consistency and a stronger feature, ω-[omega-] consistency.) A corollary of this result is that, if a theory is finitely axiomatizable, consistent, and sufficient to derive the Peano postulates, then that theory cannot be used as a metalanguage to show its own consistency; that is, a finitely axiomatized set theory cannot be used to show the consistency of finitely axiomatized set theory, if set theory is consistent. This is often called Gödel's second incompleteness theorem.

These results were widely interpreted as a blow to both the logicist and formalist programs. Logicists seemed to have taken as their goal the construction of rigorously described theories that were sufficient for deriving mathematics and also consistent and complete. Gödel showed that, if this was their goal, they would necessarily fail. It was also a blow to the longer-standing axiomatic, or formalist, program, since it seemed to show that precise axiomatic descriptions of valuable domains like mathematics would also necessarily fail. Gödel himself eventually interpreted the result as showing that there exist entities with well-defined properties, namely numbers, that are beyond our ability to describe precisely with standard logical tools. This is one source of his inclination toward what is usually called mathematical Platonism.

One reply of the logicists could have been to abandon as ideal the first-order, finitely axiomatized theories, such as first-order predicate logic, the system of Russell and Whitehead, and NBG, and instead to accept theories that were less rigorously described. First-order theories allow explicit reference to, and quantification over, individuals, such as numbers or sets, but not quantification over (and hence rules for manipulating) properties of these individuals. For example, one possible logicist reply is to note that the Peano postulates themselves seem acceptable. It is true that Gödel's result implies that we cannot prove (as Hilbert hoped in his second problem) that these postulates are consistent; furthermore, the fifth postulate is a schema or second-order formulation, rather than being strictly in the finitely axiomatizable first-order language that was once preferred. This reply, however, clashes with another desired feature of a formal theory, namely, decidability: that there exists a finite mechanical procedure for determining whether a proposition is, or is not, a theorem of the theory. This property took on added interest after World War II with the advent of electronic computers, since modern computers can actually apply algorithms to determine whether a given proposition is, or is not, a theorem, whereas some algorithms had only been shown theoretically to exist. (See the article COMPUTER SCIENCE: *Theory of computation.*) The decidability of propositional logic, through the use of truth tables, was known to Frege and Peirce; a proof of its decidability is attributable to Jan Łukasiewicz and Emil Post independently in 1921. Löwenheim showed in 1915 that first-order predicate logic with only single-place predicates was decidable and that the full theory was decidable if the first-order predicate calculus with only two-place predicates was decidable; further developments were made by Skolem, Heinrich Behmann, Jacques Herbrand, and Quine. Herbrand showed the existence of an algorithm which, if a theorem of the first-order predicate logic is valid, will determine it to be so; the difficulty, then, was in designing an algorithm that in a finite amount of time would determine that propositions were invalid. As early as the 1880s, Peirce seemed to be aware that the propositional logic was decidable but that the full first-order predicate logic with relations was undecidable. The proof that first-order predicate logic (in any general formulation) was undecidable was first shown definitively by Alan Turing and Alonzo Church independently in 1936. Together with Gödel's (second) incompleteness theorem and the earlier Löwenheim-Skolem theorem, the Church-Turing theorem of the undecidability of the first-order predicate logic is one of the most important, even if "negative," results of 20th-century logic.

Decidability

By the 1930s almost all work in the foundations of mathematics and in symbolic logic was being done in a standard first-order predicate logic, often extended with axioms or axiom schemata of set- or type-theory. This underlying logic consisted of a theory of "classical" truth functional connectives, such as "and," "not," and "if . . . then," and first-order quantification permitting propositions that "all" and "at least one" individual satisfy a certain formula. Only gradually in the 1920s and '30s did a conception of a "first-order" logic, and of alternatives, arise—and then without a name.

Certainly with Hilbert and Ackermann's *Grundzüge der Theoretischen Logik* (1928; "Basic Elements of Theoretical Logic"), and Hilbert's and Paul Bernays' minor corrections to this work in the 1930s, a rigorous theory of first-order predicate logic achieved its mature state. Even Hilbert and his coworkers, however, sometimes deviated from previous and subsequent treatments of quantification, preferring to base their theory on a single term-forming operator, ε, which was to be interpreted as extracting an arbitrary individual satisfying a given predicate. In the 1920s and '30s considerable energy went into formulating various alternative but equivalent axiom systems for classical propositional and first-order logic and demonstrating that these axioms were independent. Some of these efforts were concentrated on the "implicational" (if . . . then)

fragment of propositional logic. Others sought reductions of truth-functional connectives to a short list of primitive connectives, especially to the single Sheffer or, in modern terminology, NAND function, named for the American logician Henry M. Sheffer. Peirce had been aware in the 1880s that single connectives based either on not-both or on neither-nor sufficed for the expression of all truth-functional connectives. Alternative formulations of classical propositional logic reached their apex in J.G.P. Nicod's, Mordchaj Wajsberg's, and Łukasiewicz's different single-axiom formulations of 1917, 1929, and 1932. A basic underlying classical propositional logic and a first-order quantificational theory had become widely accepted by 1928, and different systems varied primarily in provably equivalent, notational aspects.

Intuitionistic logic

A notable exception to this orthodoxy was intuitionistic logic. Arising from observations by the Dutch mathematicians Arend Heyting and L.E.J. Brouwer concerning the results of indirect proof in traditional mathematics and distantly inspired by Kant's views on constructions in mathematics (and less distantly by views of French mathematicians Henri Poincaré and Émile Borel at the turn of the century), these theorists proposed that a proof in mathematics should be accepted only if it constructed the mathematical entity it talked about, and not if it merely showed that the entity "could" be constructed or that supposing its nonexistence would result in contradiction. This view is called intuitionism or sometimes constructivism, because of the weight it places on mental apprehension through construction of purported mathematical entities. (A still more severe form of constructivism is strict finitism, in which one rejects infinite sets; for further discussion, see MATHEMATICS, THE FOUNDATIONS OF: *Intuitionism*.)

The central focus of Brouwer's logical critique was directed at the principle of the excluded middle—which states that, for any proposition p, "p or not-p" is a theorem of logic—and at what one could typically infer with it. So, if not-p can be shown to be false, then in classical, but not intuitionistic, propositional logic, p is thereby proven. Intuitionistic propositional logic was formulated in 1930 by Heyting; the independence of Heyting's axioms was shown in 1939 by J.C.C. McKinsey. The primary difference between classical and intuitionistic propositional logics is concentrated in axioms and rules involving negation. Heyting in fact used the symbol $\neg$ for intuitionistic negation, to distinguish it from the symbol $\sim$ of classical logic.

The intuitionistic first-order predicate logic, aside from the differing propositional logic on which it is based, differs from classical first-order predicate logic only in small respects. A number of results concerning Heyting's system, as well as stronger and weaker versions of the intuitionistic propositional theory, were produced in the 1930s and '40s by the Russian theorist Andrei Nikolayevich Kolmogorov and by Mordchaj Wajsberg, Gentzen, McKinsey, Tarski, and others. Few practicing mathematicians have followed the intuitionistic doctrine of constructivism, but the theory has exerted attraction for and elicted respect from many researchers in the foundations and philosophy of mathematics. (One oddity is that metalogical results for intuitionistic logics have nearly always been shown using the theory of classical logic.)

Frege's theory of properties

The other major competitor to first-order predicate logic based on a classical propositional logic arose with the renewed interest in Frege's theory of properties begun by Alonzo Church in the late 1930s. The first result was a logical theory called the λ calculus, which allowed one by the application of a λ operator to a formula precisely to characterize or "extract" that property. Later developments included his investigation of formal Fregean theories ("A Logic of Sense and Denotation") that allow quantification over properties and incorporate Frege's semantic views in distinguishing between the highly individuated "sense" of an expression and its denotation (extension, or referent). These two developments laid the basis for formal theories of second- and higher-order logical theories that permit quantification over properties and other non-individuals, and for intensional logics. While Boolean and most first-order theories, including type and set theories, had dealt with individuals and collections of these (collective extensions), intensional logics allow one to develop theories of properties that have the same extension but differ in intension—such as "polygons with three sides" and "polygons with three angles" or Frege's example of the morning and the evening star (*i.e.*, Venus).

Intension had often been equated with how a property is thought (its associations for the conceiver), while Frege, Church, and a number of philosophers and philosophers of language equated it with abstract, formally described entities that constitute the "meaning" or "sense" of expressions. Second-order theories and intensional logical systems have been extensively developed, and the metalogical features have been well explored. For a system like that described in Church's "A Formulation of the Logic of Sense and Denotation" (1946), consistency was shown by Gentzen in 1936, and for many similar systems it was less rigorously demonstrated by Herbrand in 1930. Weak completeness was demonstrated by Leon Henkin in 1947, although what counts as the intended interpretation and domain of such a powerful theory is problematic; strong completeness has yet to be shown, and, since it embraces first-order predicate logic, it is not decidable by a corollary of Church's own theorem. Debates about whether second-order logic is philosophically acceptable, technically usable, or even should count as "logic" in comparison with first-order theories have raged since its resurrection in the 1940s and '50s.

NONMATHEMATICAL FORMAL LOGIC

Early 20th-century formal logic was almost entirely fixated upon the project of exploring the foundations of mathematics. Furthering or exploring the logicist program and the related formalist programme of Hilbert and linking mathematics with pure logic or with rigorous formal theories had been the original motivation for many developments. The Löwenheim-Skolem theorem might have seemed also to have given a reason for this mathematical, and specifically numerical, fixation, since there is a sense in which any consistent (first-order) formal theory is always about numbers. These developments reached their height in the 1930s with the finite axiomatizations of NBG and with the formulations of the first-order predicate logic of Hilbert, Ackermann, and Gentzen. Major metalogical results for the underlying first-order predicate logic were completed in 1936 with the Church-Turing theorem. After first-order logic had been rigorously described in the 1930s and had become well understood and after set theory coalesced into ZF (with the exception of the then outstanding independence results), a period of reflection set in. There were now increasing doubts about the ability of the logicist and formalist program to connect mathematics and logic. The intuitionist critiques became well known, if not always accepted. A number of authors suggested approaching logic with entirely different formalisms—without quantifiers, for example. These included the American mathematician Haskell Curry and the category theorists, as well as algebraists who urged a return to algebraic—though not always Boolean—methods; the latter included Tarski and Paul Halmos. There were doubts about the exact form or notation and the general approach of the first-order, set-theoretic enterprise. As with many large-scale completed projects—and this project, moreover, had been accompanied by considerable disappointment, owing to the negative results of Gödel, Church, and Turing—there was also a search for new logical terrain to explore.

Increasing doubts about the logicist program

Łukasiewicz had, as early as 1923, begun exploring the logical theories of Aristotle and the Stoics and formalizing them as modern logical systems; this work culminated in his 1951 and 1957 editions of *Aristotle's Syllogistic* and in further work on Aristotle's logic by John Corcoran and T.J. Smiley. Benson Mates' careful study of Stoic logic similarly served to renew interest in older logics. These theories had no obvious bearing on the foundations of mathematics, but they were of interest as formal theories in their own right—and perhaps as theories of ideal reasoning, of abstract conceptual entities, or as theories of the referents of terms in natural language. Similarly, not all of Church's work on Fregean theories of properties and

intensions had obvious utility for constructing the simplest possible foundation for mathematics with the fewest arguable postulates, but his work was also motivated by more general theoretical features in the theory of properties and of language—especially by the richness of natural languages. These might be termed nonmathematical influences in the development of 20th-century logic. Another challenge to "classical" propositional logic—specifically to the standard interpretation of propositional logics—has been posed by many-valued logics. Propositions can be regarded as taking more than (or other than) the traditional "values" of true or false. Such possibilities had been speculated about by Peirce and Schröder (and even by medieval logicians) and were used in the 1920s and '30s by Carnap, Łukasiewicz, and others to derive independence results for various propositional calculi. In the 1940s and after, formal theories for many-valued (including infinitely valued, probabilistic-like) logics have been taken increasingly seriously—albeit for nonmathematical purposes.

Many nonmathematical goals and considerations arose from philosophy (especially from metaphysics but also from epistemology and even ethics), from the study of the history of logic and mathematics, from quantum mechanics (quantum logic), and from the philosophy of language, as well as, more recently, from cognitive psychology (starting with Jean Piaget's interest in syllogistic logics). This work has rekindled interest in logic for purposes other than giving or exploring the foundations of mathematics.

Development of modal logic

Foremost among the nonmathematical interests was the development of modal logic beginning with C.I. Lewis' theories of 1932 and, specifically, a study of the alethic modal operators of necessity, possibility, contingency, and impossibility. Viable semantic accounts for modal systems in terms of Leibnizian "possible worlds" were developed by Saul Kripke, David Lewis, and others in the 1960s and '70s and led to greatly intensified research. Tense logics and logics of knowledge, causation, and ethical or legal obligation also moved rapidly forward, together with specialized logics for analyzing the "if . . . then" conditional in ordinary language (first due to C.I. Lewis as a theory of entailment, then elaborately developed by Alan Ross Anderson, Nuel Belnap, Jr., and their students as relevance logic).

From the turn of the century through the mid-1930s and with the almost singular exception of Russell and Whitehead's *Principia Mathematica,* logic was dominated by mathematicians from the German-speaking world. The work of Frege, Dedekind, and Cantor at the end of the 19th century, even if little recognized at the time, as well as the more widely recognized work of Hilbert and Zermelo, had given German mathematical logic a strong boost into the 20th century. Widespread institutional interest in the new mathematical logic in the early decades of the 20th century seemed to have been far weaker in the United States, France, and, rather surprisingly, in the United Kingdom and Italy. In the 1920s and into the early 1930s, Poland developed an specially strong logical tradition, and Polish logicians made a number of major contributions, writing in both Polish and German; in the 1920s and '30s Polish logicians posed the only exceptions to almost absolute German logical hegemony.

By the late 1930s, both the political and the logical situations had shifted dramatically. American logic, as represented by younger figures such as Church, McKinsey, and Quine, made a number of important contributions to logic in the late 1930s; the young Alan Turing in England contributed to logic and to the infant field of the theory of computation. France's place dwindled prematurely with the untimely death of Jacques Herbrand. The Moravian-Austrian Gödel fled to the United States as the political situation in central Europe worsened, as did Tarski and Carnap. Set theory and some set theorists fell under the pall of anti-Semitism, as did other logical theories, together with the theory of relativity and several philosophical orientations. Communication between scholars in Germany, both with each other and with the increasing number of reseachers outside the country, was hindered in the late 1930s and '40s. With the death of Hilbert in 1943, interest in logic and in the foundations of mathematics at the University of Göttingen—interests that had flourished there since the time of the German mathematician Bernhard Riemann—declined. With the flight of promising students and the lack of political stability and academic support, German logic became critically weakened. Heinrich Scholz, primarily a historian of logic, but also one of the few figures in Germany of the time in a philosophy, rather than a mathematics, department, attempted to rally German logic with the establishment of the Ernst Schröder Prize in mathematical logic. Its winner in 1941 was J.C.C. McKinsey, an American.

The influence of 20th-century logic

Especially because of its often predominating mathematical orientation (and this in several respects), the influence and place of 20th-century logic in all intellectual activity has changed dramatically. On the one hand, it has regained the respectability as an academic discipline through its affiliation with rigorous mathematics—the "queen of the sciences"—that it had lost in the Renaissance. On the other hand, the number of people who could profitably study modern symbolic logic and understand its more impressive achievements has dwindled as its techniques have become more austere and distant from ordinary language and have also required more and more background simply to understand. Consequently, one could say of Gödel's incompleteness theorem (for example) what Einstein once said about the theory of special relativity: that there have at times been only a handful of people who understand it. Few general university programs required an understanding of symbolic logic in the way they had once required an understanding of the rudiments of Aristotelian syllogistic or even of Venn's version of Boolean logic. Twentieth-century symbolic logic has also reexperienced its traditional problem of finding a place in modern universities.

In the early decades of the 20th century, the study of logic and the foundations of mathematics (metamathematics) acquired considerable prestige within mathematics departments, especially owing to the influence of Hilbert and the Göttingen school. In the 1920s and '30s, existing on the borderline between philosophy, mathematics, and the burgeoning interest in the philosophy of science, logic also achieved additional legitimacy through the work and participation of Wittgenstein (and Russell's philosophy of logical atomism), Carnap, and others in the Vienna and Berlin schools of scientific philosophy. (Gödel sometimes attended sessions of the Vienna Circle.)

The usefulness of logic in philosophy reached a critical point, however, with Gödel's incompleteness theorem and then with Church's logical critique of one version of the principle of verification. Roughly since the death of Hilbert, logicians and mathematical foundationalists have often been accepted less readily in mathematics departments, and after solutions to the major problems in metalogic were achieved, many practicing mathematicians in the Western Hemisphere have increasingly regarded logic and foundational work as mere tinkering. (This is less true in Russia, other former Soviet republics, and Poland, where logic has survived as a major mathematical subject.) Philosophy departments in the English-speaking world have often proved to be more stable homes for symbolic logicians, especially as they increasingly addressed issues in formal philosophy that are not necessarily issues in the foundations of mathematics, such as theories of properties and the development of nonstandard philosophical logics.

BIBLIOGRAPHY

General works. The best starting point for exploring any of the topics in logic is D. GABBAY and F. GUENTHNER (eds.), *Handbook of Philosophical Logic,* 4 vol. (1983–89), a comprehensive reference work. See also GERALD J. MASSEY, *Understanding Symbolic Logic* (1970), an introductory text; and ROBERT E. BUTTS and JAAKKO HINTIKKA, *Logic, Foundations of Mathematics, and Computability Theory* (1977), a collection of conference papers.

Formal logic. MICHAEL DUMMETT, *Elements of Intuitionism* (1977), offers a clear presentation of the philosophic approach that demands constructibility in logical proofs. G.E. HUGHES and M.J. CRESSWELL, *An Introduction to Modal Logic* (1968, reprinted 1989), treats operators acting on sentences in first-order logic (or predicate calculus) so that, instead of being

interpreted as statements of fact, they become necessarily or possibly true or true at all or some times in the past, or they denote obligatory or permissible actions, and so on. JON BARWISE *et al.* (eds.), *Handbook of Mathematical Logic* (1977), provides a technical survey of work in the foundations of mathematics (set theory) and in proof theory (theories with infinitely long expressions). ELLIOTT MENDELSON, *Introduction to Mathematical Logic*, 3rd ed. (1987), is the standard text; and G. KREISEL and J.L. KRIVINE, *Elements of Mathematical Logic: Model Theory* (1967, reprinted 1971; originally published in French, 1967), covers all standard topics at an advanced level. A.S. TROELSTRA, *Choice Sequences: A Chapter of Intuitionistic Mathematics* (1977), offers an advanced analysis of the philosophical position regarding what are legitimate proofs and logical truths; and A.S. TROELSTRA and D. VAN DALEN, *Constructivism in Mathematics*, 2 vol. (1988), applies intuitionist strictures to the problem of the foundations of mathematics.

Metalogic. JON BARWISE and S. FEFERMAN (eds.), *Model-Theoretic Logics* (1985), emphasizes semantics of models. J.L. BELL and A.B. SLOMSON, *Models and Ultraproducts: An Introduction*, 3rd rev. ed. (1974), explores technical semantics. RICHARD MONTAGUE, *Formal Philosophy: Selected Papers of Richard Montague*, ed. by RICHMOND H. THOMASON (1974), uses modern logic to deal with the semantics of natural languages. MARTIN DAVIS, *Computability & Unsolvability* (1958, reprinted with a new preface and appendix, 1982), is an early classic on important work arising from Gödel's theorem, and the same author's *The Undecidable: Basic Papers on Undecidable Propositions, Unsolvable Problems, and Computable Functions* (1965), is a collection of seminal papers on issues of computability. ROLF HERKEN (ed.), *The Universal Turing Machine: A Half-Century Survey* (1988), takes a look at where Gödel's theorem on undecidable sentences has led researchers. HANS HERMES, *Enumerability, Decidability, Computability*, 2nd rev. ed. (1969, originally published in German, 1961), offers an excellent mathematical introduction to the theory of computability and Turing machines. A classic treatment of computability is presented in HARTLEY ROGERS, JR., *Theory of Recursive Functions and Effective Computability* (1967, reissued 1987). M.E. SZABO, *Algebra of Proofs* (1978), is an advanced treatment of syntactical proof theory. P.T. JOHNSTONE, *Topos Theory* (1977), explores the theory of structures that can serve as interpretations of various theories stated in predicate calculus. H.J. KEISLER, "Logic with the Quantifier 'There Exist Uncountably Many'," *Annals of Mathematical Logic* 1:1–93 (January 1970), reports on a seminal investigation that opened the way for Barwise (1977), cited earlier, and CAROL RUTH KARP, *Language with Expressions of Infinite Length* (1964), which expands the syntax of the language of predicate calculus so that expressions of infinite length can be constructed. C.C. CHANG and H.J. KEISLER, *Model Theory*, 3rd rev. ed. (1990), is the single most important text on semantics. F.W. LAWVERE, C. MAURER, and G.C. WRAITH (eds.), *Model Theory and Topoi* (1975), is an advanced, mathematically sophisticated treatment of the semantics of theories expressed in predicate calculus with identity. MICHAEL MAKKAI and GONZALO REYES, *First Order Categorical Logic: Model-Theoretical Methods in the Theory of Topoi and Related Categories* (1977), analyzes the semantics of theories expressed in predicate calculus. SAHARON SHELAH, "Stability, the F.C.P., and Superstability: Model-Theoretic Properties of Formulas in First Order Theory," *Annals of Mathematical Logic* 3:271–362 (October 1971), explores advanced semantics.

Applied logic. Applications of logic in unexpected areas of philosophy are studied in EVANDRO AGAZZI (ed.), *Modern Logic—A Survey: Historical, Philosophical, and Mathematical Aspects of Modern Logic and Its Applications* (1981). WILLIAM L. HARPER, ROBERT STALNAKER, and GLENN PEARCE (eds.), *IFs: Conditionals, Belief, Decision, Chance, and Time* (1981), surveys hypothetical reasoning and inductive reasoning. On the applied logic in philosophy of language, see EDWARD L. KEENAN (ed.), *Formal Semantics of Natural Language* (1975); JOHAN VAN BENTHEM, *Language in Action: Categories, Lambdas, and Dynamic Logic* (1991), also discussing the temporal stages in the working out of computer programs, and the same author's *Essays in Logical Semantics* (1986), emphasizing grammars of natural languages. DAVID HAREL, *First-Order Dynamic Logic* (1979); and J.W. LLOYD, *Foundations of Logic Programming*, 2nd extended ed. (1987), study the logic of computer programming. Important topics in artificial intelligence, or computer reasoning, are studied in PETER GÄRDENFORS, *Knowledge in Flux: Modeling the Dynamics of Epistemic States* (1988), including the problem of changing one's premises during the course of an argument. For more on nonmonotonic logic, see JOHN MCCARTHY, "Circumscription: A Form of Non-Monotonic Reasoning," *Artificial Intelligence* 13(1–2):27–39 (April 1980); DREW MCDERMOTT and JON DOYLE, "Non-Monotonic Logic I," *Artificial Intelligence* 13(1-2):41–72 (April 1980); DREW MCDERMOTT, "Nonmonotonic Logic II: Nonmonotonic Modal Theories," *Journal of the Association for Computing Machinery* 29(1):33–57 (January 1982); and YOAV SHOHAM, *Reasoning About Change: Time and Causation from the Standpoint of Artificial Intelligence* (1988).

History of logic. A broad survey is found in WILLIAM KNEALE and MARTHA KNEALE, *The Development of Logic* (1962, reprinted 1984), covering ancient, medieval, modern, and contemporary periods. Articles on particular authors and topics are found in *The Encyclopedia of Philosophy*, ed. by PAUL EDWARDS, 8 vol. (1967); and *New Catholic Encyclopedia*, 18 vol. (1967–89). I.M. BOCHENSKI, *Ancient Formal Logic* (1951, reprinted 1968), is an overview of early Greek developments. On Aristotle, see JAN ŁUKASIEWICZ, *Aristotle's Syllogistic from the Standpoint of Modern Formal Logic*, 2nd ed., enlarged (1957, reprinted 1987); GÜNTHER PATZIG, *Aristotle's Theory of the Syllogism* (1968; originally published in German, 2nd ed., 1959); OTTO A. BIRD, *Syllogistic and Its Extensions* (1964); and STORRS MCCALL, *Aristotle's Modal Syllogisms* (1963). I.M. BOCHENSKI, *La Logique de Théophraste* (1947, reprinted 1987), is the definitive study of Theophrastus' logic. On Stoic logic, see BENSON MATES, *Stoic Logic* (1953, reprinted 1973); and MICHAEL FREDE, *Die stoische Logik* (1974).

Detailed treatment of medieval logic is found in NORMAN KRETZMANN, ANTHONY KENNY, and JAN PINBORG (eds.), *The Cambridge History of Later Medieval Philosophy: From the Rediscovery of Aristotle to the Disintegration of Scholasticism, 1100–1600* (1982); and translations of important texts of the period are presented in NORMAN KRETZMANN and ELEONORE STUMP (eds.), *Logic and the Philosophy of Language* (1988). For Boethius, see MARGARET GIBSON (ed.), *Boethius, His Life, Thought, and Influence* (1981); and, for Arabic logic, NICHOLAS RESCHER, *The Development of Arabic Logic* (1964). L.M. DE RIJK, *Logica Modernorum: A Contribution to the History of Early Terminist Logic*, 2 vol. in 3 (1962–1967), is a classic study of 12th- and early 13th-century logic, with full texts of many important works. NORMAN KRETZMANN (ed.), *Meaning and Inference in Medieval Philosophy* (1988), is a collection of topical studies.

A broad survey of modern logic is found in WILHELM RISSE, *Die Logik der Neuzeit*, 2 vol. (1964–70). See also ROBERT ADAMSON, *A Short History of Logic* (1911, reprinted 1965); C.I. LEWIS, *A Survey of Symbolic Logic* (1918, reissued 1960); JØRGEN JØRGENSEN, *A Treatise of Formal Logic: Its Evolution and Main Branches with Its Relations to Mathematics and Philosophy*, 3 vol. (1931, reissued 1962); ALONZO CHURCH, *Introduction to Mathematical Logic* (1956); I.M. BOCHENSKI, *A History of Formal Logic*, 2nd ed. (1970; originally published in German, 1962); HEINRICH SCHOLZ, *Concise History of Logic* (1961; originally published in German, 1959); ALICE M. HILTON, *Logic, Computing Machines, and Automation* (1963); N.I. STYAZHKIN, *History of Mathematical Logic from Leibniz to Peano* (1969; originally published in Russian, 1964); CARL B. BOYER, *A History of Mathematics*, 2nd ed., rev. by UTA C. MERZBACH (1991); E.M. BARTH, *The Logic of the Articles in Traditional Philosophy: A Contribution to the Study of Conceptual Structures* (1974; originally published in Dutch, 1971); MARTIN GARDNER, *Logic Machines and Diagrams*, 2nd ed. (1982); and E.J. ASHWORTH, *Studies in Post-Medieval Semantics* (1985).

Developments in the science of logic in the 20th century are reflected mostly in periodical literature. See WARREN D. GOLDFARB, "Logic in the Twenties: The Nature of the Quantifier," *The Journal of Symbolic Logic* 44:351–368 (September 1979); R.L. VAUGHT, "Model Theory Before 1945," and C.C. CHANG, "Model Theory 1945–1971," both in LEON HENKIN *et al.* (eds.), *Proceedings of the Tarski Symposium* (1974), pp. 153–172 and 173–186, respectively; and IAN HACKING, "What is Logic?" *The Journal of Philosophy* 76:285–319 (June 1979). Other journals devoted to the subject include *History and Philosophy of Logic* (biannual); *Notre Dame Journal of Formal Logic* (quarterly); and *Modern Logic* (quarterly). (M.L.Sc./P.V.S./R.R.Di.)

London

The capital city of the United Kingdom, London lies astride the River Thames 50 miles (about 80 kilometres) upstream from its estuary on the North Sea. It has a population of about 6.6 million. In satellite photographs the metropolis can be seen to sit compactly in a Green Belt of open land, with the M25 orbital motorway threaded around it at a radius of about 20 miles from the city centre. The growth of the built-up area was halted by strict town planning controls in the mid-1950s. Its physical limits more or less correspond to the administrative and statistical boundaries separating London from the "Home Counties" of Kent, Surrey, and Berkshire (in clockwise order) to the south of the river and Buckinghamshire, Hertfordshire, and Essex to the north.

If the border of the metropolis is well defined, its internal structure is immensely complicated and defies description. Indeed, London's defining characteristic is an absence of overall form. It is physically a polycentric city, with many core districts and no clear hierarchy among them. London has at least two (and sometimes many more) of everything: cities, mayors, dioceses, cathedrals, chambers of commerce, police forces, opera houses, orchestras, and universities. In every aspect it functions as a compound or confederal metropolis.

Historically, London grew from three distinct centres: the walled settlement founded by the Romans on the banks of the Thames in the 1st century AD, today known as "the Square Mile" or simply "the City"; facing it across the bridge on the lower gravels of the south bank, the suburb of Southwark; and a mile upstream, on a great southward bend of the river, the City of Westminster. The three settlements had distinct and complementary roles. London, "the City," developed as a centre of trade, commerce, and banking. Southwark, "the Borough," became known for its monasteries, hospitals, inns, fairs, pleasure houses, and the great theatres of Elizabethan London—the Rose (1587), the Swan (1595), and Shakespeare's Globe (1599). Westminster grew up around an abbey, which brought a royal palace and, in its train, the entire central apparatus of the British state—its legislature, executive, and judiciary. It also boasts spacious parks and the most fashionable districts for living and shopping—"the West End." The north-bank settlements merged into a single built-up area in the early decades of the 17th century, but they did not combine into a single enlarged municipality. The City of London was unique among Europe's capital cities in retaining its medieval boundaries. Westminster and other suburbs were left to develop their own administrative structures—a pattern replicated a hundred times over as London exploded in size, becoming the prototype of the modern metropolis.

The population of London already exceeded one million by 1800. A century later it reached 6.5 million. The city's physical expansion was not constrained either by military defenses (a highly influential factor on mainland Europe) or by the intervention of state power (so evident in the town planning of Paris, Vienna, Rome, and other capitals of continental Europe). Though much of the land around London was owned by the aristocracy, the church, and other institutions with feudal roots, its development was the work of unfettered capitalism, driven by the housing demands of the rising middle class. Free-ranging building speculation engulfed villages and small towns over an ever-widening radius with each improvement in transport technology and purchasing power. The solidly built-up area of London measured some 5 miles from east to west in 1750, 15 in 1850, and 30 in 1950.

The evacuation and bombing during World War II were a turning point in London's history because they brought the long era of expansive suburbanization to a sudden end. It was decided by the government that the metropolis had grown too much for its own economic and social good and that its growth was a strategic risk. A Green Belt was imposed after the war, and subsequent growth was diverted beyond it. Later, London's administrative boundaries were redrawn to incorporate almost the entire physical metropolis, an area of 610 square miles (1,580 square kilometres).

The London known to international visitors is a much smaller place than that. Tourist traffic concentrates on an area defined by the main attractions, each drawing between one and seven million visitors in the course of the year: the British Museum, the National Gallery, Westminster Abbey, Madame Tussaud's waxwork collection, the Tower of London, the three great South Kensington museums (Natural History, Science, and Victoria and Albert), and the Tate Gallery. In scale, visitors' London resembles the metropolis as it was in the late 18th century, a city of perhaps 10 square miles, explorable on foot in all directions from Trafalgar Square.

Resident Londoners see the metropolis in even more localized terms. Property correspondents and estate agents like to describe London as a collection of villages, and there is some truth in their cliché. Because London had developed in a dispersed, haphazard fashion from an early stage, many of its later suburbs were able to grow around, or within reach of, some existing nucleus such as a church, coaching inn, mill, parkland, or common. Buildings of different ages and types help to define the character of residential areas as well as to relieve suburban monotony. The population in the various neighbourhoods tends to be diverse because the working of the English housing market has provided most areas, even the most exclusive, with at least some public rental housing. The chemistry of location, building stock, local amenities, and property values combines with that of a multiethnic population to give rise to a great variety of residential microcosms within the metropolis. Neighbourhood ties are strong. Wherever Londoners meet and talk, they avidly compare nuances of the districts they live in because where they live seems to count for as much as who they are.

This article is divided into the following sections:

Physical and human geography

THE LANDSCAPE

Site. *The geologic foundation.* The landscape of southeastern England is shaped by an undulating bed of thick white chalk, consisting of a pure limestone speckled with flint nodules in the upper beds. Under the chalk are an incomplete layer of Upper Greensand (a Cretaceous rock; 66.4 to 144 million years old) and a 200-foot- (60-metre-) thick waterproof layer of Gault clay. Beneath them in turn lies London's true geologic foundation, a stable platform of old hard rocks of Paleozoic age (about 245 to 540 million years old). This basement is buried nearly 1,000 feet below London, sloping away southward to depths more than 3,300 feet below the English Channel.

The London Basin is a wedge-shaped declivity bounded to the south by the chalk of North Downs, running north to south, and to the north by the chalk outcrop of the Chiltern Hills, running up in a northeasterly direction from the Goring Gap. The chalk floor of the basin carries a sequence of clays and sands of the Tertiary Period (those 1.6 to 66.4 million years old), chiefly the stiff, gray-blue London Clay, which lies up to 433 feet thick under the metropolis and supports most of its tunnels and deeper foundations. The subsoil is topped with deposits of gravel up to 33 feet deep, consisting mostly of pebbles with flint, quartz, and quartzite. There are also patchy deposits of brick-earth, a mixture of clay and sand often excavated for building materials. Lastly, modern London is built on "made ground," the deposits of centuries of continuous human occupation, which have accumulated on average between 10 and 16 feet in the oldest urban nuclei of the City and Westminster.

The valley of the Thames. The metropolis grew and spilled over a more or less symmetrical valley site defined by shallow gravel and clay ridges rising to about 450 feet on the north at Hampstead and about 380 feet at Upper Norwood 11 miles to the south. Between these broken heights to the north and south, the ground falls away in a series of graded plateaus formed by gravel terraces—some at 100–150 feet (the Boyn terraces, such as Islington, Putney, and Richmond) and a second and more extensive level, the Taplow terraces, at 50–100 feet, on which sit the City of London, the West and East Ends, and the elevated southern districts such as Peckham, Battersea, and Clapham. The lowest ground, just a few feet above high-tide level, is the extensive floodplain of the valley floor. The Thames scours the confining terraces to the north and south as it meanders toward the sea. The Romans founded the city of London where the northernmost meander undercuts the higher gravel terrace to form a steep bluff. Here, at the upper limit of tidal navigation, was an ideal location for defense and commerce alike. Most of London's subsequent growth extended from this nucleus along the better-drained terraces of the north bank. Building remained more difficult in the alluvial ground south of the river until the completion of tidal embankments in the 19th century.

Tributaries of the Thames

To complete the picture of London's site in its natural state before building took place, one must add the tributary streams running north and south from the hills to the great river on the valley floor, many of them rising from springs in the gravel. Those in the centre of town have long since been culverted over, except where they do duty as ornamental water in parks (*e.g.*, the Serpentine in Hyde Park). Their names survive in the topography of London: Holborn, Fleet Street, Walbrook. Away from central London are a series of larger tributaries, used variously for navigation and associated industries, drinking water collection, gravel extraction, and ornament and recreation. To the northwest the River Colne and the River Crane join the Thames at Staines and at Isleworth, respectively; to the northeast the Lea, a substantial river draining much of Hertfordshire, enters the Thames just beyond the Isle of Dogs at Blackwall; and the River Roding merges into it four miles downstream at Barking. South London has a series of much smaller rivers leading north to the mainstream: the Ravensbourne flows through Bromley, Lewisham, and Deptford, entering the tidal Thames at Greenwich; the River Wandle rises near Croydon and flows down through Merton and Tooting to join the Thames at Wandsworth; Beverley Brook rises in Sutton and runs at the foot of Wimbledon Common and through Richmond Park and Barnes Common, emerging from a culvert at Barn Elms; the Hogsmill River flows down from the Epsom Downs to Kingston-upon-Thames; and, in the southwest corner of modern London, the River Mole drains the Surrey hills to join the Thames opposite Hampton Court.

Panorama of the city. The natural lay of the land can be appreciated from several public vantage points. Hampstead Heath offers the finest panorama over the central basin of the metropolis. But from Shooters Hill, Upper Norwood, or Alexandra Palace one has a choice of views: inward to the crowded skyline of the City and West End or out to the open expanses of the Home Counties, the Thames estuary, the South Downs, and the Weald. Such panoramas show that London, for all its immensity, resembles more closely the limited metropolises of the early 20th century than the amorphous and sprawling megalopolises of today, such as Tokyo or Los Angeles. The line of the post-World War II Green Belt runs quite comfortably along the encircling hills of the London Basin—the long ridge of the downs to the south of London and, to the north, the more broken chain of heights running from Iver Heath (above Heathrow Airport) clockwise through Ruislip Common, Bushey Heath, Enfield Chase, Epping Forest, Hainault Forest, and South Weald.

Records of London's weather

Climate. Continuous records of London's weather extend back to 1659, with specific data for wind direction available since 1723 and for rainfall since 1697. The fluctuations show a cyclic pattern, with troughs of hard winters and cold springs during the 1740s, 1770s, 1809–17, 1836–45, and 1875–82 followed by a long upswing after 1919, in which London's climate became warmer, largely because of milder weather in the autumn months.

Modern London has the equable climate of South East England, with mild winters and temperate summers. The average daytime air temperature is 52° F (11° C), with 42° F (5.5° C) in January and 65° F (18° C) in July. Statistics show that the sun shines, however briefly, on five days out of six. Londoners shed their winter overcoats in April or May and begin to dress warmly again in late October. The prevailing wind is west-southwest. Because of the sheltering effect of the Chiltern Hills and North Downs, the city has slightly less rainfall than the Home Counties. In an average year one can expect 200 dry days out of 365 and a precipitation total of about 23 inches quite evenly distributed across the 12 months.

The incidence of sleet and snow is less predictable. It varies greatly from year to year around a long-run statistical average of 20 days. The snowiest winter on record was 1695, with snow falling on 70 days. When snow does fall (generally only in the first three months of the year), it rarely accumulates. Semihardy plants can winter over in London gardens, though only in the most sheltered and sunny spot will a London vine bear grapes sweet enough for wine making.

Climatic variations across the metropolis show very clearly that there is a heat island created by concentration of buildings, internal-combustion engines, and heating and air-conditioning plants. Temperatures are higher toward the centre of the city, and the air is drier. Overall, the average difference in minimum temperatures between London and the surrounding country is 3.4° F (1.9° C), but on individual nights the difference can be as much as 16.2° F (9° C). The chemical, mechanical, and thermal effects of the city also affect wind speed and precipitation. Downpours of heavy rain are liable to be more intense within London because pollution particles act as condensation nuclei for water vapour.

Environment. *Smog and air pollution.* For years London was synonymous with "smog," the word coined at the turn of the 20th century to describe the city's characteristic blend of fog and smoke. The capital's "pea-soupers" were caused by suspended pollution of smoke and sulfur dioxide from coal fires. The most severely affected area was the 19th-century residential and industrial belt of inner

London—particularly the East End, which had the highest density of factory smokestacks and domestic chimney pots and the lowest-lying land, inhibiting dispersal. As recently as the early 1960s, the smokier districts of east Inner London suffered a 30 percent reduction in winter sunshine hours. That problem was alleviated by parliamentary legislation (the Clean Air Acts of 1956 and 1968) outlawing the burning of coal, combined with the clearance of older housing and the loss of manufacturing.

Clean Air Acts

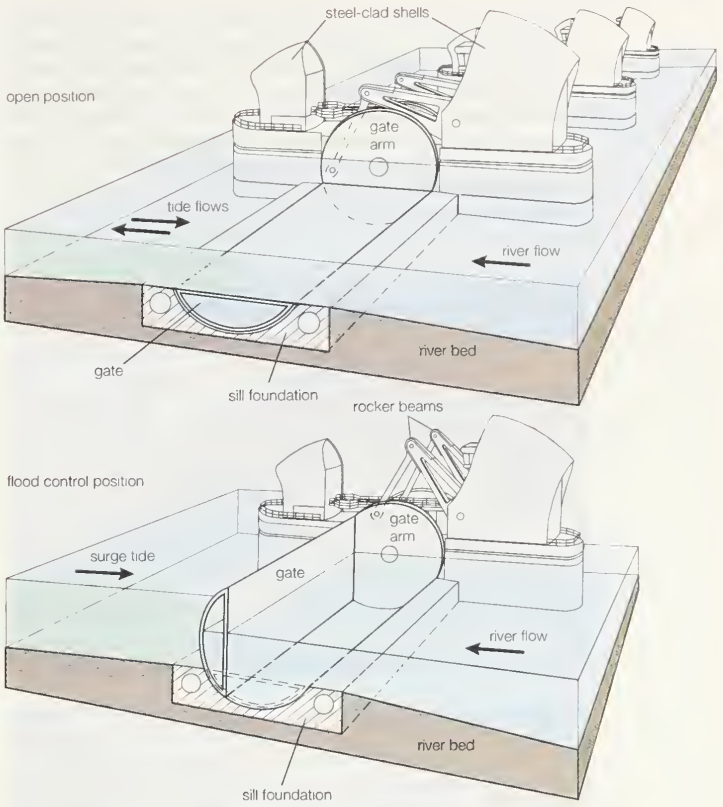
The less visible but equally toxic pollutants of carbon monoxide, nitrogen dioxide, ozone, benzines, and aldehydes continue to spoil London's air. Traffic fumes and other exhausts are liable to become trapped between the surrounding hills and below a stagnant capping mass of warm urban air at 3,000 feet, causing immediate increases in eye irritation, asthma, and bronchial complaints. But London's weather is too fickle for the development of a full-scale photochemical smog of the kind that can build up under the more stable weather conditions of cities such as Los Angeles.

Water pollution. Until the 1960s the waters of London's rivers were as polluted as its air. Deoxygenated and black with scum, they showed the effects of sewage pollution and uncontrolled industrial effluents. Then tighter environmental standards combined with the closure of factories to produce an improvement in water quality. Salmon, sea trout, roach, and flounder returned to the tidal Thames, together with shrimps, prawns, sea horses, and (at the other end of the size range) giant conger eels. Large-scale fishing of eels, a traditional Cockney delicacy, was restarted after a hiatus of 150 years. Herons, cormorants, gannets, grebes, shelducks, pochards, and terns recolonized the river.

Flood control. The greatest concern in the management of the River Thames has been the risk of flooding. Its waters are rising at the rate of 2.8 feet per century. The record floods of 1791 reached a height of 14 feet above the fixed measuring point, Ordnance Datum at London Bridge; those of 1953 rose to 17.7 feet. At high tide on a spring day, when the river is swollen with rain, it is awesome to see ships moored along the Victoria Embankment riding high above the roadway, and it is sobering to reflect on the damage that would result if the waters overtopped the walls. A serious flood would threaten 45 square miles of London's low-lying land, affecting one and a quarter million people and a quarter of a million buildings and paralyzing the capital's dense infrastructure of underground railways; sewers; gas, water, and electricity mains; telephone cabling; and service tunnels.

The flood risk results from a combination of factors. All of southeastern Britain is being tilted down into the sea (and the Hebrides tilted up) by tectonic movements resulting from the melting of Pleistocene ice sheets. London is sinking faster than the remainder of the region because modern techniques of water extraction from the chalk aquifer have dried up the underlying beds of clay. Meanwhile, sea levels in general are rising because of the effect of global warming on the polar ice caps. In addition, the tidal rhythm of the Thames has been amplified by dredging for navigation and by the embankment of its estuary marshes for cultivation.

The traditional method of protection was to build up the river walls and embankments. Long stretches were raised after the Thames Flood Act of 1879; further protective measures were taken after serious flooding in 1928, when 14 people drowned in basements in Westminster, and again after the still more serious inundations in 1953. The official inquiry into the 1953 floods recommended that "apart from erecting further walls and banks, an investigation should be made into the building of a flood barrier across the Thames." After 20 years of debate about the best design and location for a barrier, the Greater London Council settled on an unusual form of flood protection that leaves the tidal Thames intact. At Silvertown, eight miles downstream of London Bridge, it erected a line of piers from which are suspended 10 mighty steel gates and counterweights, the 4 main ones weighing 3,000 tons each. Normally laid face-downward on the bed of the river, at a time of flood risk they can be swung up by



The Thames Barrier consists of 10 movable gates separated by 9 piers. Each gate has a curved face that lies in a recessed chamber in the riverbed when the barrier is fully open. When the signal is given, the gates rotate 90° to a closed position, blocking the path of the surge tide in less than 30 minutes.

electrohydraulic machinery to form a continuous barrier sealing London off from the sea. Downstream of the Thames Barrier, to protect against the backsurge caused by its closure, elaborate walls were built along the estuary marshes with guillotine-style floodgates at the mouths of tributary rivers.

The city layout. *Three basic patterns.* London's complicated topography can be made simple by means of three basic patterns. First, there is the wiggling line of the Thames separating north from south London. For historical reasons, most important destinations lie north of the river. The south is essentially an intricate patchwork of residential districts joined by miles of conventional through streets. It has no fast through roads.

Second, London differs from east to west. The waters of

the Thames and the prevailing winds flow eastward. Therefore, shipping, heavy haulage, manufacturing, and labouring districts developed downstream in the East End, while the affluent and leisured classes built their homes and pursued their pleasures in the West End. This social gradient was reinforced by the location of the royal palaces at Westminster, Kensington, Richmond, and (beyond London's boundary) Windsor. Partly in consequence, the western sector has a series of tranquil and elegant open spaces to either side of the river, from St. James's Park, by the prime

minister's house at No. 10 Downing Street, through Hyde Park, Kensington Gardens, Battersea Park, Wimbledon Common, Richmond Park, the Royal Botanic Gardens at Kew, the Richmond riverbank, Hampton Court Park, and Bushey Park. Their landscapes soften the effect of noise pollution under the flight path of Heathrow Airport, on the western border. Proximity to the world's busiest international airport has itself reinforced the favoured position of western London.

The east-west divide is entrenched equally in the physical fabric of London and in the psychology of Londoners. Its significance did, however, diminish in the later years of the 20th century as the port economy and manufacturing industry declined and as white-collar work and residents began taking their place. This process became accelerated after 1981 by a generously funded government regeneration project for the 5,000 derelict acres of the London Docklands.

London's historic ring pattern

Overlying the north-south and east-west distinctions is a simple concentric ring pattern that reflects the historical phases of London's growth. At the centre is the area familiar to visitors, with its offices, shops, and public buildings. Next comes the suburban belt—known for statistical purposes as Inner London—developed from the late 18th century until the beginning of World War I. Terraced houses predominate, and the building scale is domestic and intimate, except where the original units were replaced by higher-density rental housing built by local councils in areas of bomb damage or postwar clearance. The third concentric zone—Outer London—consists of 20th-century suburban housing, chiefly created in a short, intensive building boom in 1925–39. The most common building type is the semidetached unit, a distinctively British compromise between row housing and the freestanding homestead. The Metropolitan Green Belt forms a final concentric ring, defining the shape of the whole capital.

Population density. The metropolis has an overall population density of just above 10,500 persons to the square mile (just over 4,000 persons to the square kilometre), which is about average by British standards (Birmingham's is 9,900 and Liverpool's 11,000) but only one-fifth that of Paris. The 20 boroughs of Outer London have an average of 8,000 people to the square mile, while the 13 inner boroughs have 21,200. Yet even in Inner London the pattern of the streets and the style of the housing lacks the intense urban density of the great cities of mainland Europe. Only one residence in three was meant to be an apartment house. More than half of London's dwellings are houses with their own patch of land. The most common type is the terraced, or row, house. Monumental and institutional buildings take their place in a loose and predominantly residential urban fabric that leaves much land unbuilt even in the areas of densest development. The city's architecture is individualistic and variable, reflecting a political aversion, in this bourgeois metropolis, to the imposed order of a set piece. Only rarely are buildings used as component parts of a larger townscape composition.

THE PEOPLE

Demographic trends. From a total population of 5,600,000 in 1891, London grew by 3,000,000 to its peak magnitude at the outbreak of World War II. For the remainder of the 20th century its population shrank by approximately 2,000,000, an average loss of 40,000 people per year. Its demographic decline occurred for reasons common to all large cities of its type. Increasing leisure and holiday time, shorter working hours, and access to the automobile freed people from the ties of proximity to their place of work. Families moved out of town in search of a better quality of life. Firms moved for similar reasons, seeking more spacious and accessible sites. As the remaining population spread itself more comfortably in the dwelling stock, the three-generation household became a rarity except among ethnic minorities. Mass housing initiatives and individual "gentrification" of terraced houses tended equally to reduce population density.

Population decline

The steepest fall occurred in the densest areas. Inner London boroughs lost more than a third of their population in the decades after World War II. In the 1980s the slump was eased by a fall in the rate of out-migration and a rise in the birth rates of new immigrant families. At the time of the 1991 census, one birth in three was to a mother born outside the United Kingdom. London's birth rate stood somewhat above the national average, and its mortality rate was lower. Its population was stabilizing at about 6.6 million, almost comparable in size to that of New York City, which also happens to sit in a wider urban region of approximately 20 million people.

Ethnic composition. *The historical base.* The stabilization of total population numbers masked a continuing population flux. London, like any great metropolis, acts as a nursery, perpetually taking in young and aspiring immigrants and releasing mature firms and families. But the hinterland has shifted. In the 19th century most movement into London was domestic; the majority of immigrants came from the neighbouring Home Counties, with additional long-distance streams from Wales, Ireland, and Scotland. Overseas immigrants came too, but London was less cosmopolitan than New York City or Boston. Its alien communities were small (mostly less than 1,000 people) and localized, and some were long-established. Bevis Marks, the City synagogue of the Sephardic Jews, was founded in 1656. St. Peter's Italian Church (1863) was the first Italian church ever to be built outside Italy.

Immigrants from Europe. In late 19th-century London, Italians clustered in Holborn and Finsbury, French in Soho, and Chinese near the docks in Limehouse, and there

was a scattering of Germans and Scandinavians around the City. Communities of Irish (at that time still subjects of the British crown) were established in Wapping and Camden. The pogroms of the 1880s and '90s brought about 20,000 Polish and Russian Jews to settle on the eastern edge of the City at Whitechapel. A further wave of Jewish emigrants fled to London from German fascism in the 1930s, followed by a wave of refugees from central Europe in the upheavals at the end of World War II.

After the war, the Polish community sank its roots in Ealing in western London. Jewish families became suburban, concentrating especially in Edgware, Golders Green, Hendon, and Finchley to the northwest and Ilford to the northeast. The extreme orthodox did not move as far, only to the northern edge of the East End in Hackney. Sizable communities of Greek and Turkish Cypriots arrived to open shops, restaurants, and small businesses on the City fringe, rising rapidly to suburban prosperity along the radial roads northward.

London's black population

Immigrants from the Commonwealth. London's black population grew significantly during the economic boom years of the 1950s and '60s. It was a time of labour shortage, particularly for public service industries such as transportation (buses and underground) and hospitals. To fill the places of blue-collar workers who had been encouraged to leave London to take jobs in the new towns, employers began to recruit from the former colonies, which were now independent members of the British Commonwealth. The first wave of immigration was from the Caribbean. Black Londoners found it hard to gain access to public rental housing, and so concentrated as private tenants in lodging-house districts of North Kensington and south of the river in Brixton. Kensington's Notting Hill Carnival, at the end of August, remains the chief annual celebration of West Indian life in London. Later groups of immigrants from the Commonwealth settled in different parts of the city: Indians in Ilford, Ealing, and Hounslow; Bangladeshis in Whitechapel (where they replaced the Jews in an unusually exact immigrant succession); and Africans in Hackney, Southwark, and Lambeth.

The multiethnic metropolis. London, always a cosmopolitan city, grew steadily more polyglot and multicultural. The Commonwealth connection accounted for only part of the transformation. Despite restrictive immigration laws, the flux of refugees and asylum-seekers from many countries continued, and new communities of Vietnamese, Kurds, Somalis, Eritreans, Iraqis, Iranians, Brazilians, and Colombians sprang into being. Many of the foreigners settled into hard-to-let housing estates in the poorer parts of Inner London, particularly the crescent of inner boroughs to the east of the City. At the other end of the economic spectrum, London's position at the crossroads of the global economy brought transient populations of the international business world as well as the schools, shops, and renting agencies and services to support them. Their social geography was entirely different, spreading in an arc through the northwest and southwest suburbs. London also attracted wealthy foreigners to become property owners and seasonal residents. Thus, people from the Middle East, East Asia, and Latin America purchased real estate and internationalized neighbourhoods such as Mayfair, Park Lane, and Belgravia. Shopping streets that lead north from Hyde Park, such as Queensway and the southern end of Edgware Road, are almost entirely taken over by Arabs.

Though it is not easy to establish reliable figures on London's ethnic composition, the columns of names in the telephone books and school registers are testimony to the transformation of a population that in the middle years of the 20th century had still been chiefly British-born and Anglophone. Just under one-quarter of the resident population of modern London comes from overseas. The transformation of London into a multiethnic city has gone furthest in the western boroughs (partly because of the proximity to Heathrow), while the boroughs of Havering, Barking and Dagenham, Bexley, and Bromley form an arc of almost entirely British-born white population on the far eastern edge of London. These are also the areas least touched by the cosmopolitan restaurants, clubs, and shops that have banished the old, insular dining habits elsewhere in the metropolis.

London's social geography

Residential patterns. London's social geography is never static. The city has never had ghettoes or strong policies of segregation. The areas of local government are too large and the housing stock too diverse for exclusionary practices of the kind encountered in some North American cities. There is intermixture even in the areas having a high concentration of one particular group, such as those of the extreme orthodox Jews at Stamford Hill, the Sikhs at Southall, or the West Indians at Brixton. Boundaries and distributions are perpetually shifting. Minorities follow one another in the familiar sequence of arrival, consolidation, and outward and upward mobility. Jews who came to Whitechapel in the 1890s shifted eastward to the semi-detached suburb of Ilford. Cypriots who had settled along the Seven Sisters Road moved north along the old drovers' road, Green Lanes, to Tottenham and Haringay. Traces of earlier diasporas are scattered through Inner London. Most of London's 11 Welsh churches are grouped around the centre. The Welsh Congregational Church at Radnor Walk in Chelsea today serves a dispersed instead of a local congregation. Swedish, Norwegian, and Danish Lutherans drive eastward on Sunday mornings to worship in their old churches at the dockyard gates.

THE ECONOMY

Trade, administration, and leisure. London has been described above as a polycentric city. The map of Elizabethan London shows that fields and the river separated distinct centres: the City of London with its shipping, trade, and crafts; Southwark with its gardens, hospitals, and theatres; and the royal court at Westminster. The economy of modern London has evolved continuously from the three complementary elements of trade, administration, and leisure. In trade London is one of a handful of centres—along with New York City, Tokyo, and Hong Kong—where dealers in currencies, equities, commodities, and insurance operate on a global scale. In the first half of the 20th century it was also a substantial manufacturing centre. In contrast to the other great cities of Britain, London's factory closures have been compensated at least partly by the city's dynamism in financial services and the media.

As an administrative centre, London dominates the national life to an exceptional degree. The United Kingdom is constitutionally a unitary state and politically the most centralized in Europe. Scotland, Wales, and Northern Ireland, England's three national partners within the United Kingdom, have administrative identity but lack political institutions. All legislative activity is concentrated in the English capital, at Westminster. Pressure groups and lobbyists needs must follow. British local governments raise less than one-quarter of their needs in tax revenues and are heavily dependent on fiscal transfers from the centre. In British politics, all roads lead to London.

If London is a place to win influence and make money, it is also a great playground—a leisure metropolis. Historically the landed classes flocked to London each year to spend "the season" in the proximity of the court. The legacy of aristocratic consumption still survives in the gunsmiths, art dealers, tailors, and vintners of the West End, serving a modern market of London's international visitors. Each year more than 100 million nights are spent by tourists in the capital's hotels. Though its full impact is difficult to trace, the tourism industry has clearly overtaken manufacturing as a source of employment for Londoners, offering direct employment for more than 200,000 workers and perhaps as many more again through economic multiplier effects, some of them in the black market.

Industry. *Shipping.* For centuries, shipping was at the heart of the economy of London. The city retained its lead as the largest, busiest port in the world until World War II, with an average of 1,000 ship arrivals and departures every week. The Port of London Authority, founded in 1909, supervised seven systems of enclosed docks with a combined water area of 720 acres (291 hectares). It had 35 miles of dock quays and as many again of riverside moorings, wharfage, shipyards, and heavy industry along the

banks of the Thames from Gravesend to London Bridge.

Shipping left London quite suddenly between 1968 and 1981 for a combination of reasons, including the containerization of ocean traffic and the growing scale of bulk cargoes, poor labour relations, and competition from new private ports based in small towns around the coast. After consolidating its activities in docks at Tilbury on the Thames estuary 26 miles downstream of London, the Port of London Authority was left with a diminished share of about 8 percent of the nation's total port traffic.

Manufacturing. In addition to its importance in administration and banking, London used to be a substantial manufacturing centre. In the 18th and 19th centuries its industries were quite comparable to those of other European capitals and court cities, producing such luxury items as silks, fine furniture, gilded work, watches, musical instruments, millinery, and women's clothing. Such highly skilled trades with their own systems of apprenticeship clustered tightly around the City of London and adjacent districts. In the 20th century London became the preferred location for a new generation of electrically powered industries serving mass consumption markets. Many of the companies were American multinationals, including Heinz Company, Hoover, Ford Motor Company, and Firestone, while others had grown out of conventional craft industries. Their factories, often built in a hygienic white-tiled Art Deco style, lined the new arterial roads out of London: the Great West Road, Western Avenue, and Purley Way. In both new and old sectors, London's manufacturing base rested upon industries producing consumer goods (rather than intermediate and capital goods) such as leather products, clothing, timber and furniture, food and drink, pharmaceuticals, and specialized goods as well as products generated by printing and publishing, instrument engineering, and electrical engineering.

Production of consumer goods

This manufacturing success in London presented such a striking contrast to the high levels of unemployment in the old, established industrial regions of northeastern England and Clydeside (Scotland) that the government, fearing massive expansion of the metropolis, decided to halt the city's growth. It did so by imposing a Green Belt, or stopline, to keep postwar London within strict bounds. Many growth industries, with their young and skilled workforces, were relocated to public satellite towns. Grants and incentives attracted firms into peripheral regions of high unemployment, while administrative controls discouraged the building of factories in London. At the local level, there was a tendency in the 1950s and '60s to sweep away older mixed industrial districts in urban renewal programs, while scattered industrial premises were weeded out as "non-conforming uses" under zoning powers.

Even without such public discouragement, London's industry would probably have declined in modern times because of wider shifts in the geography of manufacturing. Firms have tended to move out of large cities everywhere, drawn by access to the national highway network and by the flexibility and efficiency of low-density units on greenfield sites. The deindustrialization of London was a drawn-out and painful process. In the 1950s the decline of older craft-based manufacturing in the inner parts was concealed or compensated by continued growth of the newer industries of the interwar period. As late as 1961 half of the jobs in the London suburbs were in manufacturing. Thereafter, however, the curve of employment in manufacturing sloped remorselessly downward. A third of a million jobs were lost in the 1960s, almost half a million in the 1970s, and a further third of a million in the 1980s. Toward the end of the 20th century, Britain's greatest manufacturing city had become a "postindustrial" metropolis, with only a residual one-tenth of its workforce in manufacturing.

The main surviving concentrations of industry in London were along transport corridors. The first and still the foremost of these are the River Thames and (to a lesser extent) its tributaries, especially for industries linked to sea-carried bulk cargoes such as petrochemicals, sugar, grains, and timber. Industrial plants continued to dominate the riverside landscape downstream of Greenwich, but upstream they were almost entirely replaced by residential apartments and office blocks. Other significant manufacturing districts were on the arterial roads leading out of London and around the North Circular Road that rings London five miles from the centre.

Finance. *International significance.* The London economy was relatively fortunate in being able to offset manufacturing decline by participation in the growth of global financial markets. By 1990 one in six of London's workforce was in financial or business services—one-third of Britain's total employment in these sectors. The City claimed to have the largest concentration of financial employment in the world.

London's role as a world financial centre has long historical roots. At the end of the 19th century more than half the world's trade was financed in British pounds sterling. In the early 20th century the City played a more modest role as banker to the British Empire and the sterling area of trading nations. It regained a global presence thanks to the relaxation of exchange controls in 1958, the development of the Eurocurrency and Eurobond markets in the 1950s, and the deregulation of capital and securities markets—the "Big Bang"—in the 1980s.

In the 1990s London's most significant revenue-earning function was to provide a centre for the international banking market. A unique concentration of banks from every corner of the globe allowed an exceptional range of currencies to be traded. In the competitive climate of late 20th-century global finance, it captured a large share of activity in the newer, esoteric markets—swaps, cross-exchange equity trading, and currency options—and also maintained its historical position in the conventional fields of international bank lending, underwriting, bond trading, foreign exchange trading, and investment management. London had become Europe's main centre for large volume trading in securities. It dominated the world market in marine and aviation reinsurance.

Centre of the international banking market

Financial districts. The office towers of the financial services sector cluster tightly in the historic central business district of the City of London, or "Square Mile." Banking, insurance, maritime services, commodities, and stockbroking are each associated with particular districts within the City. The advantages of proximity and face-to-face dealing are offset by the shortage of space. The Square Mile is not Hong Kong or Manhattan or Chicago's Loop but a medieval city in which building opportunities are limited at every turn by the presence of ancient monuments and by fragmented and complex patterns of land ownership. During the 1980s, financial service activity began to spill into neighbouring areas with better availability of land. Obsolete railway stations provided many opportunities for office redevelopment—notably the renowned Broadgate project at Liverpool Street Station to the north of the Square Mile—as did the great premises in Fleet Street, to the west, that had been vacated by the newspaper industry in its shift from hot-lead production to computer typesetting. The most spectacular secondary centre was the business city of Canary Wharf, built by the Canadian Reichmann brothers in the derelict docks a mile and a half to the east of the Square Mile. The project bankrupted its developers but left London with an enduring memorial of the boom years of the financial services revolution.

Transportation. *The Thames.* London's oldest highway is the Thames. Until the opening of Westminster Bridge in 1750, London Bridge was the only crossing. Most journeys across the river and many trips within London were made by boat. Both banks were punctuated by stairs leading down to ferries. The Thames watermen, who had been regulated since the 14th century, formed their own guild or company by 1603. After the development of the railways, the river ceased to carry significant traffic in passengers, despite periodic attempts to revive its function as a mass transit artery with hydrofoils, catamarans, and hovercraft.

Roads. London's most striking physical feature is the absence of a grand road layout. Town planners have made repeated attempts to impose a greater degree of formal order on the capital. The most celebrated efforts in modern times have been Sir Patrick Abercrombie's Greater London Plan of 1944 and the Greater London Devel-

Failure of road building

opment Plan of 1969, both of which attempted to drive modern highways through the fabric of the city. Fortunately, both plans were frustrated, leaving London with isolated stretches of high-speed road instead of a coherent network. A representative example is the quarter mile of dual carriageway that runs along the north of the Square Mile—a relic of Abercrombie's scheme for an inner ring road around the central business district. After years of economic blight, the scheme for a westward extension of the road was abandoned and the land sold off. A postmodern office block for a firm of city solicitors now closes the abandoned vista of the inner ring road known as Route 11.

The failure of road building has actually proved beneficial to London, which has Britain's highest rate of travel by public transport. The use of automobiles for travel to work in central London is small and declining. Each morning a million or so people enter central London, and well over three-quarters of them arrive by rail.

Railroads. The basis of the capital's rail infrastructure was laid in four heroic decades between 1836 and 1876. Competing railway companies brought 10 separate systems of track into London from every point of the compass, each with its own terminus station perched at the edge of the high-value metropolitan core of the City and West End. Linkage between the terminals was achieved in 1884 with the opening of the Metropolitan Railway, London's first "underground." Early development of underground railways in London was helped by the clay, which was easy to excavate, the spoil providing raw material to make bricks for lining the tunnel walls. Improved deep tunneling techniques after World War I allowed a rapid expansion of the underground network, while the Piccadilly, Bakerloo, Central, and Northern lines opened up hundreds of square miles of rural Middlesex and Essex for suburbanization. South of the Thames a similarly dense network of railway stations had been developed along the electric suburban lines of the Southern Railway out of Victoria, Waterloo, and London Bridge stations. Raised on handsome brick viaducts above the floodplain or sunk into cuttings through the rolling uplands, the converging railways form one of the most distinctive topographic features of south London. Together the underground of the north and the overground of the south equipped London with a network of lines and stations that is rivaled only by that of Tokyo for scale and density. Most of the network was already built and in service by 1939. In the second half of the 20th century it only remained to fill in the gaps in the network map with projects such as the Heathrow extension of the Piccadilly Line, the Jubilee Line, the Victoria Line, and the Docklands Light Railway.

Taxicabs. The black taxicab is a familiar feature of the London scene. The cabs and their drivers, the London cabbies, are products of a system of licensing that extends back to 1639. About 1900 there were more than 11,000 registered cabs plying for hire on the streets of London, and double that number a century later. Motorized cabs first made their appearance in 1904 and soon displaced the horse-drawn cab (the last survived until 1947). A regulation of 1906 required the new mechanical cabs to be designed in such a way that they could turn, like the two-wheeled hansom cab, in a circle of at most 25 feet. Still in force, it accounts for the surprising maneuverability of black cabs in congested London streets and their distinctive "sit up and beg" design. Cabbies themselves are subjected to even older regulations, which require them to pass a detailed test on topography, street names, and principal destinations throughout a six-mile radius from Charing Cross. Trainee taxi drivers acquiring "the knowledge," as it is called, are a familiar sight on the streets of the capital.

Cabbies

ADMINISTRATION AND SOCIAL CONDITIONS

Government. *The City Corporation.* The Lord Mayor and City Corporation of London form one of the oldest local governments in the world, with a history of municipal autonomy extending in unbroken succession to the folkmoots of the early Middle Ages. The Square Mile remains an autonomous jurisdiction within its historic boundaries, with its own police force and a complete range of municipal services attending to the needs of a resident population of less than 6,000 and a weekday working population of 300,000. Through the centuries the City Corporation has accumulated immense resources of capital and property, entrenching itself alongside its historic foes, the crown and the aristocracy, at the pinnacle of Britain's stratified society. The City has never concerned itself with the wider issues of local government in the metropolis, except insofar as they impinge upon its own position and privileges, which are tenaciously defended.

Envision/© Pictures of London

Modern and historic buildings cluster tightly in the City of London. A statue of the Duke of Wellington stands before the Royal Exchange (1844) at right, with the Bank of England (18th century) at left. The National Westminster Tower, at right rear, stands behind the two London Stock Exchange buildings at centre.

Around the unyielding nucleus of the Square Mile, arrangements for the wider metropolis have developed by stages. The City's indifference left a mid-19th-century population of almost three million under an anarchic miscellany of more or less undemocratic bodies based either on medieval ecclesiastical parishes or on ad hoc service agencies created under local legislation. In 1855 water and sewerage provision for the entire built-up area were brought under the control of the Metropolitan Board of Works. Following charges of corruption and lack of accountability, the organization was transformed in 1889 into the administrative nucleus of an elected local government for London as a whole, the London County Council (LCC). However, the City Corporation successfully lobbied to preserve its autonomy and secured the creation of a second tier of elected local governments, the metropolitan boroughs, to function as a political counterweight to the LCC.

Greater London. The same two-tier pattern, with its attendant tensions, was repeated in 1965 when the LCC was replaced by the Greater London Council. Its boundaries were extended to include all the suburbs developed after 1888—*i.e.,* more or less the entire built-up area within

the Green Belt. At the same time, more than 100 existing local councils were amalgamated to form a modernized system of 33 boroughs, including the City of London and its young neighbour, the City of Westminster, chartered in 1900. The strategic authority and the local councils were at loggerheads from the outset, and their rivalries were intensified by shifts of political control at national, Greater London, and borough levels. Conservative Prime Minister Margaret Thatcher put these wranglings to an end in 1986 by the drastic expedient of abolishing the Greater London Council (then dominated by the opposition Labour Party) and stripping away its municipal assets. The majestic County Hall, across the bridge from the Palace of Westminster, was sold to a Japanese developer for conversion into a luxury hotel. London was left, uniquely among the world's great cities, with no form of civic leadership. Municipal affairs were distributed among the 33 borough councils, supplemented by a variety of ad hoc groupings and centrally appointed bodies for single services.

In a 1998 referendum, Londoners accepted a plan by the new Labour government to reestablish a citywide administration, which would operate in conjunction with existing Greater London boroughs. Established in 2000, the new Greater London Authority comprised a directly elected mayor and a 25-member assembly, and it assumed some of the local responsibilities that the central government had handled since 1986—notably over transport, planning, police, and other emergency services.

The London boroughs

The London boroughs are large units, with populations usually of one or two hundred thousand, designed to achieve efficiencies of service provision rather than reflect local loyalty and sense of identity. When Londoners are asked where they live, they are more likely to give the name of their nearest railway station or shopping centre or of the pre-1965 administrative unit than of the modern borough.

Postal districts. At the local level, areas are often identified by postal district. The capital postal area is divided into 120 districts, each centred on a sorting office. An address in, say, SW1 carries a status that can be translated into property values. The dense urban core is divided into east central (EC) and west central (WC) areas with six numbered subdivisions (EC1–4 and WC1–2). The remainder of the metropolis is divided into six compass sectors, north (N), east (E), southeast (SE), southwest (SW), west (W), and northwest (NW), with each sector comprising up to 28 numbered districts. The district nearest the city centre always has the number one, so that N1 (Islington), E1 (Stepney), SE1 (Southwark), SW1 (Westminster), W1 (Soho, Mayfair), and NW1 (Marylebone and Camden Town) form a ring around the central area.

The remaining London postal districts follow no geographic logic but are dotted randomly within their sector according to the alphabetical order of sorting-office names. Moreover, the outer boundaries of the London Postal Area fall short of the administrative and physical boundaries of the metropolis, giving several thousand suburbanites a postal address in the Home Counties though they live in a London borough. The one exception is the E4 postal district, which thrusts some miles out of London into the county of Hertfordshire.

Police. The Metropolitan Police was founded by Home Secretary Sir Robert Peel in 1829 and remains accountable to his successor, not to local councillors. By 1900 the Metropolitan Police District, which inherited responsibility for patrols against highwaymen, extended into the countryside in a 20-mile radius around London, an area of 700 square miles. Increased to 786 square miles, the area is still large enough to accommodate the entire metropolis and some of its rural fringe.

Two police forces

The Metropolitan Police District surrounds but excludes the City of London, which maintains its own police force. Metropolitan officers can be identified by their white shirts with silver buttons and City officers (who are recruited for height and wear lofty helmets) by their blue shirts with gold uniform trim. The British Transport Police and the Royal Parks Constabulary also maintain separate forces within the metropolitan area.

Hospitals. The history of London's great hospitals begins with medieval monastic charity. St. Bartholomew's, the oldest, was founded in 1123, and St. Thomas's at Lambeth dates to 1213. Other hospitals, all founded since 1700, include Guy's, St. George's, the London Hospital, the Middlesex, Charing Cross, the Royal Free, University College, and King's College. These hospitals combine the roles of medical school, research laboratory, general hospital, and specialized clinic at the highest level of excellence. Because of the concentration of medical resources in the heart of London, the administrative map of the health service divides the capital into four wedge-shaped regions, each hav-

ing teaching hospitals at the inner tip and an outer catchment area extending far beyond the physical metropolis.

Education. School provision in London is a responsibility of the 33 boroughs. Nine out of 10 children attend borough schools. The remainder are at fee-paying private schools, of which the oldest and most august are Westminster School (originally monastic, refounded by Elizabeth I in 1560), St. Paul's School (1509), Harrow School (1572), Dulwich College (1618), and the City of London School (1834).

The panorama of higher education in London is characteristically complicated. Perhaps because of its civic fragmentation and the dominance of Oxford and Cambridge, the city lagged far behind other European capitals in the advancement of learning. The University of London, which was established as an examining body in 1836, did not become a teaching institution until 1900, centuries after its counterparts in Paris, Rome, and Madrid. Modern London has 12 universities in all, with more than 110,000 full-time and 50,000 part-time students. Despite the imposing monumentalism of its administrative buildings in Bloomsbury, the original London University is little more than a weak federation of 42 institutions ranging from small specialized schools to organizations such as Imperial College, University College, King's College, and the London School of Economics and Political Science, each of which operates in practice as a university in its own right.

Apart from a cluster of university buildings to the north of the British Museum in Bloomsbury, London's higher education facilities are spread widely through the metropolis. Halls of residence are even more scattered, and a high proportion of students live at home or in lodgings. The capital lacks an identifiable student quarter. Instead, that compound of offbeat bohemianism, nightlife, and political radicalism is sprinkled like yeast throughout Inner London.

CULTURAL LIFE

Centres of the arts. The competitive, localist streak that complicates public administration in London makes for exceptional cultural vitality. Artistic creativity flourishes in the diversity of rival centres of patronage. Royal patronage created Albert Hall, which every summer provides the setting for one of the world's greatest music festivals, the Sir Henry Wood Promenade Concerts known popularly as the "Proms." Municipal patronage, first of the London County Council and later of the Greater London Council, turned former industrial and warehousing land on the Waterloo riverbank into the South Bank arts complex, which combines the Royal Festival Hall, the Queen Elizabeth Hall, the Hayward Gallery, the Purcell Room, the National Film Theatre, the Museum of the Moving Image, and the Royal National Theatre. Not to be outdone, the City Corporation launched its own arts complex within the Square Mile at the Barbican, a high-density urban renewal scheme built on World War II bomb sites immediately north of the central business district. The Barbican has a concert hall, cinemas, an art gallery, a library, and a theatre that is the London home of the Royal Shakespeare Company. Each centre generates its own program of festivals and special events, as do borough councils and commercial promoters. No other city in Europe offers so many entry points to the young and talented musician, writer, artist, filmmaker, or performer. Though the figures are elusive, one estimate puts London's share of total national employment in cultural industries at 40 percent. Listings for the performing arts present a choice of more than 100 venues on a typical Friday or Saturday evening. Though the fragmentation of arts funding is often contrasted unfavourably with strong public sponsorship elsewhere, it is hard to resist the conclusion that London thrives on its distinctive combination of wide-open internationalism and local particularism.

Rival centres of patronage

Museums. The British Museum originated in 1753 in the government's purchase and amalgamation of three collections: the antiquities and natural history specimens assembled by the physician Sir Hans Sloane, the Cottonian Library and antiquities accumulated over 50 years by the Cotton family of Westminster, and the Harleian Collection of Manuscripts built up by the 1st and 2nd Earls of Oxford. A public lottery raised the purchase price of the collections and a building in Bloomsbury to house them. This original nucleus was rapidly expanded by purchases and gifts as well as by the plunder of war and colonial conquest. In 1823–46 the Bloomsbury premises were totally rebuilt to the design of Robert Smirke, who graced the south front of the museum with a massive Ionic portico. The heart of Smirke's design, a large internal quadrangle, was roofed over in the 1850s with an immense copper dome to create the famous Reading Room in which Karl Marx wrote *Das Kapital*. In the late 1990s the inner courtyard and the Reading Room were enclosed by a 2-acre (0.8-hectare) square glass roof, transforming this area into what has been billed as the largest covered public square in Europe. Christened the Queen Elizabeth II Great Court, it was formally opened in December 2000.

The British Museum

The collections continued to outgrow the space available at Bloomsbury. During the 1880s the British Museum's botanical and zoological materials were reestablished in South Kensington as The Natural History Museum, housed in a richly carved and ornamented Victorian Romanesque building by Alfred Waterhouse. It formed part of a precinct of science and art developed at the direct initiative of Queen Victoria's husband, Prince Albert, on 87 acres of land purchased from the profits of the 1851 Great Exhibition. Its immediate neighbours are the Science Museum, the Geological Museum, and the immense collection of fine and applied arts from all over the world gathered under the roof of the Victoria and Albert Museum.

The full list of London museums has more than 250 entries catering to almost every industry, religion, ethnicity, profession, or foible. Opened in 2001, Firepower! The Royal Artillery Museum, at Woolwich, consolidates the holdings of the former Royal Artillery Regimental Museum and the Museum of Artillery at the Rotunda. Other outstanding collections include the National Maritime Museum at Greenwich (ships and the sea), the Museum of London at the Barbican (local history), the Museum of Mankind off Piccadilly (ethnography), the Bethnal Green Museum of Childhood (toys), and the Geffrye Museum in Shoreditch (domestic interiors).

Art galleries. *Exhibition spaces.* London is thought to possess about a third of the nation's art galleries and perhaps half the total hanging space in Britain. The greatest of the permanent collections is the National Gallery in Trafalgar Square. Behind it sits the National Portrait Gallery, which houses a vast collection of paintings, drawings, sculptures, etchings, photographs, and miniatures of famous faces past and present. The Tate's impressive holdings are displayed at two London locations: Tate Britain, at Millbank, which exhibits British art; and Tate Modern, at Bankside, where international modern painting and sculpture are housed. (The Tate also has galleries in St. Ives and Liverpool.) The Courtauld Institute Galleries at Somerset House on the Strand contain a major collection of French Impressionists and Postimpressionists. The Wallace Collection in Manchester Square combines paintings by great masters from several countries with furniture, ceramics, and goldsmiths' work in the ambience of an aristocratic town house. South of the river, Dulwich College has England's oldest public art gallery, built for important collections of 17th- and 18th-century masterpieces, including works by Rembrandt, Peter Paul Rubens, Thomas Gainsborough, and Nicolas Poussin. Its architect, Sir John Soane, incidentally also designed his own home in Lincoln's Inn Fields in 1812–13 to house an extraordinary personal collection of art (especially engravings and paintings by William Hogarth and Canaletto), works of art from the Middle Ages, and antiquities (classical and Egyptian). He bequeathed it to the nation, and today's visitors find it as he left it.

Both the National Gallery and the Tate mount special exhibitions. The other main venues for art shows are the Hayward Gallery on the South Bank, a sculptural concrete box of 1960s vintage, and the neoclassical Royal Academy of Arts in Burlington House on Piccadilly. The leading commercial galleries are concentrated in the West

Commercial galleries

End of London around the epicentre of Bond Street. Specialist and avant-garde galleries are scattered throughout London, with a preponderance to the north and west.

Artists' quarters. Artists have long since been priced out of their traditional quarters in Chelsea and Hampstead. Today the prime areas for the bohemian life are the inner industrial suburbs of Hackney and Tower Hamlets to the east and Southwark to the south, where derelict work spaces and plentiful, loosely managed public rental accommodations have attracted many hundreds of artists. Scores of studios are thrown open in conjunction with the biennial exhibit of the Whitechapel Art Gallery in the East End.

Theatres. London offers every shade of dramatic experience, from authentic open-air Shakespeare performances in the replica Globe Theatre built by Sam Wanamaker to the bizarre offerings of the biennial London International Festival of Theatre (LIFT). On any given day the publicly sponsored National Theatre Company on the South Bank and the Royal Shakespeare Company in the Barbican have several shows in repertory. The West End has about 40 commercial theatres, playing to audiences composed in almost equal parts of Londoners, out-of-town theatregoers (many of whom come by coach), and overseas tourists. Many of London's centres—for example, Stratford, Ilford, Greenwich, Croydon, Battersea, Richmond, Kilburn, and Hammersmith—have fine theatres catering to local audiences. If one adds the fringe and studio performance venues, many in the upper rooms of pubs, the total offering of drama exceeds 100 shows a night before any count is made of amateur theatrical activity in churches, schools, and parish halls.

Music. The competitive ethos generated by London's administrative fragmentation is most evident in the realm of classical music. Five full-scale symphony orchestras vie for audiences and funding: the London Symphony Orchestra, the Royal Philharmonic Orchestra, the Philharmonia Orchestra, the London Philharmonic Orchestra, and the BBC Symphony Orchestra. On a slightly smaller scale, London also has the ensembles of the Academy of St. Martin-in-the-Fields, the London Sinfonietta, the City of London Sinfonia, the Sinfonietta 21, the Orchestra of the Age of the Enlightenment, and the pit orchestras of the Royal Opera House in Bow Street, Covent Garden, and the English National Opera at the Coliseum Theatre north of Trafalgar Square. This immense pool of instrumental talent continually generates new performing groups and chamber ensembles. The Musicians' Union estimates that as many as 44 percent of Britain's working musicians are based in the capital.

Tributes. Every London district has a deposit of historical associations many centuries thick. Earlier generations of Londoners are present in street names, public statues and busts, and thousands of funerary monuments and inscriptions. Since 1867 London has paid tribute to distinguished citizens and visitors by attaching circular blue plaques to their places of residence. Among those honoured are Geoffrey Chaucer, Wolfgang Amadeus Mozart, Florence Nightingale, and James Joyce. The first plaque was put up on the wall of Lord Byron's birthplace in Holles Street, Westminster.

Soccer

Sports. *Football.* Football (soccer) tops the lists of both participant and spectator sports in London. Amateur players turn out in the hundreds for games in every park and open space. Hackney Marsh, along the River Lea in the east of London, has a swathe of 100 pitches. The professional game, like almost every branch of London life, is organized locally, not citywide. As a result, nobody plays for London, yet the capital has 13 football clubs: Arsenal (based in Islington), Barnet, Brentford, Charlton Athletic, Chelsea, Crystal Palace, Fulham, Millwall, Orient, Queens Park Rangers (based in Shepherd's Bush), Tottenham Hotspur, West Ham United, and Wimbledon. Between them the clubs cover every part of London, and their colours can inspire strong local loyalty. The playing season lasts from August until May. Matches attract an average crowd of 15,000, rising to 30,000–40,000 for a big first-division game.

Cricket. In the summer months, county cricket and (international) Test Matches are played at Lord's in St. John's Wood and at the Oval ground in Kennington, between Lambeth and Vauxhall on the south bank. The Surrey County Cricket Club has leased the Oval ground from the Duchy of Cornwall since 1845. London, England's most populous county, has no cricket team of its own but is partly represented by the historic counties corresponding to areas of the modern metropolis—Kent, Surrey, Essex, and the former Middlesex.

London has nearly 1,000 cricket clubs, and the amateur game is widely played on summer weekends, often on open greens and parks. The club at Woodford Green in northeastern London claims to keep up the country's longest tradition of village cricket, beneath the statue of the former local member of Parliament Sir Winston Churchill.

Other spectator sports. June brings international tennis stars to the All England Lawn Tennis and Croquet Club at Wimbledon in southern London. An earlier highspot of the sporting calendar is the spring boat race between the Universities of Oxford and Cambridge, rowed up the turbulent waters of the tideway from Putney Bridge to Chiswick. Since the closure of the racecourse at Alexandra Park in September 1970, Londoners must travel out of town for the horse races—as they do by the thousands in June for the Derby on Epsom Downs, also in June for the Royal Week at Ascot near Windsor, and in July for the Goodwood races in Sussex. (M.J.H.)

Horse races

History

THE EARLY PERIOD

Foundation and early settlement. Although excavations west of London have revealed the remains of circular huts dating from before 2000 BC, the history of the city begins effectively with the Romans. Beginning their occupation of Britain under Emperor Claudius in AD 43, the Roman armies soon gained control of much of the southeast of Britain. At a point just north of the marshy valley of the Thames, where two low hills were sited, they established Londinium, with a bridge giving access from land to the south. The first definite mention of London refers to the year AD 60 and occurs in the work of the Roman historian Tacitus, who wrote of a celebrated centre of commerce, filled with traders. In the same year, Iceni tribesmen under Queen Boudicca (Boadicea) sacked the settlement. From traces of the fires they set, it can be determined that the city had already begun to spread across the Walbrook valley toward the hill where St. Paul's Cathedral was later built. After the sack, the city was reconstructed, including a great basilica—an aisled hall 500 feet long. On the same spot today stands Leadenhall Market, an 1881 creation of cast iron and glass. To protect the city, Cripplegate Fort was built by the end of the 1st century, with an amphitheatre nearby. The first half of the 2nd century was a prosperous time, but the fortunes of Londinium changed about AD 150, and areas of housing and workshops were demolished. A landward wall was built about AD 200 for defense. Remains of the wall can be seen at the edge of the Barbican (near the street called London Wall) and on Tower Hill. In medieval times the walls were rebuilt and extended, requiring new gateways in addition to the six Roman ones. During the 3rd century timber quays along the Thames and public buildings were rebuilt, and a riverside wall was constructed. An area of some 330 acres (about 135 hectares) was enclosed. Londinium in the 3rd and 4th centuries was less populous than in AD 125. When the legions were recalled to Rome early in the 5th century, the was widespread abandonment of property. What happened to London over the next two centuries is a matter of conjecture.

The Roman foundation

No records tell how or when London fell into Saxon hands, but it was still, or had once again become, a city of great importance by 597, when Pope Gregory I the Great sent St. Augustine to England from Rome. Aethelberht I, king of Kent, founded St. Paul's Cathedral, and Mellitus was installed as bishop there in 604. By the late 7th century London had emerged again as a major trading centre. Reinterpreting evidence from various excavations, archaeologists now argue that in the 8th century there was

Londinium, c. AD 200.

a large and apparently densely built-up settlement (at least 150 acres) of craftsmen and traders just upstream of the depopulated Roman city and extending inland to what is now Trafalgar Square. The settlement was called Lundenwic; however, virtually nothing is known about this phase of London's history until the time of Alfred the Great (849–899) and the wars with the Danes, who invaded England in 865. A little farther west a church was founded on marshy Thorney Island in 785, later to be replaced by a great abbey (the Westminster) built at the behest of the pious Anglo-Saxon king Edward the Confessor.

Medieval London. The city's future importance as a centre of financial and military—and therefore political—power became clear at the time of the Norman Conquest (1066). One of the first acts of William I the Conqueror was to accord a charter promising the citizens of London that they should enjoy the same laws as under Edward the Confessor and that he would suffer no one to do them wrong. Just outside the city walls he established the Norman keep (the White Tower), which was the central stronghold of the fortress-castle known as the Tower of London. A roughly square (118 by 107 feet) structure, the White Tower is 90 feet high, with a tower at each corner of the walls. When in the late 12th century King Richard I returned from the Third Crusade with a new concept of fortification, he began surrounding the keep with concentric systems of curtain walls with towers at intervals, a project completed by Henry III (ruled 1216–72). Because virtually every reign since then has added its contribution, the Tower incorporates architecture from many periods. An official royal residence through the reign of James I in the early 17th century, it has also housed the Royal Mint, the Royal Menagerie, the public records, an observatory, an arsenal, and a prison. Some executions took place within the confines of the Tower, but most were carried out on Tower Hill just beyond. The Crown Jewels are now on display in the Tower, as is a superb collection of arms and armour.

The Tower of London

The Norman kings selected Westminster as the site for their permanent residence and government. Edward the Confessor (ruled 1042–66) constructed an enormous church dedicated to St. Peter (and later referred to as Westminster Abbey) as well as a royal palace. The ancient "city" of London, meanwhile, reestablished its role as a centre of trade. In 1085 London had between 10,000 and 15,000 inhabitants (less than 2 percent of England's population) and was the largest city in Europe north of the Alps. About 1087 a major fire destroyed many of the city's wooden houses and St. Paul's. In the rebuilding, houses of stone and tile began to appear, and some streets were partially cleansed by introducing open sewers and conduits, but wooden houses remained the norm. By 1200 the city and its suburbs involved a jurisdiction covering 680 acres (about 275 hectares)—which still defines the official limit of the City of London—and contained a population of 30,000 people. Between 1050 and 1300 construction of quays on the northern banks of the Thames led to the waterfront being extended southward by some 100 yards (90 metres). A colony of Danish merchants was outnumbered by Germans, who had their own trading enclave, the Hanseatic Steelyard, on the waterfront until they were expelled in 1598. Other important trading groups, who assimilated easily into London's population, were the Gascons, Flemish, and northern Italians. When members of the last group were firmly established as bankers, the Jews, who had arrived with the Normans, were banished in 1290; they were not to return until 1656.

In 1300 London had about 80,000 inhabitants that were provisioned by a food-supply network extending 40–60 miles into the surrounding countryside. The city also drew "sea coal" from Newcastle-upon-Tyne (300 miles distant by sea), and air pollution became a problem in London. The dynamism of this period came to a sudden end with the outbreak of the Black Death in 1348–49, with 10,000 Londoners being buried beyond the city walls at West Smithfield. Recovery of urban life was to prove a slow process.

By astute purchase from needy monarchs, the guilds—100 of them by 1400—were able to buy increasing freedom from royal intrusion in their affairs and further their self-government. The first mayor of London, Henry Fitzailwyn, probably took office in 1192. The first evidence of a Court of Common Council dates from 1332. Since disorder in the realm provoked unrest in the city, London usually supported strong, orderly government, especially in such crises as the deposition of Edward II (1327) and

The Royal Naval College on the Thames at Greenwich. Begun in the 1660s as a palace for Charles II, it was completed as a naval hospital from designs by Sir Christopher Wren; it became the Royal Naval College in 1873. At centre, between Wren's twin domes, is the Queen's House (now part of the National Maritime Museum).

Richard II (1399), the Peasants' Revolt in 1381, and the rebellion headed by Jack Cade (1450).

Tudor London. By 1520 London was again enjoying prosperity, with 41 halls of craft guilds symbolizing that well-being. Toward the middle of the 16th century London underwent an important growth in trade, which was boosted by the establishment of monopolies such as those held by the Muscovy Company (1555), the Turkey (later Levant) Company (1581), and the East India Company (1600). It also grew in population, with the number of Londoners increasing from over 100,000 in 1550 to about 200,000 in 1600. The additional population at first found living space in the grounds of the religious institutions seized during the Reformation by Henry VIII (after 1536).

Relief for the poor

To fill the void left by the cessation of the religious charities, the city organized poor relief in 1547, providing grain in times of scarcity and promoting the foundation or reconstitution of the five royal hospitals: St. Bartholomew's, Christ's, Bethlehem (the madhouse known as Bedlam), St. Thomas's, and Bridewell. Many of the private charities founded at this time are still in operation.

The population of the City and its surrounding settlements had reached 220,000 by the early years of the 17th century despite laws that attempted to contain the size of the capital. Indeed, the City Fathers (members of the Court of Common Council), tried to stop the subdivision of old houses into smaller, densely packed dwellings (a process known as "pestering"). New industries, including silk weaving and the production of glass and majolica pottery, were established, often outside the gates in order to avoid the restrictive regulations of the livery companies, which were successors of the craft guilds and were so named because of the distinctive clothing of their members. Slaughterhouses and numerous polluting industries were sited beyond the walls, especially to the east. The establishment of Henry VIII's naval dockyard at Deptford on the south bank was accompanied by a straggle of waterfront hovels on the north bank at Wapping.

When Henry VIII in 1529 began to convert Cardinal Wolsey's York Place into the royal palace of Whitehall and to build St. James's Palace across the fields, the City of Westminster began to take more definite shape around the court. Between Westminster and the City of London the great houses of nobles began to be built, with gardens down to the river and each with its own water gate. Along the Strand opposite these houses were distinguished lodgings for gentlemen who were in town during legal sittings. By the early 17th century the name London began to embrace both the City of London and the City of Westminster as well as the built-up land between them, but the two never merged into a single municipality.

The reign of Elizabeth I (1558–1603) arguably marked the apogee of the city's domination of England. The queen based her strength on its militia, its money, and its love. It provided one-quarter of the men for service abroad in 1585 and formed its armed "trainbands" (trained bands) to defend England against the threatened Spanish invasion.

17th-century London. The trainbands remained a force to be reckoned with, and Charles I, who had damaged the City's trading interests and flouted its privileges as cavalierly as he had Parliament's, was deterred from attacking London in 1642 by their presence at Turnham Green. Hostility toward the king made the fortified City the core of parliamentary support, and Parliament's success in the Civil Wars was due in good part to City allegiance.

In the early 1630s the 4th Earl of Bedford began developing Covent Garden, originally the convent garden of the Benedictines of Westminster, thereby initiating the process of building estates of town houses on land acquired from former religious houses.

The Great Fire

In 1664–65 the plague, a frequent invader since the Black Death of 1348, killed about 70,000 Londoners. In 1666 the Great Fire of London burned from September 2 to September 5 and consumed five-sixths of the City. St. Paul's Cathedral, 87 parish churches, and at least 13,000 dwellings were destroyed, but there were only a few human fatalities. Because reconstruction had to be undertaken rapidly, adoption of a rational street plan was rejected, but the old streets were made wider and a bit straighter. Between 1667 and 1671 most of the houses were rebuilt (in brick since half-timbering was no longer allowed). Because many of the tiny parishes were combined and a few churches had escaped the fire, only about 50 churches were rebuilt, in addition to a new St. Paul's. Sir Christopher Wren, mathematician, astronomer, and physicist, though only informally trained as an architect, was given the formidable task of designing them and supervising their construction.

There is a famous inscription by Wren's son in St. Paul's Cathedral, addressing the visitor in the following words: *Lector, si monumentum requiris, circumspice* ("Reader, if you seek a memorial, look about you"). Much of the historic legacy of the City is in fact Wren's memorial. His churches are a series of virtuoso variations on basic architectural concepts. They range in style from the homely Dutch to the Gothic, but most of them embody his own conception of the classical style. The dome of St. Paul's is one of the most perfect in the world and, like the rest of the cathedral, is classical in theme with Baroque grace notes. The Monument for the Great Fire was adapted from a Wren design and erected near Pudding Lane, where the fire had started in the house of the king's baker. Wren constructed four other churches outside the City, built the Royal Hospital located in Chelsea, and designed parts of Kensington Palace, Greenwich Hospital, the Royal Observatory of Greenwich, and Hampton Court Palace.

Under Charles II royal abrogation of City rights was resumed, and, although James II restored forfeited City charters before his flight to France in 1688, it was in Guildhall under protection of the trainbands that the lords spiritual and temporal met to declare allegiance to William, the Dutch Prince of Orange (thenceforth known as William III of Great Britain).

To support the War of the Grand Alliance (1689–1713),

Aspects of the City's power

City merchants in 1694 formed the Bank of England, and thenceforth the City's money market became a prime factor in the affairs of state. Another aspect of the City's power in the nation was the centring of the national press in Fleet Strect (*The Times*, founded in 1785 off Blackfriars Lane, moved to new premises only in 1974). Finance, commerce, and port activities dominated the City and eastern London, while expansion of government and the attractions of fashionable society stimulated development of the West End.

As London continued to grow, the greater part of the metropolis lay outside the boundaries of the City. Whereas in 1550 75 percent of Londoners had lived under the Lord Mayor's jurisdiction, by 1700 (when there were 500,000 Londoners) only 25 percent did so, and in 1800 (1,110,000) the proportion was only 10 percent. Starting with Westminster Bridge (1750), half a dozen new bridges were built over the Thames, allowing new areas to be built up to the south. Important expansion occurred around the docks to the east as well as to the north and in the fashionable west. The rapidly expanding capital was governed by a patchwork of authorities, some of which were very ineffective. By 1700 London had overtaken Paris in population.

EVOLUTION OF THE MODERN CITY

18th-century London. By 1820, when George IV succeeded to the throne, many of the villages and hamlets that in the 17th and 18th centuries had been the destination of summer outings from the heart of the city had been covered by a tide of bricks and mortar. Some of the building was the well-planned work of great landowners; some, however, was the sorry work of the small or greedy. The Bedford, Portman, and Grosvenor estates, laid out on land that had passed from the monasteries into the hands of noble families, produced streets and squares that embellished the western part of town. On the other hand, to the east, parts of Stepney and Bethnal Green were constructed with ill-built cottage terraces. Agar Town and Somers Town, which lay near the modern King's Cross and St. Pancras railway stations, were very poorly built.

The changes brought during the years 1689–1820 followed no conscious plan. The government of the City was in full control and reasonably active within its jurisdiction. Beyond its boundaries, unchanged since the Middle Ages, government services and communications for the new areas came piecemeal. Important developers obtained local acts of Parliament enabling them to levy rates out of which to finance paving, lighting, cleansing, and the watch (a group of persons charged with protecting life and property). Because the popularity of the developers' streets depended in part on such services, they were usually adequately administered. Lesser developers left a legacy of slums and neglect for later generations to clear and repair.

Services for London's new areas

Socially, commercially, and financially, London was the hub of the kingdom. It was also the centre of the world economy from the late 18th century to 1914, having taken over that role from Amsterdam. As a corollary to its great wealth, fed by the profits of the trade with the East and West Indies and with the Americas—indeed with most of the world—it reigned supreme in matters of the theatre, literature, and the arts. Eighteenth-century London was the city of David Garrick, Oliver Goldsmith, Samuel Johnson, and Sir Joshua Reynolds; of the great furniture makers and silversmiths; and of renowned foreign musicians, including George Frideric Handel, Joseph Haydn, and Mozart. London experienced important growth throughout the 19th century, with its total population exceeding 2,685,000 in 1851, the year of the Great Exhibition staged in Hyde Park to celebrate the commercial might of Britain and its empire. Fifty years later London's population reached 6,586,000, and the metropolis housed one-fifth of the population of England and Wales.

Organization, innovation, and reform. But the city's massive size brought increasing problems. Although new dispensaries and new or enlarged hospitals were reducing mortality, the former riverside town required new forms of government, communication, and sanitation if it was to continue to grow. These were slowly and painfully introduced between 1820 and 1914, and the innovations came piecemeal. In 1829 a centralized Metropolitan Police force was provided, under the ultimate control of the home secretary, in place of the uncoordinated watchmen and parish constables. The lighting of streets by feeble oil lamps was revolutionized by the introduction of gas, and soon the Gas-Light and Coke Company (1812) was followed by similar companies scattered throughout London. Omnibuses (1829) began a revolution in passenger transport, and carriage by rail came less than 10 years later.

In 1842 an inquiry into public health exposed London's many deficiencies. Cholera in 1831–32 had caused the deaths of about 6,000 Londoners, and there were further outbreaks in 1848–49, 1854, and 1866. Legislation was passed in 1852 to assist provision of pure water. In 1854 the physician John Snow demonstrated the water transmission of cholera by analyzing water delivered by various private pumps in the Soho neighbourhood to a public pump well known as the Broad Street Pump in Golden Square. He arrested the further spread of the disease in London by removing the handle of the polluted pump. A statute of 1855 (the Metropolis Management Act) combined a number of smaller units of local government and replaced the medley of franchises with a straightforward system of votes by all ratepayers. Major works, such as main drainage and slum clearance, were put in the hands of the Metropolitan Board of Works.

The momentum of these changes, created by such reformers as Bishop C.J. Blomfield, Sir Robert Peel, Edwin (later Sir Edwin) Chadwick, and the Earl of Shaftesbury, continued throughout the century. New churches, new schools, better law and order, main drainage, pedestrian tunnels under the Thames, and care for social outcasts were some of the reformers' legacy. Their most visible bequests were Trafalgar Square, the Embankment, and roads, such as Shaftesbury Avenue and Charing Cross Road, driven through the worst of the slums. On another level, the School Board for London, established under the Education Act of 1870, set about the task of providing elementary education for all. Changes in local government continued, if not so drastically. The London County Council superseded the Metropolitan Board of Works in 1889, areas supervised by the vestries were reorganized into metropolitan boroughs by the London Government Act (1899), and various water companies were combined in 1902 into a publicly owned Metropolitan Water Board.

Public and private works continued to transform the appearance of London. The opening of the Metropolitan Line, a steam railway, in 1863 and the construction of Holborn Viaduct in 1869 were accompanied by the building of new Thames bridges and the rebuilding of Battersea, Westminster, and Blackfriars bridges. After years of discussion and agitation, the road bridges outside the City passed into public ownership, and the tollgates were removed. Main line railway termini were built on the edge of the built-up area (Paddington, Euston, St. Pancras, King's Cross), but eventually most of the railways from the south carried their lines across the Thames to the central business district on the north bank, with termini at Victoria, Charing Cross, Blackfriars, and Cannon Street. It was an era in which an abundance of initiative and capital was joined to abundant labour to make the widest use of new skills, cheap transport, and copious raw materials.

Railways and bridges

Technical progress continued gradually to alter the lives of Londoners and the appearance of the town. Cheap suburban train services enabled artisans or clerks to live farther and farther from their workplaces. Trams or streetcars (horse-drawn), after an unsuccessful beginning in 1861, became important in the 1870s and a major factor in metropolitan transport as their electrification developed in the early years of the 20th century. By then electricity was being used as the motive power for traffic below ground; the Prince of Wales (later Edward VII) opened the world's first electric underground railway, from King William Street in the City to Stockwell in the south, on Nov. 4, 1890. With the arrival, in 1897, of the gasoline-driven omnibus, transport in modern London was enhanced and the way opened for still faster development of suburbia. This was to be associated with the construction

of additional underground railway lines (especially north of the Thames) and the electrification of surface railway lines serving south London. The most celebrated suburban development involved what was to be known after 1915 as "Metroland" along the Metropolitan railway to the northwest of the capital.

Such changes were accompanied by rising land values in the central zone, by the construction of ever larger offices, factories, and warehouses in place of small houses, and by a continuous outlay of public and private funds on better housing and on street improvements. World War I, in which air raids inflicted some 2,300 casualties on London, brought only a temporary pause, and development resumed on a mounting scale after the war. The First British Empire Exhibition, held at Wembley in 1924–25, proclaimed the recovery of the nation and its colonies after the Great War. As a national and in some respects a world capital, London required institutions capable of meeting its needs. An era of amalgamation and expansion ensued, affecting almost all institutions. The docks continued to be enlarged, with London's last great enclosed dock (the King George V Dock) being opened in 1921. Street congestion increased, despite the rationalization of traffic authorities. By 1939 the population of the Greater London conurbation had risen to 8.6 million.

Era of amalgamation and expansion

Reconstruction after World War II. London suffered widespread damage during World War II as a result of aerial bombardment, which devastated the docks and many industrial, residential, and commercial districts, including the historic heart of the City. About 30,000 Londoners died because of enemy action in the skies above the capital, and a further 50,000 were injured. The end of hostilities brought a return of evacuees, and reconstruction of the city began at once even though building materials were in desperately short supply. During the war the Greater London Plan (1944) had been prepared as a blueprint for reconstruction and also for relocating some Londoners and their jobs in new towns around the capital and in "assisted areas" in parts of the English provinces. Construction of new housing was discouraged and tightly controlled in a Green Belt around London, and the subsequent dispersed growth of the metropolis occurred in more distant sections of southeastern England. The New Towns Act (1946) gave rise to eight new settlements outside the metropolis. Passage of town and country planning acts, notably in 1947 and 1968, gave municipal authorities unprecedented powers of land purchase and control over development in London. The Festival of Britain (1951) proclaimed national recovery and produced the Royal Festival Hall on the south bank of the Thames as well as Lansbury Estate (a redevelopment area in Poplar). However, severe air pollution from coal-burning domestic hearths and industrial chimneys contributed to the great "smog" in 1952, which played a part in the death of 4,000 Londoners.

During the subsequent quarter century there was vast investment in slum clearance, construction of new houses and apartments, and improvement of services. Urban planning was more widely accepted, together with a broad policy to divert a share of employment and housing to localities beyond London's continuously built-up area. As a result, the number of residents in greater London contracted from about 8,193,000 in 1951 to about 6,600,000 in 1991; however, growth continued in outer parts of the southeast.

The port of London, which had been devastated during World War II, was restored in the 1950s. However, between 1968 and 1981 the city's docks were closed to traffic because of their small size, difficult labour relations and poor management, and powerful competition from major ports in continental Europe, especially Europoort in Rotterdam, Neth. During the 1980s the London Docklands Development Corporation encouraged major changes in Docklands, including construction of new housing and a large number of new offices (notably at Canary Wharf). London had experienced substantial deindustrialization by this time, with old industries that had been installed in Victorian times collapsing and many newer industries, dating from the interwar years and located along radiating main roads laid out in those decades, sharing the same fate. London's economy had become increasingly geared to financial transactions and many other kinds of service activity. These sectors of the economy were strengthened by legislative changes in the mid-1980s affecting financial dealings. In consequence, the townscape of many parts of the City and the West End was transformed as vast new office complexes were constructed. Notable examples are Broadgate, on the site of the former Broad Street station, London Bridge City alongside the Thames, and the new Lloyd's building. In addition, London's airports at Heathrow and Gatwick were expanded, a major new airport opened at Stansted (30 miles north of the City), and a small airport for flights to western Europe began operating in Docklands. Completion of the M25 orbital motorway enabled vehicles to pass around the capital rather than move through it. However, road congestion remained a major problem, with even the M25 seriously overloaded with traffic. (B.E./H.D.C.)

New office complexes

ROY PORTER, *London: A Social History* (1994), provides an account of the capital from medieval times to the present. FELIX BARKER and PETER JACKSON, *London: 2,000 Years of a City and Its People* (1974, reissued 1984), provides a well-illustrated discussion of a broad time span. RALPH MERRIFIELD, *London: City of the Romans* (1983), presents recent archaeological discoveries. CHRISTOPHER N.L. BROOKE and GILLIAN KEIR, *London, 800–1216: The Shaping of a City* (1975), deals with political and economic changes in the early medieval period. MARY D. LOBEL and W.H. JOHNS (eds.), *The City of London from Prehistoric Times to c. 1520* (1989), contains scholarly essays and a number of extremely detailed maps. SYLVIA L. THRUPP, *The Merchant Class of Medieval London, 1300–1500* (1948, reprinted 1989), remains the classic scholarly study of the socioeconomic life of London's commercial elite. GERVASE ROSSER, *Medieval Westminster, 1200–1540* (1989), provides a detailed analysis of London's western settlement during its important medieval formative phase. JOHN SCHOFIELD, *The Building of London: From the Conquest to the Great Fire,* rev. ed. (1993), traces changes in the growth and internal character of the city over a wide period. JOHN STOW, *A Survey of London,* ed. by CHARLES LETHBRIDGE KINGSFORD, 2 vol. (1908, reprinted 1971), contains Stow's text of 1603 with additional notes tracing his sources of information. NORMAN BRETT-JAMES, *The Growth of Stuart London* (1935), is a well-referenced work based largely on original sources. T.F. REDDAWAY, *The Rebuilding of London After the Great Fire* (1940, reissued 1951), discusses the economic and social forces that shaped the rebuilding. M. DOROTHY GEORGE, *London Life in the XVIIIth Century* (1925, reissued 1984), chiefly records the life and work of poorer Londoners, using many quotations to provide contemporary points of view. JOHN SUMMERSON, *Georgian London,* new ed. (1988), a scholarly study, deals with the great estates and architecture of 18th-century London. DONALD J. OLSEN, *The Growth of Victorian London* (1976), well illustrated, discusses the key aspects of metropolitan growth during the 19th century. ANDREW SAINT (ed.), *Politics and the People of London: The London County Council, 1889–1965* (1989), contains thematic discussions of the important activities of the Council. (H.D.C.)

Los Angeles

A semitropical southern California metropolis of palm trees and swimming pools, television studios and aerospace factories, Los Angeles has become the second most populous city and metropolitan area (after New York) in the United States. The city sprawls across some 464 square miles (1,202 square kilometres) of a broad coastal plain agreeably situated between the San Gabriel Mountains on the east and the Pacific Ocean on the west. Its hallmark is an architecturally dramatic network of freeways. The automobile so dominates life in this uniquely mobile community that Reyner Banham, an English observer who took his cue from scholars who study Italian in order to read Dante, is said to have learned to drive a car so he could "read Los Angeles in the original."

The city is the seat of Los Angeles county, which contains more than 80 other incorporated cities, including Beverly Hills, Pasadena, and Long Beach, within its 4,081 square miles. The county also encompasses two channel islands, Santa Catalina and San Clemente; a mountain peak, Mount San Antonio, familiarly known as Old Baldy, 10,080 feet (3,072 metres) high; more than 900 square miles of desert; and 75 miles (140 kilometres) of seacoast. The metropolitan area has paid for its spectacular growth by acquiring such urban attributes as smog-filled skies, polluted harbours, clogged freeways, crowded classrooms, explosive ethnic enclaves, and annual budgets teetering on the brink of bankruptcy. Since the city and the county are so intertwined physically and spiritually, any consideration of Los Angeles must move back and forth between the two entities.

Angelinos live in enclaves walled off from one another by ethnic, cultural, and economic differences. They go their own way, surfing, riding, skiing, yachting, hiking, playing golf and tennis. Nowhere in the world is the pursuit of happiness more unabashedly hedonistic, and, perhaps, no city in modern times has been so universally envied, imitated, ridiculed, and, because of what it may portend, feared. As early as 1927 it was recognized by Bruce Bliven as "a melting pot in which the civilization of the future may be seen bubbling darkly up in a foreshadowing brew."

This article is divided into the following sections:

Physical and human geography

THE LANDSCAPE

The city layout. The city is grotesquely shaped, like a charred scrap of paper, with independent municipalities such as Beverly Hills and Culver City as well as unincorporated county land lying within its boundaries. Elevation averages about 275 feet, ranging from sea level to 5,082 feet at Mount Lukens (also called Sister Elsie Peak). The Santa Monica Mountains, covering an area of 92 square miles and reaching heights of 3,000 feet, bisect the city, separating Hollywood, Beverly Hills, and Pacific Palisades from the southern boundary of the San Fernando Valley (the Valley: home to "Valley girls"), a 220-square-mile area with such suburban communities as Burbank, Glendale, North Hollywood, Studio City, Sherman Oaks, Encino, Tarzana, Woodland Hills, and the mission city of San Fernando.

The Valley's principal east–west artery, Ventura Boulevard, is a 17-mile bazaar of specialty shops, ethnic restaurants, banks, medical buildings, shopping malls, automobile agencies, and realtors' offices. In the 1920s it was a dirt road. The post-World War II boom turned it into the main street of what would now be one of the country's largest cities if the Valley were an independent entity.

Once the sanctuary for middle-class white families fleeing the city's congestion and racial tensions, the Valley has broken up most of its rural estates to make room for condominiums and shopping centres. Walnut orchards and truck gardens have given way to housing for blacks, Hispanics, and Asians who have gone to work in new plants ranging from basic industry to high technology. Burbank, long the butt of television comedians ("Burbank has a low suicide rate, because living in Burbank makes suicide redundant"), now proclaims itself the country's entertainment centre. It is home for recording companies, the National Broadcasting Company, and three major motion-picture studios (Walt Disney Productions, Warner Bros. Studios, and Columbia TriStar Television Division).

Hollywood, eight miles northwest of the central city, was laid out in 1887 by Horace Wilcox, a Prohibitionist, who intended his subdivision to be a sober, God-fearing community. In 1910, when its water supply ran low, Hollywood was gobbled up by Los Angeles. The following year Blondeau Tavern, at the intersection of Sunset Boulevard and Gower Street, was turned into Hollywood's first motion-picture studio—to be abandoned 60 years later when Columbia Pictures moved to Burbank. By then the stars had long since left Hollywood, many of them moving into secluded hillside mansions above Beverly Hills, the most famous of which was Pickfair, built by Douglas Fairbanks for Mary Pickford in 1919 (since demolished). This level of glamour has been eclipsed by such edifices as the 123-room mansion of television producer Aaron Spelling.

Climate. Coastal mountain ranges to the north and east act as buffers against extremes of summer heat and winter cold. Even in the hottest months, the humidity tends to be mercifully low and the nights cool. "Night and morning low clouds" is the most common summer forecast, with the sun breaking through in the afternoon. Pronounced climatic differences occur in different sections of the city. The San Fernando Valley is generally several degrees cooler in winter and warmer in summer than communities on the opposite side of the Santa Monica Mountains. The city's mean temperature is about 64° F (18° C). Daytime high temperatures can reach 90° F (32° C) in any month; on occasion nighttime lows approach freezing. The average annual rainfall is 14 inches (356 millimetres), with most of it falling in the winter months.

The city of Los Angeles and vicinity.

Environmental blessings and blights

Natural phenomena. *Smog.* Juan Cabrillo, California's first European explorer, reported "many smokes" in 1542 hanging over "a large bay," which was probably the future harbour of Los Angeles. Four centuries later, in September 1943, Angelinos had their first massive doses of air pollution. Southern California's highly publicized sunshine, they learned, was creating an inversion, a warm layer of air that clamped a lid on the cooler air of the saucer-like basin below.

The sun continues to cook the noxious vapours rising from factories and oil refineries, and, most of all, from the tail pipes of the county's millions of cars, vans, and trucks. After many years and the expenditure of billions of dollars, Angelinos have had to settle for measures designed not to make the air really clean but to keep it from getting appreciably worse. No significant curtailment of smog can be achieved, they have been told by the head of their urban air-pollution management agency, "without a major overhaul of the industrial and transportation structure, severe limits on growth, and a radical change in lifestyle."

Earthquakes. The great San Andreas Fault is 33 miles from downtown Los Angeles at its closest point, but more than 40 known lesser faults crisscross the metropolitan area. No earthquakes of major intensity—*i.e.*, higher than 7 on the Richter scale of 10—have hit southern California since the 1850s, but, aside from the periodic minor jolts that Angelinos take for granted, destructive temblors have struck Santa Barbara (1925), Long Beach–Compton (1933), and the San Fernando Valley (1971 and 1994).

Winds. The city is occasionally buffeted by a Santa Ana, a hot, dry wind named for the canyon through which it often blows. Santa Anas occur when air rushes down from the high inland plateaus and is heated by compression.

Angelinos are noticeably restless during a Santa Ana. The author Raymond Chandler wrote, "Meek little wives feel the edge of the carving knife and study their husbands' necks."

Fires. Dry winds whipping through narrow canyons on hot days heighten the ever-present danger of fire in the brush-covered mountains. Costly brushfires in 1961 destroyed 484 homes in Bel Air, an affluent west-side community; in 1993 brushfires throughout the Los Angeles region scorched 200,000 acres and destroyed more than 800 homes. Hillside homeowners run the risk not only of fire but also of mud slides when winter rains pelt canyon walls denuded by flames.

THE PEOPLE

When the city celebrated its bicentennial in 1981, whites had become a minority, as they had been when the city was founded. The 2000 census confirmed what everyday experience indicated, that Latinos had become the most numerous element of both the city and the county. Asians displaced African Americans as the third largest ethnic group. While some neighbourhoods retained an ethnic solidarity, the clearest dividing lines were along economic strata.

The changing ethnic mix

Latinos. As throughout the state, Latinos increasingly demanded their share of jobs, opportunities, and political clout. Long confined to barrios where gangs are plentiful, streets drug-infested, schools overcrowded, and housing substandard, the community began to rise to middle-class status as it dispersed over the county. As whites and African Americans left the city centre, their places were filled by waves of Spanish-speaking immigrants. The language barrier, long a bar to social and economic progress, was becoming less of an impediment.

Asians and Pacific Islanders. In the late 1970s, the city's growing Asian and Pacific Island population helped to resettle refugees from Vietnam, Cambodia, and Laos. Little Tokyo, a few blocks from City Hall, has been the country's largest mainland concentration of Japanese Americans since the early 1900s. During World War II some 40,000 southern Californians of Japanese ancestry were placed in isolated detention camps. For two decades following their release, Little Tokyo languished, but in the 1980s it blossomed once again, redeveloped largely with capital from Japan. In both the city and suburbs, the distinctive Hangul signs announcing Korean businesses and restaurants could be seen.

African Americans. Although 26 of the city's 44 founders were of African ancestry and the granddaughter of a black tailor at one time owned the land now occupied by Beverly Hills, there were only 38,894 black Angelinos in 1931. Sixty years later, streams of blacks, mostly from the rural South, had raised the figure to about 500,000. By 2000, few solidly black communities remained in the central city, and the proportion of African Americans had dropped to about one-tenth of the overall population.

Watts, the 2.5-square-mile core of what was then the city's south-central black ghetto, exploded on a hot summer night in August 1965. The flames of Charcoal Alley gave whites a glimpse of the misery and anger of rural blacks trapped in an urban slum. After six days of burning and looting, 34 people were dead and 1,032 wounded and 3,952 had been arrested. Racial tensions erupted again into riots in 1992 after police were cleared of criminal charges in the beating of Rodney King; the episode had been caught on videotape and was endlessly replayed, fueling outrage. The community's interaction with police had long been a sore point, but the rage was turned against businesses and hapless civilians caught in the rampage. The riot resulted in 52 deaths and $775 million in property damage.

THE ECONOMY

Once a land of vineyards, orange groves, and dairy farms, Los Angeles has become the nucleus of a vast industrialized urban area radiating from the city's bustling financial district. If this "Golden Circle" were a separate country, its gross national product would be among the highest in the world.

Agriculture. While its population rose almost 50 percent in the 1950s, Los Angeles county sacrificed 3,000 acres (1,200 hectares) of farmland a day to the bulldozer (freeways alone consumed about 40 acres per mile), and it ceased to be the nation's wealthiest agricultural county. Agriculture nonetheless continues to play a role in the county's economy; principal crops include nursery and greenhouse plants, vegetables, fruits, nuts, seeds, and hay.

Services. The service sector is the primary factor in the Los Angeles economy. Business and professional management services, health services and research, and finance are important, as are trade and tourism.

Industry. Before World War I, San Francisco was the state's manufacturing hub, but since the 1920s it has been far outstripped by Los Angeles. Major products include aerospace equipment (although cuts in federal defense spending reduced this industry in the 1990s), petroleum and refining, processed food, electronics, medical equipment, aluminum, furniture, automotive parts, and toys. Apparel design and production is a primary industry (and high-end shopping is a favourite pastime). High-technology industries—including the manufacture of computers, communications equipment, missiles, and space vehicles as well as computer software development—have become important to the modern economy.

Aviation. The first international air meet in the Western Hemisphere was held on the outskirts of Los Angeles in 1910. A dozen years later Donald W. Douglas was turning out an airplane a week in his Santa Monica plant. One-third of the nation's World War II military aircraft were built in the Los Angeles area. The city's preparation for the 1984 Summer Olympics included a major refurbishing of its international airport.

Oil. Los Angeles sits on one of its major resources, as Edward L. Doheny demonstrated in 1892 when he started selling local crude oil for industrial fuel. In 1921, after the automobile had created a ravenous appetite for petroleum products, the world's richest deposit in terms of barrels per acre turned up on Signal Hill. In its first half-century its 2,400 wells produced 859,000,000 barrels of oil.

James Randklev—Shostal Assoc.

The campus of the University of California at Los Angeles.

Motion pictures. Generations of moviegoers have looked up to Los Angeles as the world's film capital. It still plays a leading role in the motion-picture, television, radio, and recording industries, although some major studios have disposed of their valuable real-estate holdings. The back lot of the 20th Century-Fox Film Corporation was converted to Century City, a multimillion-dollar "instant city." The filmmaking activities at Universal Studios in the San Fernando Valley are a popular attraction for the area's millions of visitors each year.

Demise of the urban transit system

Transportation. The vast majority of Angelinos working in the metropolitan area drive to their jobs in a car, van, or truck, while only a small percentage use public transportation. A light rail and subway system was begun in the late 1980s; its first segment opened in 1990. Ironically, much of the city's astonishing growth in the early 1900s was due to the superb interurban transit service provided by the big red electric cars of the railroad magnate and art collector Henry E. Huntington. The system became a freeway casualty beginning in the early 1940s.

The Port of Los Angeles is one of the busiest in the nation and the world. Located in San Pedro Bay, about 20 miles south of downtown, its international trade includes automobiles, furniture, apparel, paper products, chemicals, and grains. It is also an important cruise-ship port. Main trading partners are Japan and China. Los Angeles International Airport began as an airfield in 1928 and started commercial airline service in 1946.

The communications media. The city's first newspaper, the *Star,* began weekly publication in 1851. Thirty years later the *Los Angeles Times* published its first issue. Acquired the following year by Gen. Harrison Gray Otis, it became the bible for the city's boosters, conservative Republicans, and antilabour forces. When it passed into the hands of Otis' grandson, Otis Chandler, in the 1960s, it took a more liberal and worldly stance. After the demise in 1989 of its afternoon rival, the *Herald-Examiner,* the San Fernando Valley's *Daily News* became its chief competitor. More than two dozen of the area's radio stations broadcast in languages other than English. The Spanish-language television station KMEX holds its own against network stations.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. The city's mayor and its 15 council members are elected to four-year terms, along with the city attorney, controller, and the seven-member board of education. The county is run by a five-member board of supervisors serving four-year terms. They preside over a jurisdictional jungle of overlapping city-county agencies.

Institutions of higher learning

Education. There are about 20 junior colleges in the county and five state colleges. The area's two oldest institutions of higher learning are the University of Southern California (USC; 1880) and Occidental College (1887). USC is noted especially for its schools of law, medicine, dentistry, engineering, and performing arts. The state-supported University of California at Los Angeles (UCLA; 1919) has a wide range of undergraduate and graduate offerings, with a particularly heavy commitment to the life and geophysical sciences and the arts. California Institute of Technology, founded in 1891 as Throop Polytechnic Institute, moved to its present location in Pasadena in 1910. Researchers there conduct probes of outer space in conjunction with the Jet Propulsion Laboratory and the Mount Wilson Observatory.

RECREATION AND CULTURAL LIFE

Parks. Hancock Park, the 23-acre site of the Rancho La Brea pits, was given to the county in 1916 by G. Allan Hancock, an oil magnate. Excavations between 1906 and 1913 of the black, bubbling pools had revealed a unique repository of fossilized skulls and bones of long-extinct mammals trapped in the seepage of *brea,* or "tar" (actually asphalt). In addition to the tar pits, the park features life-size figures of such creatures as the imperial mammoth, the American mastodon, the sabre-toothed tiger, the ground sloth, and the short-faced bear.

Griffith Park is spread across some six square miles of rugged mountains, an area larger than Beverly Hills. Mule deer wander down from the hillsides to peer at the exotic creatures in the city's 80-acre zoo. Within easy reach of the city by freeway are such commercial ventures as Disneyland, Knott's Berry Farm, and Magic Mountain.

Sports. Intercollegiate athletics is highlighted by the intense USC-UCLA rivalry. The annual New Year's Day Rose Bowl football game is played in Pasadena. Angelinos also support professional major-league teams in baseball, football, basketball, ice hockey, and association football (soccer). There is horse racing at Santa Anita Park and Hollywood Park.

Historic landmarks. Angelinos have held onto little of their Spanish-Mexican past, but largely through the efforts of Charles F. Lummis, a colourful turn-of-the-century editor and writer, the missions of San Gabriel Arcángel (1771) and San Fernando Rey de España (1797) have been preserved. Olvera Street, a narrow, block-long string of Mexican shops, cafés, and the Ávila family's adobe townhouse (*c.* 1818), has been a popular tourist attraction since its opening in 1930. It is now part of El Pueblo de Los Angeles Historic District, an area of some 40 acres, which includes the plaza where the city got its start and the first church its residents built (dedicated in 1822, rebuilt in 1861–62).

The three Towers of Simon Rodia (99, 97, and 55 feet high), better known as the Watts Towers, were built of broken tiles, dishes, bottles, and seashells over a 33-year period by Rodia, an unschooled Italian immigrant who later explained, "I had in mind to do something big, and I did." When his work was completed in 1954, he gave the property to a neighbour and left, never to return.

The city's early 20th-century Mission-style architecture gave way to the wood-sheathed California bungalow modeled on the work of Charles and Henry Greene, whose 8,000-square-foot Gamble House, built in Pasadena in 1908, is now used as a study centre for student architects and designers. Frank Lloyd Wright received several commissions in southern California in the early 1920s following completion of Hollyhock House in what is now Barnsdall Art Park. R.M. Schindler helped supervise the

project before setting out to build his own masterpieces. Irving Gill is generally regarded as the city's most neglected architect. Richard Neutra's steel-frame Lovell House, built in the late 1920s, stands as a monument to the International Style; striking structures by Richard Meier and Frank Gehry set the tone for the last quarter of the 20th century.

One of the delights of downtown Los Angeles is the Bradbury Building (1893). Sunlight warms and illuminates the five-story inner court with its delicate French ironwork, Belgian marble, and Mexican tile. Union Station (1939), among the last of the country's railroad cathedrals, is a charming interpretation of Spanish Mission architecture. The city's Central Library (1926), incorporating Egyptian motifs, was the last building designed by Bertram Goodhue, whose low, buff-coloured, stuccoed building recalls the work of Irving Gill, although the basic form was Beaux-Arts. After two fires in 1986, a new wing was built, doubling the library space, and a striking eight-story atrium was added.

The arts. Los Angeles has from time to time sheltered outstanding composers and writers such as Igor Stravinsky, William Faulkner, F. Scott Fitzgerald, and Aldous Huxley. The city has been the subject of innumerable novels, the most durable of which appear to be Fitzgerald's *The Last Tycoon* (1941), Huxley's *After Many a Summer Dies the Swan* (1940), Evelyn Waugh's *The Loved One* (1948), and Nathanael West's *Day of the Locust* (1939). Crime novels set in Los Angeles abound. In addition to those by Raymond Chandler and Ross Macdonald, the Easy Rawlins series by Walter Mosley, set in Watts, is notable for its sense of time and milieu and its African American protagonist. The city is also well known to the world's book collectors for the works of such fine-printers as Saul Marks, Grant Dahlstrom, and Ward Ritchie.

Los Angeles has developed a lively marketplace for works of art. Many of its leading galleries are scattered among the fine restaurants, antique shops, and rare book stores on La Cienega and Melrose boulevards in West Hollywood.

Performing arts

The performing arts are housed at the Music Center, which includes the elegant Dorothy Chandler Pavilion, home of the Los Angeles Philharmonic Orchestra; the Ahmanson Theater, used for plays, musical comedies, and light operas; and the cake-shaped Mark Taper Forum, designed for experimental stage productions. The Los Angeles Opera opened in 1985, filling a long-felt need. There is no resident ballet company, but visiting companies regularly perform at the Music Center, and Los Angeles-based companies present performances of modern, tap, jazz, ethnic, and experimental dance.

The Hollywood Bowl, a natural amphitheatre in the Hollywood Hills, offered its first production, *Julius Caesar*, on May 19, 1916, and initiated its programs known as Symphonies Under the Stars in 1922. The out-of-doors Greek Theatre in Griffith Park provides a wide range of summer entertainment, mostly musical. The Universal Amphitheatre in Universal City has offered year-round entertainment since it reopened in 1982 with a dome covering its seats. The Shubert Theatre in Century City is a few blocks from the massive 1880s New York set built for the motion-picture version of *Hello, Dolly!* (1969). Small, innovative theatres continue to spring up in the motion-picture capital.

Museums and libraries

The delightful California Science Center—an interactive facility, opened in 1998 in Exposition Park, not far from the Natural History Museum—is one of the largest natural history museums in the United States. Its unique fossil collection has been transferred to the Page Museum at La Brea Discoveries in Hancock Park. It shares the historic acreage with the Los Angeles County Museum of Art, which seems to float in the black pools of tar. Arata Isozake, a Tokyo-based architect, designed the red sandstone, aluminum, and glass Museum of Contemporary Art (MOCA), housing art from the 1940s to the present. Large-scale installations are displayed in MOCA's Geffen Contemporary venue. The Southwest Museum in Highland Park, devoted to Native American art and artifacts, has one of the country's richest collections of textiles, pots, baskets, photographs, and books in this field. A touch-and-play Children's Museum has enriched and enlivened the Civic Center, and a Junior Arts Center is part of the Barnsdall Art Park complex built around the Municipal Art Gallery.

Pasadena's Norton Simon Museum houses a notable art collection spanning 2,000 years. In nearby San Marino the Henry E. Huntington Library, Art Collection, and Botanical Garden is a hospitable, parklike retreat, where visitors are invited to enjoy its roses, camellias, desert plants, and Japanese Garden as well as its wealth of rare books, manuscripts, and British art works. The travertine-clad Getty Center, designed by Richard Meier, opened in 1998 on a 110-acre hilltop campus. The Center, funded by a $700,000,000 bequest from oil magnate J. Paul Getty, houses a world-class collection of fine and decorative arts and is a major tourist draw. In addition to local libraries in such cities as Pasadena, Santa Monica, Burbank, and Beverly Hills, Angelinos draw on the resources of the city's system and the county's regional and community libraries. UCLA has one of the country's finest academic libraries. The off-campus William Andrews Clark Memorial Library is noted for its John Dryden collection.

History

THE GROWTH OF THE METROPOLIS

The Spanish-Mexican town and city. On August 2, 1769, a Spanish expedition headed by Gaspar de Portolá, searching for mission sites, camped near a river they named the Porciúncula, in honour of Our Lady the Queen of the Angels of Porciúncula (Nuestra Señora la Reyna de los Angeles de Porciúncula). The area's first Europeans exchanged gifts with the peaceful, Uto-Aztecan-speaking peoples of the nearby village of Yang-na and left on the following morning. Despite three earthquakes during his overnight stay, Father Juan Crespi noted in his diary that "this delightful place among the trees on the river" had "all the requisites for a large settlement."

Early settlers

Two years later the Mission San Gabriel Arcángel was established about nine miles northeast of the campsite. A decade went by before Gov. Felipe de Neve succeeded in colonizing the fertile river basin with 44 recruits from Mexico, most of them of Native American and African descent. The illiterate settlers assembled on the west bank of what is now the Los Angeles River on September 4, 1781, to claim the land they had been promised. Little is known about the events of that momentous day, but mythmakers have cloaked the city's founding in a ceremonial splendour worthy of its destiny and its high-sounding name, which has long been confused with the name given the river. It is now generally agreed that the city's correct name is El Pueblo de la Reyna de Los Angeles ("The Town of the Queen of the Angels").

El Pueblo, as it was commonly called, remained so isolated from the United States during the settlement's formative years that Joseph Chapman, the first Yankee to become an Angelino, was thought of as an Englishman ("El Inglés"). An engaging pirate from Boston, Chapman landed in 1818 with a black fellow privateer, Thomas Fisher. The first outsider to arrive by way of the arduous overland route was a fur trapper, Jedediah Smith, who turned up in 1826, four years after an independent Mexico had hoisted its flag above El Pueblo.

Los Angeles, with a population of nearly 1,250, had become a *ciudad* (city) in 1835 when Richard Henry Dana looked in on it. "In the hands of an enterprising people," he mused in *Two Years Before the Mast* (1840), "what a country this might be." By the time war broke out between the United States and Mexico in 1846, the California capital was so overrun with enterprising people that Gov. Pío Pico felt helpless against "the hordes of Yankee immigrants," who were "cultivating farms, establishing vineyards, erecting mills, sawing up lumber, building workshops, and doing a thousand other things which seem natural to them, but which Californians neglect or despise." When American forces under Capt. John C. Frémont and Commo. Robert F. Stockton entered the city on August 13, 1846, not a shot was fired. A revolt was put down the following January, and on July 4, 1847, Los Angeles celebrated its first Independence Day.

The American city. Los Angeles was incorporated on April 4, 1850, and designated the seat of Los Angeles county. The lawless, adobe cow town—"gambling, drinking and

whoring are the only occupations," grumbled a pioneer physician in 1849—prospered in the wake of the Gold Rush when hungry miners in San Francisco and Sacramento gorged on beef from southern California. A catastrophic drought (1862–65) following several years of declining cattle prices brought an end to the era of the ranchos. Vast Spanish and Mexican land grants, mortgaged and bankrupt, their owners ignorant of *Yanqui* laws and *Yanqui* interest rates, were broken up, fenced, and planted by a new breed of Angelino. By 1860 the city had become so Americanized that it had banned bullfighting and formed a baseball club.

With the arrival of the railroads (the Southern Pacific in 1876, the Santa Fe in 1885), Los Angeles began to ship its oranges back east and, by means of a massive advertising campaign, to lure immigrants westward to the New Eden. Aided by a railroad rate war, the boom of the 1880s more than quadrupled the city's population, from 11,183 in 1880 to 50,395 in 1890. Father Crespi's campsite was overrun by shrewd, aggressive Yankee boosters determined to build a city in their own image and requiring only two things denied them by a bountiful providence: a harbour and an adequate water supply.

The search for a port and water

Unlike San Francisco and San Diego, Los Angeles has no natural harbour. A narrow, artfully gerrymandered "shoestring strip" connects the inland city with its port, 23 miles south of City Hall. Los Angeles acquired its two harbour communities, San Pedro and Wilmington, by consolidation in 1909 following an epic struggle between the powerful Southern Pacific Railroad interests and the Free Harbor League. Work began on the harbour in 1899. The opening of the first municipal wharf in 1914 coincided with the completion of the Panama Canal, which put the ports of the Atlantic seaboard some 8,000 miles closer to Los Angeles. Its harbour became the busiest on the West Coast.

In 1904, casting about for new sources of water to sustain the city's relentless growth, William Mulholland, water-bureau superintendent, explored the Owens Valley some 250 miles northeast of Los Angeles and returned with a bold plan for an aqueduct to carry melted snow from the southern slopes of the Sierra Nevada to Los Angeles faucets. The plan outraged Owens Valley ranchers, enriched two syndicates of Los Angeles speculators, gave rise to rumours of wrongdoing and, highly fictionalized, ended up on the motion-picture screen as *Chinatown* (1974).

"There it is; take it," Mulholland told the thousands of Angelinos who assembled on November 5, 1913, to watch the Owens River water come cascading into a San Fernando Valley spillway. The 233-mile-long aqueduct, with 142 separate tunnels totaling 52 miles in length, has been supplemented by a 105-mile extension into the Mono Basin. The system supplies 80 percent of the city's water needs. The remainder comes from local wells, the California Aqueduct, and the Colorado River.

A severe drought in 1976–77 gave Angelinos a foretaste of the time (1985) when their Colorado River water would, by court order, be shared with Arizona. Meanwhile, with rain and snow dumping about three-fourths of California's usable surface water in the north, while more than half of its people live in the south, the "water wars" between powerful corporate farmers and resourceful urban environmentalists continue to be fought out in the legislature, the courts, and the voting booth.

THE MODERN CITY

In the first decade of the 20th century, while San Francisco tidied up the rubble of its 1906 earthquake, Los Angeles tripled its population, from about 100,000 to nearly 320,000. One local entrepreneur opened the first motion-picture theatre in the United States, in 1902, and another built the city's first garage to accommodate its growing number of automobiles, but the parasol-shaded girls from the red-plush brothels run by Pearl Morton and Cora Phillips still drove about in open carriages, much to the distress of the retired druggists, dentists, and wheat farmers from the Midwest who kept streaming into Los Angeles.

"Virtue has become virulent," reported a writer in *Smart Set* (March 1913), who described an "overgrown village" swarming with "spiritualists, mediums, astrologists, phrenologists, palmists and all other breeds of esoteric windjammers." Successive waves of migratory writers, taking much the same tack, have stereotyped the city as an open-air institution for the eccentric.

The bizaare in the city

"Los Angeles represents the ultimate segregation of the unfit," Bertrand Russell declared, and Frank Lloyd Wright agreed. "It is as if you tipped the United States up and all the commonplace people slid down there into Southern California," he remarked in 1940, but within the next few years Los Angeles had become so overrun with such gifted European refugees as Heinrich and Thomas Mann, Arnold Schoenberg, Bertolt Brecht, Bruno Walter, Franz Werfel, Lion Feuchtwanger, and Alfred Neumann that the city had come to be dubbed "The Fourth Weimar Republic."

In the ensuing decades, Los Angeles prospered from its both natural and manmade attractions. When Disneyland opened in nearby Anaheim in 1955, it was an immediate hit and brought a new influx of tourism to the area. The 1984 Summer Olympic Games were a financial success, despite their being boycotted by communist nations in retaliation for the U.S. boycott of the 1980 Summer Games in Moscow. Los Angeles had also been host to the 1932 Summer Games.

But all is not perpetual sunshine: the city struggles with both natural and manmade disasters. An earthquake in January 1994, centred in the San Fernando Valley, resulted in some 60 deaths and the terrifying collapse of sections of major freeways. Forest fires and mud slides present a continual threat to multimillion-dollar houses. In 1999 and 2000 a police corruption scandal engulfed the city, and ethnic tensions are chronically close to a flash point.

BIBLIOGRAPHY. Introductions to the history of the city are JOHN CAUGHEY and LAREE CAUGHEY (eds.), *Los Angeles: Biography of a City* (1976); and JOHN D. WEAVER, *Los Angeles: The Enormous Village 1781–1981* (1980). LEONARD PITT and DALE PITT, *Los Angeles A to Z: An Encyclopedia of the City and County* (1997), is a useful and well-researched reference guide. Three standard works, although dated, are still indispensable: J.M. GUINN, *A History of California and an Extended History of Los Angeles and Environs*, 3 vol. (1915); CAREY MCWILLIAMS, *Southern California Country: An Island on the Land* (1946, reissued as *Southern California: An Island on the Land*, 1973); and WRITERS' PROGRAM, *Los Angeles: A Guide to the City and Its Environs*, completely rev. 2nd ed. (1951). The city's early years are discussed in ROBERT GLASS CLELAND, *The Cattle on a Thousand Hills: Southern California, 1850–1880*, 2nd ed. (1951, reissued 1990); and ROBERT M. FOGELSON and ROBERT FISHMAN, *The Fragmented Metropolis: Los Angeles 1850–1930* (1967; reissued 1993). Two volumes that focus on southern California and Los Angeles from 1850 through the 1920s are KEVIN STARR, *Inventing the Dream: California Through the Progressive Era* (1985), and *Material Dreams: Southern California Through the 1920s* (1990). Urban planning and the urban-suburban paradox are explored in GREG HISE, *Magnetic Los Angeles: Planning the Twentieth-Century Metropolis* (1997); WILLIAM FULTON, *The Reluctant Metropolis: The Politics of Urban Growth in Los Angeles* (1997); and ALLEN J. SCOTT and EDWARD W. SOJA (eds.), *The City: Los Angeles and Urban Theory at the End of the Twentieth Century* (1996).

Three early-day Angelinos have left invaluable recollections: HORACE BELL, *Reminiscences of a Ranger* (1881, reissued 1965–67), although it should be read with caution; HARRIS NEWMARK, *Sixty Years in Southern California, 1853–1913*, 4th ed. rev. and augmented (1970, reissued 1984); and BOYLE WORKMAN, *The City That Grew* (1936). One of the most useful records of pioneer days is JOHN ALBERT WILSON, *History of Los Angeles County, California* (1880, reprinted as *Reproduction of Thompson and West's History of Los Angeles County, California*, 1959). JOHN WALTON, *Western Times and Water Wars* (1992), is an excellent study of this key subject. The ethnic diversity of Los Angeles is explored in LYNELL GEORGE, *No Crystal Stair: African-Americans in the City of Angels* (1992); and ANTONIO RÍOS-BUSTAMANTE and PEDRO CASTILLO, *An Illustrated History of Mexican Los Angeles, 1781–1985* (1986). DAVID GEBHARD and ROBERT WINTER, *Architecture in Los Angeles* (1985), provides both description and history of important architecture. The first child of the freeway generation to make a serious appraisal of his off-ramp heritage is DAVID BRODSLY, *L.A. Freeway: An Appreciative Essay* (1981).

Luther

The founder of the 16th-century Reformation and of Protestantism, Martin Luther is one of the pivotal figures of Western civilization, as well as of Christianity. By his actions and writings he precipitated a movement that was to yield not only one of the three major theological units of Christianity (along with Roman Catholicism and Eastern Orthodoxy) but was to be a seedbed for social, economic, and political thought. For further treatment of the historical context and consequences of Luther's work, see PROTESTANTISM.

LUTHER AS EDUCATOR AND MONK

Early life and education. Martin Luther was born on November 10, 1483, at Eisleben in Thuringian Saxony (Germany). His parents, Hans and Margarethe Luther, who had moved there from Möhra, soon moved on again to Mansfeld where Hans Luther worked in the copper mines, prospering enough to be able to rent several furnaces and to obtain a position among the councillors of the little town in 1491. Luther's few recollections of childhood that have survived reflect a sombre piety and strict discipline common in that age. His schooling seems to have been unremarkable: the Latin school at Mansfeld, a year at a school in Magdeburg (run by Brethren of the Common Life, a medieval lay group dedicated to Bible study and education) and at Eisenach in his 15th year, where he made valued older friends. In the spring of 1501 he matriculated in arts at the University of Erfurt, one of the oldest and best attended universities in Germany. There he talked long and seriously enough to be nicknamed "the Philosopher," and played the lute. He took the usual arts course and graduated with the B.A. degree in 1502. He took his M.A. in 1505, placing second among 17 candidates. In an age when few students got as far as the master of arts degree, he had fulfilled his parents' hopes. Like many other parents of his time, Hans Luther intended his son to become a lawyer, and he paid cheerfully enough for the expensive textbooks when Martin began legal studies. He was chagrined to learn that his son, without consulting his parents, had decided to enter religion and had sought admission to the house of Augustinian Hermits in Erfurt.

Brother Martin Luther. Evidence on the reason for his decision to enter the religious life is scanty. In his later, not always reliable, *Tischreden* ("Table Talk"), it is related that on July 2, 1505, he was returning from a visit to his parents when he was overtaken by a thunderstorm near the village of Stotternheim and cried out in terror, "Help, St. Anne, and I'll become a monk." In his *De votis monasticis* ("Concerning Monastic Vows," 1521) Luther says "not freely or desirously did I become a monk, but walled around with the terror and agony of sudden death, I vowed a constrained and necessary vow." He sold most of his books, keeping back his Virgil and Plautus, and on July 17, 1505, entered the monastery at Erfurt.

The thunderstorm experience

Augustinian Order at Erfurt. In joining the eremitical order of St. Augustine, Luther had joined an important mendicant order, which by the middle of the 15th century had over 2,000 chapters. As a result of reforms carried through in 1473, the house at Erfurt, to which Luther went, accepted the strict, observant interpretation of the rule. Under Johann von Staupitz, Luther's mentor and vicar general to the order, a revised constitution was made in 1504. Luther made his profession as a monk in September 1506 and was then prepared for ordination. He was ordained priest in April 1507 and his first mass took place at the beginning of May. He had studied a treatise on the canon of the mass by a famous Tübingen Nominalist Gabriel Biel (d. 1495), who, like other "modern" Nominalists, claimed that only named particulars exist and that universal concepts are formed through intuition, and he approached the ceremony with awe. To this occasion his father came with a group of friends, and Luther took this first opportunity to explain personally the imperious nature of his vocation. His father's disgruntled retort, "Did you not read in Scripture that one shall honour one's father and mother?" struck deep into his memory.

Wittenberg University. Luther was selected for advanced theological studies; some of his university teachers were Nominalists of the "modern" way of the English philosopher theologian William of Ockham, whose views undercut the prevailing rationalism of Scholasticism, the school of thought founded in the 11th century in an attempt to reconcile revelation with reason. In 1508 Luther went to the University of Wittenberg (founded 1502), where, though Ockhamism had a foothold, the school of Realism that claimed that universals exist and can be known by reason was championed by scholars such as Martin Pollich. The little town was a contrast to Erfurt, but at least the university was young and forward-looking, and to its comparative remoteness Luther would one day owe his life. The Schlosskirche (called the Church of All Saints) was closely connected with the university, and the elector of Saxony, Frederick III the Wise (1463–1525), lavished generous patronage on both. In March 1509 Luther took the degree of *baccalaureus biblicus* at Wittenberg, returning to Erfurt for his next degree, of *sententiarius,* which involved expounding on the *Sentences*, a medieval theological textbook by Peter Lombard. He had begun his teaching with a course on Aristotle's *Nicomachean Ethics* and now began his career as a theologian with lectures on the *Sentences.* Some of his notes have survived, and if their theology is unexciting there is apparent an acid vehemence at the intrusion of philosophy and above all of Aristotle into the realm of theology.

Influence of Johann von Staupitz

Johann von Staupitz, vicar general of the German Augustinians, was very important in Luther's career as his teacher, friend, and patron. Staupitz seems to have been theologically trained as a Thomist (Realist) and was also influenced by the Augustinian tradition of his order, though his theology shows elements derived from the conflation in the late 15th century of the *devotio moderna* (modern devotion, a term used to describe the spirituality of the Brethren of the Common Life) with German mysticism.

His attempt to revive stricter discipline and to unite the observant and conventual Augustinians in Germany led to dispute, and Luther was one of two monks chosen to go to Rome to present the appeal of some dissident houses. He made the journey, the longest of his life, probably late in 1510, and his earnestness was shocked by the levity of the Roman clergy and by the worldliness so evident in high places. The appeal failed, and Luther returned to become a loyal supporter of Staupitz.

Staupitz became interested in his gifted pupil and, perhaps alarmed by his introspectiveness, encouraged him to proceed to his doctorate and to a consequent public teaching career. Luther took his D.Th. on October 19, 1512. The degree was important for Luther, with its implications of public responsibility. He soon took on the duties of a professor in succeeding Staupitz in the chair of biblical theology. This was his lifelong calling, and the exposition of the Bible to his students was a task that called forth his best gifts and energies, one that he sustained until ill health and old age made him relinquish it at the end of his life. In between lectures, in a manner of speaking, he began the Protestant Reformation.

Religious and theological questions. Meanwhile, Luther's own religious and theological difficulties were becoming acute. He had entered into the search for evangelical perfection with characteristic and serious zeal, and sought exactly to fulfill the rule of his order. Nonetheless, he soon found himself in problems difficult for him to understand, struggling against uncertainties and doubts, unhappily bearing a crippling burden of guilt, which neither the sacramental consolations (*e.g.,* the Lord's Supper and penance) of the church nor the wise advice of skilled directors was able to assuage. This distress, which had its centre in his unquiet conscience, brought him into states of anxiety and despair. Nor were his difficulties lessened by the emphases of the Ockhamist theology, which encouraged an extroverted moralism, stressed the human will, and left aspects of uncertainty at the very points where Luther needed most to be reassured. "Temptation" (*Anfechtung*) was to become an important word for Luther's theology, a term that suggests the fight for faith, of which Staupitz could say that such experiences were meat and drink to Martin Luther. These inward, spiritual difficulties were enhanced by theological problems.

Discovery of "the righteousness of God." At the entrance to the world of the thought of St. Paul, Luther was halted—the road blocked by a word that intensified his difficulties to an almost intolerable degree. This was the conception of the "righteousness of God." His sombre childhood piety had made him intensely aware of God's judgment, and as a lecturer in the arts faculty at Wittenberg he had had to expound the Hellenic conception of justice, as he found it in the *Nicomachean Ethics* of Aristotle. Encouraged by the use of *justitia* ("righteousness" or "justice") in the works of several Nominalists, he came to think of God's justice as being primarily the active, punishing severity of God against sinners—*i.e.,* in particular actions. It was for him a final aggravation of his trouble that in Rom. 1:17 it is asserted that the justice of God is revealed in the gospel. Thus, Luther concluded, the divine demand was shown as extending beyond outward obedience to the Law, revealed in the Commandments, to purity of heart, to inward motive and intention, so that grace itself became a demand and an exaction. Such a God could be feared but not loved, could be obeyed out of constraint but never with that happy spontaneity that Luther felt to be of the essence of Christian obedience.

Luther's sense of hypocrisy

Luther's inner conflict. To Luther's sense of failure to obey the Law was added the feeling of hypocrisy, which drove him to the edge of what moral theologians described as "open blasphemy." In 1545, in a celebrated autobiographical fragment that he prefaced to his complete works, he thus described his feelings:

> For however irreproachably I lived as a monk, I felt myself in the presence of God to be a sinner with a most unquiet conscience, nor could I believe that I pleased him with my satisfactions. I did not love, indeed I hated this just God, if not with open blasphemy, at least with huge murmuring, for I was indignant against him, saying "as if it were really not enough for God that miserable sinners should be eternally lost through original sin, and oppressed with all kind of calamities through the law of the ten commandments, but God must add sorrow on sorrow, and even by the gospel bring his wrath to bear." Thus I raged with a fierce and most agitated conscience, and yet I continued to knock away at Paul in this place, thirsting ardently to know what he really meant.

Thus, the dilemma. Illumination came at last, as in prayer and meditation he pondered the text, examining the connection of the words.

Justification by faith

> At last I began to understand the justice of God as that by which the just man lives by the gift of God, that is to say, by faith, and this sentence, "the justice of God is revealed in the Gospel," to be understood passively, that by which the merciful God justifies by faith, as it is written. "The just man shall live by faith." At this I felt myself to have been born again, and to have entered through open gates into paradise itself.

There has been great controversy about this inner conflict, but it seems certain that there was for Luther just such a crisis as he later described and that it was resolved in the manner he narrates. There has also been argument about the novelty of this discovery. There is in fact a profound difference between the Hellenic conception of distributive justice and the biblical doctrine of the righteousness of God as a divine, saving activity displayed in the field of history and of human experience, and Luther had penetrated deeply into the Pauline vocabulary at this point. The accuracy of Luther's memory about this and, indeed, his integrity have sometimes been impugned, but the verdict of a modern Catholic historian, Joseph Lortz, may stand: that if the discovery were not new, it was at any rate "new for Luther."

Salvation as grace. Had Luther not written this account, it would have been necessary to conjecture something like it to account for the new importance that he gave to justification by faith, a priority it retained in the new theological framework of Protestantism. This became for him the nerve of the gospel, that salvation is to be thought of primarily in terms of grace, and of a divine gift; that God's free, forgiving mercy is displayed in Jesus Christ; that the conscience, forgiven and cleansed, may be at peace, and that the soul, free from the burden of guilt, may serve God with a joyful, spontaneous, creative obedience. In his translation of the Bible Luther came to add "alone" after the word "faith" (*sola fide*) in the verse "For we hold that a man is justified by faith apart from works of law" (Rom. 3:28) because he felt it was demanded by the German language. The word alone or only was retained by the Reformers after him because it seemed to safeguard this important doctrine against such perversions as might seem to make salvation dependent on human achievement or a reward for human merit.

Evaluation of Luther's experience of justification. This experience ought not to be isolated, for Luther speaks of other problems of vocabulary (*e.g.,* the conception of "repentance," *poenitentia*), and it cannot be assumed that this was for him a catastrophic personal experience such as befell St. Augustine, who had a mystical experience of God in the garden at Milan, or the 18th-century founder of Methodism John Wesley, who had a conversion experience at Aldersgate Street, London. About the date of the occurrence there has been much controversy. The publication of Luther's early lectures led naturally to the examination of these firstfruits of the young professor. Though an early view that it must have occurred during the period of Luther's first lectures on the Psalms (1513–15) has been damagingly criticized, Luther's use of the many-sided allegorism of the Middle Ages, which often found three or four levels of meaning in a single text, his concentration on the one historical meaning, and the Christ-centred core of theology of justification have led some scholars to believe that the illumination must have come to him before his lectures on the Letter to the Romans (1515–16).

Something depends on how the discovery itself is assessed: if it was a discovery that justification is a gift, that it is to be taken passively rather than actively, then (as the reference to Augustine's *De spiritu et littera*—"Concerning the Spirit and the Letter"—suggests) Luther was

hardly moving beyond the Augustinian framework and it is probably from an early period. If, on the other hand, it was the more mature discovery of the relation of saving faith to the Word of God, then it must be placed later, perhaps in 1518–19. Many scholars now tend in this later direction, and they emphasize how Luther's thinking was stimulated and redirected by the urgent pressure of the church struggle that began in 1517.

The net gain of this chronological discussion has been to demonstrate how important is the whole period of Luther's development from 1509 to 1521, and that his technical vocabulary and the categories of his theology were in movement throughout the whole of this period. Certainly his great courses of lectures on the Psalms (1513–15), on Romans (1515–16), Galatians (1516–17), and Hebrews (1517–18) reveal the growing richness and maturity of his thought.

Luther's growth in theological thought

Luther as preacher and administrator. Meanwhile, his other duties had accumulated. From 1511 he had been preaching in his monastery and in 1514 he became preacher in the parish church. This pulpit became the centre of a long and fruitful preaching ministry wherein Luther expounded the Scriptures profoundly and intelligibly for the common people and related them to the practical context of their lives. Within his order, he had become prior, and, in April 1515, district vicar over 11 other houses. Thus he became involved in a world of practical administration and of pastoral care that gave him valuable experience, standing him in good stead in later years when a large part of his vast correspondence would be concerned with the care of the German churches and the cure of needy souls.

The new University of Wittenberg found it must take sides in an academic crisis that faced the European universities of that day, the tension between an old and a new academic program. Before Luther's advent Martin Pollich, a leading professor at Wittenberg, had shown himself hospitable to Humanist influences, despite his preference for the older Thomism. Now Luther took the lead in inaugurating a new program, involving the displacement of Aristotle and the Scholastic theologians by a biblical humanism that turned to the direct study of the Bible, using as tools the revival of Greek and Hebrew and a renovated Latin and as a dogmatic norm the "old Fathers" (the early Church Fathers, or teachers) and especially St. Augustine. Such a program Luther planned with the help of his senior colleague, Karlstadt, and his young friend Philipp Melanchthon. In February 1517 he penned a series of theses against the Scholastic theologians, which he offered to defend at other universities. Though this attempt to export the Wittenberg program met with no success he could write in May that the battle was won at least in Wittenberg—"our theology, and that of St. Augustine reign." But if his theses remained dormant, a very different fate awaited those that he wrote later in that same year. He could hardly have thought that these would fire a train that would explode the Western Christian world.

LUTHER AS REFORMER

The indulgence controversy. *The nature of indulgences.* The nature and scope of indulgences had been more and more defined during the later Middle Ages, but there was still an element of that dogmatic uncertainty that has been called a theological weakness of the age. Indulgences were the commutation for money of part of the temporal penalty due for sin, of the practical satisfaction that was a part of the sacrament of penance, which also required contrition on the part of the penitent and absolution from a priest. They were granted on papal authority and made available through accredited agents. At no time at all did they even imply that divine forgiveness could be bought or sold, or that they availed for those who were impenitent or unconfessed. But during the Middle Ages, as papal financial difficulties grew more complicated, they were resorted to so often that the financial house of Fugger of Augsburg had to superintend the sacred negotiations involved in them.

The way was open for further misunderstanding when in 1476 Pope Sixtus IV extended their authority to souls in purgatory. The appeal to cupidity and fear, the pomp and circumstance with which these indulgences were attended, the often outrageous statements of some indulgence sellers were a matter of complaint. Luther himself had frequently preached against these abuses, for his patron, the elector Frederick, had amassed a great collection of relics in the castle church at Wittenberg, to which indulgences were attached. But the immediate cause of Luther's public protest was an indulgence that Frederick had prohibited from his lands, though it was available in nearby territory. This was a jubilee indulgence, offering special privileges, the ostensible purpose of which was the rebuilding of St. Peter's basilica in Rome. By a secret arrangement, half of the German proceeds were to go to the young Albert, archbishop of Mainz, who was deeply in debt owing to his rapid promotion to and payment for a number of high ecclesiastical offices.

The immediate cause of the indulgence controversy

The Ninety-five Theses. Of this Luther knew nothing until some time afterward. For him, the provocation lay in the extravagant claims of an old, tried hand at this kind of thing, the Dominican salesman of indulgences Johann Tetzel. With these claims in mind, Luther drew up the Ninety-five Theses, "for the purpose of eliciting truth," and fastened them on the door of All Saints Church, Wittenberg, on October 31, 1517, the eve of All Saints' Day and of the great exposure of relics there. These were tentative opinions, about some of which Luther himself was not committed. They did not deny the papal prerogative in this matter, though by implication they criticized papal policy; still less did they attack such established teaching as the doctrine of purgatory. But they did stress the spiritual, inward character of the Christian religion, and the first thesis, which claimed that repentance involved the whole life of the Christian man, and the 62nd, that the true treasure of the church was the most holy gospel of the glory and the grace of God, showed the author's intention. The closing section attacked the false peace, that "security," which as a young lecturer Luther had so often attacked, of those who thought of divine grace as something cheaply acquired and who refused to recognize that to be a Christian involved embracing the cross and entering heaven through tribulation. Luther sent copies of the theses to the archbishop of Mainz and to his bishop. And here the invention of printing intervened. Copies were circulated far and wide, so that what might have been a mere local issue became a public controversy discussed in ever widening circles.

Reaction to the Ninety-five Theses. The archbishop of Mainz, alarmed and annoyed, forwarded the documents to Rome in December 1517, with the request that Luther be inhibited, at the same time reprimanding the indulgence sellers for their extravagance. At the time, it seemed to many that this was simply another squabble between the Dominicans and the Augustinians. Colour was given to this belief by the counter-theses prepared by a theologian, Konrad Wimpina, that Tetzel had defended before a Dominican audience at Frankfurt at the end of January 1518. When copies of these reached Wittenberg in March they were publicly burned by excited students. At Rome the pope merely instructed Gabriel della Volta, the vicar general of the Augustinians, to deal with the recalcitrant monk through the usual channels, in this case through Staupitz. Luther himself prepared a long Latin manuscript with explanations of his Ninety-five Theses, publication of which was held up until the autumn of 1518; it is a document of some theological importance, and shows how far from superficial Luther's original protest had been. Meanwhile, the chapter of the German Augustinians was held at Heidelberg, April 25, 1518. Luther was relieved of his extra duties as district vicar, in the circumstances a great relief and intended as such. He found great comfort in the support of his friends, and was himself in great form, winning over two young men, Martin Bucer, a Dominican, and Theodor Bibliander.

Counter-theses and student reaction

At this period Luther's theology was most especially a "theology of the cross"; *i.e.,* a theology that stressed the revelation of Christ on the cross. According to Luther, the "theology of the cross" seems foolishness to the wisdom of the world and is opposed to the natural theology of di-

"Theology of the cross"

vine power and majesty, which he attacked as a Scholastic "theology of glory." Important for him at this time was the inward religion preached by the 14th-century German mystic Johann Tauler and a short 14th-century mystical tract, the *Theologia Germanica*, that he himself edited and published (1516–18). In these months, therefore, he lay great stress on the need for the Christian to share the cross of Christ, in suffering and in temptation. Though these stresses were to recede into the background of Luther's developing theology, they were to remain important for the radical Reformation, for which the *Theologia Germanica* would be an important and seminal document.

Involvement of Johann Eck. During Luther's absence, and perhaps catastrophically, his senior colleague, Karlstadt, had taken action that was greatly to widen the scope and publicity of the controversy. The scholar Johann Eck (1486–1543) of Ingolstadt, a man of some learning, and with a zest for disputation, with whom Luther was already in friendly contact through a common friend, became involved in the controversy. He had written some observations on the Ninety-five Theses for his friend, the bishop of Eichstädt, and these manuscript observations, the so-called Obelisks, reached Wittenberg shortly before Luther went off to his chapter at Heidelberg; Luther himself replied with a few "Asterisks," but Karlstadt, concerned to defend the Wittenberg program, sprang into the fray with 379 theses, adding another 26 before publication. In some of these Eck was impugned. The Dominicans continued to press for Luther's impeachment, and proceedings against him for heresy began to move slowly in Rome. Luther himself did not improve matters by publishing a bold sermon on the power of excommunication that made it clear that here was not a man who would accept unquestioned whatever might be decided by the pope in terms of some undefined plenitude of power.

The Augsburg interview, 1518. *Luther before Cajetan.* A papal citation summoning Luther to Rome was sent to the cardinal Cajetan (1468–1534), a renowned Thomist, at Augsburg. But at this perilous moment politics fatefully intervened, and the period during which the Luther affair might have been swiftly, drastically disposed of without wider disaster to the church was eroded by considerations of policy. The elector Frederick, as one of the seven prince electors of the Holy Roman Empire, was most important to the pope, in view of the imminent choice of a new emperor, and the pope could not afford to antagonize him. The result was that Luther was bidden to a personal interview with Cajetan at Augsburg. He arrived there on October 7 with an imperial safe-conduct. The discussion had moved from indulgences to the discussion of the relation between faith and sacramental grace (the unmerited gifts of God in such acts as Baptism and the Lord's Supper), when an argument developed between the two theologians about the meaning of the "treasure" of merits that the papal definition of Sixtus IV said that Christ had acquired, and the incensed cardinal dismissed Luther from his presence, telling him to stay away unless he would unconditionally recant.

Dispute over meaning of merits

Luther's flight from Augsburg. While Luther waited uneasily, the Saxon councillors reported rumours that he would be taken in chains to Rome. Eventually, bundled through a postern by his friends, he fled the city. Now he wrote an appeal from the pope to a general (or ecumenical) council and a full defense of his actions to his prince. Cajetan, meanwhile, lost no time in denouncing Luther to Frederick, who was in something of a dilemma, though it counted much for Luther that he had the admiring friendship of the elector's secretary, the Humanist Georg Spalatin. At this time, too, the Wittenberg theological faculty addressed the prince on Luther's behalf, pointing out that the fate of the university and its reputation would be involved in Luther's disgrace. At one moment, it seemed that Luther might have to depart, perhaps for France or Bohemia. There then appeared Karl von Miltitz, a papal diplomat, who applied "stick and carrot" tactics to the elector, dangling before him at one moment threats against Luther and at the next the signal compliment of the golden rose, symbol of high papal honour and recognition. The diplomat promised more than he could possibly perform, and after an interview with him at Altenburg, in January 1519, Luther sensed this and came to distrust him. A papal definition about indulgences, issued at Cajetan's request, seemed to show that Luther had indeed put his finger on some fatal ambiguities.

The Leipzig disputation, 1519. *Debate between Luther and Eck.* At Augsburg Luther had been in touch with Eck and arrangements were made for a public disputation at Leipzig in the summer. This was to be in the first place a debate between Eck and Karlstadt, though Luther was Eck's ultimate objective, but the hostility of George, duke of Saxony (the elector Frederick's first cousin), toward the Reformer raised difficulties about Luther's participation. Eventually it was arranged that Eck should debate with the two Wittenberg theologians in turn, in the castle of the Pleissenburg, Leipzig, at the end of July. There was a preliminary pamphlet skirmish. The issue between Eck and Karlstadt was the Augustinian doctrine of grace and free will, and Karlstadt wished to meddle neither with indulgences nor with papal authority. Among the preliminary matters, the origin of the papal power was raised and so Luther turned to a study of church history and Canon Law in the fateful weeks before the debate. A large contingent from Wittenberg attended, and in the presence of theologians from both universities, Duke George and notables of church and state, the debate began. Eck showed some skill in manoeuvring Luther into a position in which he cast doubt on the authority of the great General Council of Constance (1414–18), and also defended some of the propositions of Jan Hus, a Bohemian Reformer who had been declared a heretic at Constance and burned to death at the stake. Leipzig was a part of Germany with a strong feeling against Bohemia, and the admission was received as damaging, giving ground for Eck's loud boast that the disputation had been his personal triumph. Luther, who had earlier said of the debate that it had not begun in God's name and would not end in his name, left Leipzig somewhat shaken and disturbed by Eck's verbal manoeuvring.

Luther's relationship to Jan Hus

Luther's questioning of authority. Eck was able to go off to Rome with new prestige to give sharpness to the process of Luther's official condemnation. Luther had now to examine the further implications of his actions to date, in relation to the authority of the church, of councils, and of Scripture; his correspondence shows that he was reaching something like a crisis in his attitude to papal authority. There had been a small pamphlet war after the disputation that made it plain that there was strong support for Luther among the Humanists in Germany and Switzerland. Luther himself became involved in controversy with diverse theologians of Leipzig, and if he now wrote in the vernacular with increasing power and violence, his polemical writings reveal also his deep perceptions of the issues between himself and contemporary theology. Two Catholic universities, strongholds of tradition, Cologne and Louvain, next condemned Luther's teaching. But polemic was not Luther's main concern, and his *Sermon von den guten Werken* ("Sermon on Good Works"), issued in June 1520, is an important exposition of the ethical implications of justification by faith. As a tract it deserves to be associated with Luther's more famous tract on Christian liberty issued in the next months. On June 15, 1520, there appeared the papal bull (a decree issued under the papal seal) *Exsurge Domine* or "Lord, cast out," against 41 articles of Luther's teaching, followed by the burning of Luther's writings in Rome. Eck and the Humanist diplomat and cardinal Girolamo Aleandro (1480–1542) were entrusted with the task of taking the bull to the cities of Germany.

The Reformation treatises of 1520. Eck and Aleandro were alarmed to discover how swiftly German opinion had moved to Luther's side. In contrast to his treatment the year before, Eck had to seek refuge in Leipzig from physical violence. Aleandro did what he could in agitated correspondence to shock the Curia (papal administrative bureaucracy) into realizing the grave danger facing the church in Germany. Luther's friends, aware of how precarious his position was, sought to moderate his violence, but he now moved well beyond their horizon. In Luther's

"Address to the Christian Nobility"

own opinion of himself, he was far too temperate in view of all the ecclesiastical hypocrisy and offenses. The result was the defiant tracts of the summer of 1520. The first, the real manifesto, was his *An den christlichen Adel deutscher Nation* ("Address to the Christian Nobility of the German Nation"), addressed to the rulers of Germany, princes, knights, cities, under the young emperor Charles V. It argued that in the crisis, when the spiritual arm had refused to take in hand the amendment of the church and the often expressed grievances of the German people against Rome (*i.e.,* the papacy), it was necessary for the secular arm to intervene and call a reforming council. The document was ill arranged and tailed off, but it found deep response among sections of the nation, and in the next months Luther was carried along with the tide of national resentment against Rome.

His second treatise, *De captivitate Babylonica ecclesiae praeludium* ("A Prelude Concerning the Babylonian Captivity of the Church"), intended for clergy and scholars, was an act of ecclesiastical revolution. It inevitably estranged many moderate Humanists, for it reduced to only three (Baptism, the Lord's Supper, and penance) the seven sacraments of the church, denied mass and attacked transubstantiation (the doctrine that the substance of the bread and wine is changed into the body and blood of Christ in the sacrament of the Lord's Supper), made vehement charges against papal authority, and asserted the supremacy of Holy Scripture and the rights of individual conscience. The third work, dedicated to the pope, was, as a still, small voice after the uproar, a minor classic of edification, *Von der Freiheit eines Christenmenschen* ("Of the Freedom of a Christian Man"), which made clear the ethical implications of justification by faith, and showed that his thought and his public actions were connected by a coherent theological core. On December 10, 1520, the students lit a bonfire before the Elster Gate in Wittenberg, and as they fed the works of the canonists to the flames Luther added the papal bull (*Exsurge Domine*) against himself with suitable imprecation—"Because you have corrupted God's truth, may God destroy you in this fire."

Excommunication

In January 1521 the pope issued the bull of formal excommunication (*Decet Romanum Pontificem*), though it was some months before the condemnation was received throughout Germany. Meanwhile, the imperial Diet was meeting at Worms, and there was a good deal of lobbying for and against Luther. In the end, Frederick the Wise obtained a promise from the emperor that Luther should not be condemned unheard and should be summoned to appear before the Diet. This enraged Aleandro, who asserted that the papal condemnation was sufficient and that the secular arm had only to carry out its orders. It also alarmed Luther's friends, who did what they could to dissuade him. Luther was firm in his determination to go, and began the journey in April 1521, undeterred by the news, on the way, that the emperor had ordered his books to be burned. What was meant to be the safe custody of a heretic turned out to be something like a triumphal procession, and when Luther entered Worms on April 16 he was attended by a cavalcade of German knights and the streets were so thronged as to enrage his enemies.

The Diet and Edict of Worms, 1521. *Luther's defiance of the Diet.* In the early evening of April 17, 1521, Luther appeared before the notables of church and state and faced the young emperor Charles V, whom he found cold and hostile. A pile of writings lay before him, but when he was formally asked whether he acknowledged them, his legal adviser insisted that the titles be read. In view of the gravity of recantation, Luther asked for time to think, a request that may have taken his enemies off guard. A day's respite was granted, and the following afternoon, in a larger hall, and before an even more crowded assembly, Luther reappeared. This time he could not be prevented from making a long speech. He distinguished between his writings: for the works of edification he need not and ought not to recant, for the violence of his polemic he would apologize, but for the rest he could not recant; and, as he went on to explain why, the demand was brusquely made for a plain, simple answer. This he now gave in words of unyielding defiance. He would recant if convinced of his error either by Scripture or by evident reason. Otherwise he could not go against his conscience, which was bound by the Word of God. Though evidence is now tilted against the authenticity of the famous conclusion, "Here I stand. I can do no other," it at least registers the authentic note of Luther's reply in a moment that captured the imagination of Europe. There was a moment of confusion with Eck and Luther shouting, and then the emperor cut short the proceedings. Luther strode through his thronging enemies to his friends, his arm raised in a gesture of relief and triumph.

"Here I stand. I can do no other."

There followed a diplomatic flurry. It was evident that Luther had powerful friends; there was some sabre rattling from the knights and the peasant emblem appeared in the streets. There is evidence to support Luther's boast that had he wished he could have started such a game that the emperor's life would not have been safe. The radical Reformer and social revolutionary, Thomas Müntzer, later asserted that had Luther recanted the angry knights would have killed him. At any rate, Luther was now given what he had long asked for in vain, something like a real hearing before reasonably impartial judges, while he was kindly handled by the archbishop of Trier. But he could not now make even minor concessions, and the discussions broke down on the fallibility of councils. He was formally dismissed and departed under his safe-conduct.

Despite his spectacular moral triumph, Luther's enemies, nonetheless, achieved something important at this point when a rump Diet passed the Edict of Worms. It declared Luther to be an outlaw whose writings were proscribed. The edict was to shadow him and fetter his movements all his days. It meant also that his prince must, for a time at least, walk delicately and could not publicly support his protégé. The result was the pretended kidnapping of Luther who was lodged secretly in the romantic castle of the Wartburg, near Eisenach.

Luther at the Wartburg. In this aerie among the trees Luther remained until March 1522. Known as Junker Georg, or Knight George, he dressed as a layman, grew a beard, and put on weight. The lack of exercise and the unwontedly rich diet brought on physical distress, whereas his mind, flung back on itself after months of crisis, knew intense reaction in a period of acute depression of the kind that Luther ranked high among temptations. But he was far from idle. He finished a beautiful exposition of the Magnificat (the song of Mary, the mother of Christ, in the liturgy) and prepared an edition of sermons on the Epistles and Gospels at mass, which he thought was perhaps his best writing. Although away from books, he wrote his ablest controversial piece, *Rationis Latomianae pro Incendiariis Lovaniensis Scholae sophistis redditae Lutheriana confutatio* ("Refutation of the argument of Latomus"—who was a member of the theological faculty of the University of Louvain), containing a luminous exposition of justification. Most important of all, he began to translate the New Testament from the original Greek into German. He did not believe that such work should be left to one mind, and soon enlisted his colleagues, notably Melanchthon, in the enterprise. But Luther's was the controlling genius, and the resulting New Testament (published in September 1522), like the Old Testament, translated from the Hebrew, which followed later (1534), was a monumental work, which had deep and lasting influence on the language, life, and religion of the German people. He had now to deal with some of the practical implications of his revolt. Private masses, celibacy of clergy, religious vows were no theoretical questions, but were themselves entangled in a network of legal, financial, and liturgical affairs. He wrote about these things forthrightly, and Spalatin tried in vain to hold up their publication, for in Wittenberg there were growing difficulties, and the prince, the university, and the cathedral chapter were all, for various reasons, anxious to go slowly.

Influence of Luther's translation of the Bible on the German language

Commotion in Wittenberg, 1521–22. *Radical reform.* There was a lively section of the town and of the university, however, that was determined to force the pace, and there were violent scenes in the streets and churches early in October 1521. Yet Luther, on a secret visit to his friends early in December, was not alarmed, and it

was his influence that led the Augustinians to decide, in the new year, that those of them who wished might return to the world. Two radical leaders now appeared, the incorrigible troublemaker Karlstadt and Gabriel Zwilling, an ebullient spellbinder from the Augustinians. When Karlstadt announced his betrothal to a girl of 16, and at Christmas administered Communion in both kinds (bread and wine) while dressed as a layman, attacked images in a violent tract and in innumerable theses denounced vows and masses, and demanded a vernacular liturgy, it was evident that here was a program that in timing and method differed from Luther's. Moreover, its appeal to Scripture was legalistic and made matters of necessity things that for Luther lay within the option of Christian liberty. In the new year, the town council issued a notable and pioneering ordinance regulating religion, public morals, and poor relief, a document that owes much to Luther's teaching and perhaps something to the initiative of Karlstadt. At the end of 1521 confusion was increased by the arrival of the so-called Zwickau prophets, radicals on the run from the town of Zwickau, who spoke impressively of revelations given them through dreams and visions, claiming that the end of the world was near and that all priests should be killed. A flustered and outmanoeuvred Melanchthon wrote urgently for advice to Luther, who sent wise and calm counsel.

Restoration of balanced reform. In the next months the situation worsened and in March 1522 Luther returned to Wittenberg, explaining the reason for his disobedience to instructions in a justly famous letter to his prince. Then, deliberately habited as an Augustinian monk once more, he took charge of his town pulpit and in a powerful series of sermons redressed the balance of reform. In these important utterances, the difference between Luther's conservatism and the radical pattern of reform is made plain.

Luther's dislike for violence

Luther deplored the use of violence, for the Word of God must be the agent of reform. He believed that revolt could not take place without destruction and the shedding of innocent blood; that the real idols are in the hearts of men and if their hearts are changed the images on church walls must fall into disuse. Moreover, the pace of reform must take into account the unconverted, weaker brethren. From this time onward Luther fought a war on two fronts, against the Catholics and against those whom he lumped together as *Schwärmer* ("fanatics"). One result of the Wittenberg crisis was to slow down the practical reforms, and though Luther introduced a reformed rite (*Formula Missae* or "Formula of the Mass," 1523) it was not until 1526 that he provided a vernacular liturgy (*Deutsche Messe,* or "German Mass"). Throughout Germany the evangelical movement continued to grow, and it was apparent that the Edict of Worms would not be everywhere enforced. A Diet at Nürnberg, 1522–23, refused to suppress the evangelical preachers and demanded a reforming, national council; though Catholic pressure was stronger in the following year, the Diet again pressed for a council and would consent only to the enforcement of the edict "as far as possible."

The Peasants' War. *Activities of the radical Reformers.* On his journeys to and from Worms Luther had been dismayed by the evident social and political unrest. In the next months he wrote open letters, warning the rulers of Saxony and the councils of such cities as Strassburg of the danger that the new radical teaching would provoke revolution. In 1523 he made his own views of secular government plain in an important treatise *Von weltlicher Obrigkeit* ("Of Earthly Government"), in which he firmly asserted the duty of a Christian prince and the place of secular government within God's ordinances for mankind;

The two realms theory

he distinguished between the two realms of spiritual and of temporal government, through which the one rule of God is administered, and stressed the duty of civil obedience and the sinfulness of rebellion against lawful authority.

In Saxony the radical teachers posed a problem for their untheological rulers. In Orlamünde, after having been rebuked at Wittenberg, Karlstadt had converted the community to his own brand of mystical quietism. Luther made a preaching tour of the area at the request of his prince, and was greeted with hostility and ridicule. Luther himself denounced such social evils as usury, but in Eisenach the fiery preacher Jakob Strauss conducted a violent campaign against usury and tithes. Most formidable of all, in the little town of Allstedt, Thomas Müntzer, an unruly genius, combined his own ingenious liturgical reforms with a program of holy war. Himself a former "Martinian" (or follower of Martin Luther), he not only shared Karlstadt's enthusiasm for the mystics but added an explosive element (perhaps influenced by Hussite teaching) that gave point to Luther's worst fears. Müntzer threatened revolution and claimed that God would rid the world of its shame. Luther's warnings and events themselves forced the rulers to take action, and in the summer of 1524 Müntzer fled and Karlstadt was exiled. Müntzer wrote in a pamphlet that Luther was nothing more than a shameless monk, "whoring and drinking," and called him Dr. Liar. Karlstadt also wrote a series of tracts against his former comrades, denouncing, among other things, the corporeal presence in the Eucharist. Luther replied in a devastating and profound treatise, *Wider die himmlischen Propheten, von den Bildern und Sakrament* ("Against the Heavenly Prophets in the Matter of Images and Sacraments"). He claimed that the radical Reformers sought glory and honour, not the salvation of men's souls.

Luther's response to the Peasants' War. In the summer of 1524 the Peasants' War had broken out in the Black Forest area. Their program was variously motivated. Their demands were for concrete medieval liberties connected with the game and forest laws or with tithes. Some of them drew on Catholic teaching, others on the theology of Zwingli and of Luther, who had set an example of successful defiance of authority, had been no respecter of dignities, and whose teachings about Christian liberty and a priesthood in which all believers shared were plainer than his subtle distinctions between two kingdoms. Thus, both where he was understood and where he was misunderstood, Luther's influence in the Peasants' War has to be taken into account. Some of the moderate peasants included Luther among possible arbitrators. He himself published in May 1525 the *Ermahnung zum Frieden* ("Exhortation for Freedom"), an analysis of the "12 articles" of the Swabian peasants, sympathizing with just grievances,

Luther's view of rebellion

criticizing the princes, but repudiating the notion of a so-called Christian rebellion: "My dear friends, Christians are not so numerous that they can get together in a mob." Luther also claimed that the worldly kingdom cannot exist without inequality of persons.

In the spring of 1525 the Thuringian peasants rose, with Thomas Müntzer among their leaders, and at first seemed likely to carry all before them. Faced with imminent political chaos, Luther wrote a brutal, virulent broadsheet, *Wider die räuberischen und mörderischen Rotten der andern Bauern* ("Against the Murdering and Thieving Hordes of Peasants"). The writing was less violent than Müntzer's hysterical manifestos, but it was bad enough. It appeared, however, as an appendix to his moderate tract about the "12 articles." Moreover, words written at the height of the peasant success read very differently after their collapse at the Battle of Frankenhausen, May 15, 1525, and in the bloody reprisal that followed. It was typical of Luther that he refused to climb down, to regain lost popularity, and neither thereafter nor at any time can he be accused of subservience to rulers. As he had once refused to become the tool of the knights, so he had never "taken up" the peasant cause. But he confirmed many peasants in their preference for the radical ideology, which was soon to find more peaceful coherence in the Anabaptist movement.

Watershed year, 1525. *Luther and Erasmus.* In other ways, too, 1525 was a watershed in Luther's career. At the height of the Peasants' War in June 1525, "to spite the devil" he had married Katherina von Bora, a former nun.

Luther's marriage

He certainly needed looking after, and she proved an admirable wife and a good businesswoman. His home meant a great deal to him and was an emblem for him of Christian vocation, so that he included domestic life among the three hierarchies (or "orders of creation") of Christian existence in this world, the other two being political and church life. In the same year there came his open break with the great Humanist Erasmus. The differences between

the two men had long been apparent, and Erasmus, who found in Luther the type of violent, dogmatic mendicant theologian he had always detested, liked what he saw of the Reformation less and less. Nonetheless, both men had a common band of admirers and friends and entered the arena with reluctance. Erasmus, in his *De libero arbitrio,* or "Concerning Free Will" (1524), attacked Luther's doctrine of the enslaved will and provoked a resounding reply in Luther's *De servo arbitrio,* or "Concerning the Bondage of the Will" (1525), a one-sided, violent treatise that, nevertheless, includes profundities still fruitfully debated. In that year, too, Frederick the Wise died. The two men had met only once, but Luther owed much to this prince. The new ruler, the elector John, and his successor John Frederick were Luther's devout supporters and with other princes, notably Philip, landgrave of Hesse, and Albert of Brandenburg, formed a coherent group in the imperial Diet.

The Diets of Speyer. The hostility of Charles V to the Reformers and his devotion to the Catholic faith never altered, but he had to take account of political exigencies, his quarrels with the Pope and with the king of France, and the need for support against the Turks. At the Diet of Speyer in 1526, the Edict of Worms was suspended, pending a national council; in the interval it was ruled that each prince must behave as he could answer to God and to the emperor. Luther stated that there was no fear or discipline any longer and that everyone did as he pleased. As a result, it was possible to plan the reorganization of the Saxon Church, and a visitation was carried out by jurists and theologians (1527–28). Some scholars have seen a tension between Melanchthon's *Instruktion für die Visitatoren,* or "Instructions for the Visitation" (1528), and Luther's comments, which may reveal his distrust of secular intervention in spiritual affairs; and though he thoroughly approved of the development of the evangelical *Landeskirchen* ("territorial churches"), there were to be aspects of Lutheranism that blurred rather than reflected Luther's theological distinctions. At the second Diet of Speyer in 1529, renewed Catholic pressure led to the reversal of earlier concessions, drawing from the evangelical princes, and from a number of cities, a protest that won them, for the first time, the name Protestant.

The eucharistic controversy. *Doctrinal differences among the Reformers.* Doctrinal differences about the Eucharist broke the common evangelical front. Though all the Reformers repudiated the sacrifice of the mass, they were deeply divided about the nature of the divine Presence. Luther, with simple biblicism, insisted that Christ's words "This is my body" must be literally interpreted, because allegory is not to be used in interpreting Scripture unless the context plainly requires it. Karlstadt's fanciful argument (that the word this referred not to bread and wine but the Lord's physical body) was soon dropped. Zwingli won many to his view that "is" must be taken as "means," and his learned friend, the Humanist John Oecolampadius, brought support from the early Church Fathers for a spiritual Presence and stressed the idea of the 2nd-century Tertullian that "body" meant "sign of the body." Thus, the initial debate was about interpretive principles, about the words of institution, though the scriptural argument moved to the relevance or irrelevance of the Gospel According to John (*e.g.,* "he who eats my flesh and drinks my blood has eternal life" [John 6:54]).

Luther and Zwingli

The debate turned to the intricate matter of Christology (*i.e.,* doctrine of Christ). Zwingli insisted on the distinction between the two natures of Christ and that because it is the property of a human body to be in one place, Christ's human body was not here but in heaven. Luther, on the other hand, stressed the indivisible unity of the one Person of Jesus Christ, the mediator. Without going into a metaphysical doctrine of "ubiquity," or Presence everywhere (which was developed by other Lutherans), he asserted that Christ is present wherever he wills to be and that we are not to think of him in heaven "like a stork in a nest." Martin Bucer and the Strassburg theologians echoed the more positive stresses of the Swiss, and Bucer used the Realist language of the early Church Fathers to support a true, spiritual Presence. Luther's treatise *Dass diese Worte Christi "Das ist mein Leib" noch fest stehen wider die Schwärmgeister* ("That these words of Christ 'This is my Body' still stand firm against the Fanatics," 1527) showed that in three years of controversy he had not budged. Zwingli's Latin tract *Amica exegesis* ("A Friendly Exegesis" 1527) was far less amicable than the title suggests and brought a great outburst from Luther, the impressive *Vom Abendmahl Christi, Bekenntnis* ("Confession of the Lord's Supper," 1528). This convinced Bucer that he had misunderstood Luther, who did not mean a local, confined Presence; and from then on he intensified his awkward, well-intended attempts to make peace.

The Marburg Colloquy and the Diet of Augsburg. The political advantages of a common front were obvious, not least to the vulnerable Zwingli and Philip, landgrave of Hesse, and the prince invited theologians of both sides to a private colloquy at Marburg in October 1529. Luther began by saying that in his opinion Zwingli did not know much about the gospel. When Zwingli asked if it was permissible for a Christian to ask how Christ could be present in the bread and wine of the Lord's Supper, Luther replied that if the Lord commanded him to eat crab apples and manure, he would do it because it was a command. After three days' debate, there was no agreement about the Eucharist, though the air had been cleared of many misunderstandings. But if the conference failed, there were agreements on other issues, and these might have been fruitful had not the coming imperial Diet caused the Wittenberg theologians to draw away from the Swiss. As an outlaw, Luther could not attend this fateful Diet of Augsburg and had to fidget in the castle of Coburg, leaving the care of the gospel to Melanchthon, who did very well and produced in the Augsburg Confession (1530), one of the great documents of the Reformation as well as a normative confession of Lutheranism.

The Augsburg Confession

Luther used his influence to stiffen the elector against compromise, though from this time onward he could not refuse his consent to political Protestantism as it took a more and more military shape in the Schmalkaldic League, which was established by Protestant princes in preparation for armed resistance to Catholic aggression. The political situation again changed swiftly, however, and, confronted with the Turkish invasion, the Emperor agreed to a truce with the Protestants in the Religious Peace of Nürnberg (1532). This was a valuable breathing space, and its effects are evident in Luther's writings in the next years. Now, more and more, Luther left matters to the action of Melanchthon. Opponents attempted to break up the friendship of the two. Luther said, regarding this matter, that if Melanchthon would allow himself to be won over by their opponents, "he could easily become a cardinal and keep wife and child."

Growth of Lutheranism, 1530–46. *Melanchthon's leadership.* Luther acquiesced in the eucharistic agreement—by which the south Germans reached agreement on the Lord's Supper—that the triumphant Bucer brought off with Melanchthon in 1536 (the Wittenberg Concord), though Bucer was unable to widen the agreement and bring in the Swiss. When an English embassy from Henry VIII arrived to discuss joining the Schmalkaldic League, it was Melanchthon who drew up the theological agenda (the Wittenberg Articles, 1535) with an ambiguous statement of justification of which Luther wrote, "this agrees well with our teaching." But he would not follow Melanchthon when he thought he wrote too irenically about the papacy, and as the papal council loomed near he penned his own uncompromising Schmalkaldic Articles (1537).

Melanchthon's great work in the field of education was to earn him the name preceptor of Germany, but Luther too was important in this matter. His open letter to the councillors of Germany about the need for schools (1524), and his published sermon *Dass man Kinder zur Schulen halten solle* ("On Keeping Children at School," 1530) show how wise and forward looking was his concern for education. He himself composed two important catechetic documents, the lovely classic, *Kleiner Katechismus* ("Small Catechism"), and *Grosser Katechismus* ("Large Catechism," 1529), for teachers and pastors.

In Wittenberg Luther had a group of able colleagues:

Justus Jonas, Johannes Bugenhagen, and Feliks Krzyzak (Cruciger). In scores of cities his disciples and friends spread the evangelical teaching that formed the Lutheran pattern of church life. Luther, though not pre-eminent as a liturgist, provided orders of worship from which numerous other *Kirchenordnungen* ("church orders") were derived. The influence of Luther's writings was everywhere felt in the Western Christian world. It was in Scandinavia that the Lutheran Church struck its deepest roots and won its most complete ascendancy, but it also had deep influence in Austrian and Hungarian lands. Luther realized the importance of hymns and encouraged his friends to write them. He wrote a score of fine hymns, four of which appeared in his first Protestant hymnbook in 1524. The famous "Ein feste Burg ist unser Gott" ("A Safe Stronghold Our God Is Still" or "A Mighty Fortress Is Our God") became almost an event in European history. During the last decade of his life, John Calvin (1509–64) was the rising portent in Switzerland, though Luther's personal contact with him was slight. He continued to attack bitterly the *Schwärmer* ("fanatics"), who then included besides the Anabaptists a number of radicals such as Kaspar Schwenckfeld, a Reformer who tried to mediate between various groups. Although he maintained to the end his view that error can be conquered only by the Word, Luther came to accept the punishment of the Anabaptists.

Luther's hymns

The affair of Philip of Hesse. In 1540 Bucer and Melanchthon took the initiative in conniving at the deplorable bigamy of Philip of Hesse, but Luther was involved and had he willed could have stopped it. It would have been easy for Philip to remedy his incorrigible incontinence by taking a mistress, but this he refused to do, though his guilty conscience kept him from the sacrament. The desperate device, as a lesser of evils, was to grant him a secret dispensation to take a second wife. When the affair became public, Luther angrily threatened to expose the whole story. He himself was so far from lowering moral standards that in the next years he threatened to leave Wittenberg because public morals there were a shame on a city that had known the evangelical teaching so long. After a serious illness in 1537, he was an almost chronic invalid, prematurely aged, seldom free from discomfort, often in pain, and he brought his teaching career to an end with lectures on Genesis. In the last decade of his life, he had to witness the recovery of the papacy, which he thought to have been mortally wounded, in the preparations for the Council of Trent (1545–63), and the growing menace of Catholic military might. His last outstanding controversial treatise was *Von den Conciliis und Kirchen* ("Of Councils and Churches," 1539). Among his last writings, *Against the Anabaptists, Against the Jews, Against the Papacy at Rome, Founded by the Devil,* the most violent is the last, coarse and angry but still defiant.

Luther's last activities. Early in 1546 Luther was asked to go to Eisleben to mediate in a quarrel between two arrogant young princes, Counts Albrecht and Gebhard of Mansfeld. He was old and ill, but they were his *Obrigkeiten* ("authorities") to whom he owed obedience, and he set off in the snowy winter, leaving his wife stiff with anxiety. His letters to her teased her, comforted her, and spoke at last of a mission successfully accomplished. But he had overtaxed his strength, and in a few hours the chill of death came upon him. He died in Eisleben, where he was born, on February 18, 1546, and his body was interred in the Church of All Saints, Wittenberg. The great funeral orations by Bugenhagen and Melanchthon, who knew him so well, are not simply panegyric. They witness that his intimates regarded him as a really great man, standing within the historic succession of prophets and doctors of the church, through whose life and witness the Word of God had gone forth, conquering and to conquer.

Luther's death

LUTHER AS THEOLOGIAN

Luther was no systematizer, like Melanchthon or Calvin, though the dissensions among Lutheran theologians after his death, each appealing to one aspect of his thought, testify to the width, coherence, and delicate balance of Luther's own teaching. The basis of his theology was Holy Scripture; and, though the differences between his own and Augustine's thought are important, Augustine must stand next to the Bible among the influences upon his mind. The doctrines of salvation were of prime importance for him, and here the two great, many-sided complex conceptions of the Word and of faith are important. His often subtle doctrine about civil obedience was not always understood by his later followers, and non-theological factors in German history perpetuated and, to a certain extent, even perverted this misunderstanding. His doctrine of Christian vocation in this world and the importance of human life in the world became part of the general Protestant and Puritan inheritance. In other matters—in the room allowed for Christian liberty, in his conception of the part played by law in Christian life, and in his insistence on the Real Presence in the Eucharist—his theology differs from the patterns that emerged in the Reformed (Presbyterian) churches, in Puritanism, and in the sects such as the Anabaptists.

MAJOR WORKS

In Latin

THEOLOGICAL WORKS: *Epistola Lutheriana ad Leonem decimum summum pontificem. Dissertatio de libertate Christiana per autorem recognita* (1519; "Concerning Christian Liberty"); *De votis monasticis* (1521); *De captivitate Babylonica ecclesiae praeludium* (1520; "A Prelude Concerning the Babylonian Captivity of the Church"); *De servo arbitrio* (1525; "Concerning the Bondage of the Will").

CONTROVERSIAL WRITINGS: *B. Martini Lutheri theses Tezelio, indulgentiarum institori oppositas* (1517; Ninety-five Theses); *Rationis Latomianae pro incendiariis Lovaniensis scholae sophistis redditae Lutheriana confutatio* (1521).

EXEGESIS: *Enarrationes epistolarum et evangeliorum, quas postillas vocant* (1521).

In German

THEOLOGICAL WORKS: *Von den guten Wercken* (1520; "Of Good Works"); *Von weltlicher Uberkeyt, wie weyt man yhr gehorsam schuldig sey* (1523; "Of Earthly Government"); *Das diese wort Christi (Das ist mein leib etce.) noch fest stehen widder die Schwermgeyster* (1527; "That These Words of Christ 'This is My Body' Still Stand Firm Against the Fanatics"); *Vom Abendmal Christi, Bekenntnis* (1528; "Confession of the Lord's Supper"); *Von den Conciliis und Kirchen* (1539; "Of Councils and Churches").

CONTROVERSIAL WRITINGS: *An den christlichen Adel deutscher Nation* (1520; "Address to the Christian Nobility of the German Nation"); *Widder die hymelischen Propheten von den Bildern und Sacrament* (1525; "Against the Heavenly Prophets in the Matter of Images and Sacraments"); *An die Radsherrn aller Stedte deutsches Lands: Das sie Christliche Schulen auffrichten und halten sollen* (1524); *Ermanunge zum Fride auff die zwelff Artikel der Bawrschafft ynn Schwaben* (1525); *Wider die mordischen uñ reubischen Rotten der Bawren* (1525); *Wider Hans Worst* (1541); *Wider das Bapstum zu Rom vom Teuffel gestifft* (1545).

TRANSLATIONS AND EXEGESIS: *Das Newe Testament Deutzsch* (1522); *Biblia, das ist, die gantze Heilige Schrifft Deudsch* (1534); *Das Magnificat verteuschet und ausgelegt* (1521).

OTHER WORKS (LITURGICAL): *Deudsche Messe* (1526). (DIDACTIC): *Der kleine Catechismus* (1559; "Small Catechism"); *Deudsch Catechismus* (1529; "Large Catechism"). Among his hymns the most famous is probably "Ein feste Burg ist unser Gott" ("A Mighty Fortress Is Our God"). (E.G.R.)

BIBLIOGRAPHY

Luther's writings. Collections are the *Works of Martin Luther*, 6 vol., Philadelphia ed. (1915–32, reprinted 1982); and *Luther's Works*, American ed., edited by JAROSLAV PELIKAN and HELMUT T. LEHMANN, 55 vol. (1955–76), henceforth an indispensable tool for English study. In German the definitive edition is *D. Martin Luthers Werke: kritische Gesamtausgabe* (1883–), known as the Weimar edition. There is a single-volume anthology edited by JOHN DILLENBERGER, *Martin Luther: Selections from His Writings* (1961); also useful is E. GORDON RUPP and BENJAMIN DREWERY, *Martin Luther* (1970). The following are important volumes in the *Library of Christian Classics*: vol. 15, *Lectures on Romans*, ed. by WILHELM PAUCK (1961); vol. 16, *Early Theological Works*, ed. by JAMES ATKINSON (1962, reprinted 1980); vol. 17, *Luther and Erasmus*, ed. by E. GORDON RUPP and PHILIP S. WATSON (1969); and vol. 18, *Letters of Spiritual Counsel*, ed. by THEODORE G. TAPPERT (1955). Another important work is *A Commentary on St. Paul's Epistle to the Galatians*, ed. by PHILIP S. WATSON (1953).

Biographical and critical studies: PETER MANNS, *Martin Luther: An Illustrated Biography*, trans. from German (1982),

emphasizes the religious context. JOHN M. TODD, *Luther* (1982), is a popular biography. HEINRICH BORNKAMM, *Luther in Mid-Career, 1521–1530,* ed. by KARIN BORNKAMM (1983; originally published in German, 1979), examines Luther and his thoughts at midlife. MARK U. EDWARDS, JR., *Luther and the False Brethren* (1975), details the years between the Diet of Worms and Luther's death. H.G. HAILE, *Luther: An Experiment in Biography* (1980), concentrates on the last 10 years of his life. DAVID C. STEINMETZ, *Luther and Staupitz: An Essay in the Intellectual Origins of the Protestant Reformation* (1980), studies the influence on Luther of his early confessor and friend. ROLAND H. BAINTON, *Here I Stand!* (1950, reissued 1990), is a respected study. Also of interest are FRANZ LAU, *Luther* (1963; originally published in German, 1959); and W.J. KOOIMAN, *By Faith Alone* (1954; originally published in Dutch, 1946). PRESERVED SMITH, *The Life and Letters of Martin Luther* (1911, reprinted 1968), is the best of the older studies. A broad survey is E.G. SCHWIEBERT, *Luther and His Times* (1950). ROBERT HERNDON FIFE, *The Revolt of Martin Luther* (1957), portrays the young Luther. A brief account is E. GORDON RUPP, *Luther's Progress to the Diet of Worms, 1521* (1951, reissued 1964). WALTHER VON LOEWENICH, *Martin Luther: The Man and His Work* (1986; originally published in German, 1982), is an introductory analysis. GERHARD BRENDLER, *Martin Luther: Theology and Revolution* (1991; originally published in German, 1983), is a biography written from a Marxist perspective. A scholarly and readable interpretation of Luther is found in ERIC W. GRITSCH, *Martin—God's Court Jester: Luther in Retrospect* (1983). JAMES M. KITTELSON, *Luther the Reformer: The Story of the Man and His Career* (1986), makes Luther accessible to readers with little background in the history of the Reformation. BERNHARD LOHSE, *Martin Luther: An Introduction to His Life and Work* (1986; originally published in German, 1981), is also of special interest. The development of Luther, the man and the theologian, is assessed in HEIKO A. OBERMAN, *Luther: Man Between God and the Devil* (1989; originally published in German, 1982). MARTIN BRECHT, *Martin Luther,* 3 vol. (1985–93; originally published in German, 1983–87), is an in-depth portrait of the man and his times. Luther and his era are addressed in JAMES ATKINSON, *Martin Luther and the Birth of Protestantism,* rev. ed. (1982); A.G. DICKENS, *Reformation and Society in Sixteenth Century Europe* (1966, reprinted 1979); JOSEPH LORTZ, *The Reformation in Germany,* 2 vol. (1968; originally published in German, 1939); and WILHELM PAUCK, *Heritage of the Reformation,* rev. ed. (1961). MARK U. EDWARDS, JR., *Luther's Last Battles: Politics and Polemics, 1531–46* (1983), explores the influence of politics on Luther's thoughts, especially in his later years. Luther's politics are appraised in W.D.J. CARGILL THOMPSON, *The Political Thought of Martin Luther,* ed. by PHILIP BROADHEAD (1984). Critical studies on Luther's theology include GERHARD EBELING, *Luther: An Introduction to His Thought* (1970; originally published in German, 1964); PHILIP S. WATSON, *Let God Be God!* (1947, reissued 1970); E. GORDON RUPP, *The Righteousness of God* (1953, reissued 1963); HEINRICH BORNKAMM, *Luther's World of Thought* (1958; originally published in German, 1947); B.A. GERRISH, *Grace and Reason* (1962, reprinted 1979); REGIN PRENTER, *Spiritus Creator* (1953; originally published in Danish, 1944); and IAN D. KINGSTON SIGGINS, *Martin Luther's Doctrine of Christ* (1970). ALISTER E. MCGRATH, *Luther's Theology of the Cross: Martin Luther's Theological Breakthrough* (1985), focuses on the evolution of Luther's theology from 1509 to 1519. Luther's influence is traced in ERNST WALTER ZEEDEN, *The Legacy of Luther* (1954; originally published in German, 1950); and EDGAR M. CARLSON, *The Reinterpretation of Luther* (1948), a survey of Scandinavian Luther studies. Important studies written in languages other than English include KARL HOLL, *Gesammelte Aufsätze zur Kirchengeschichte,* 3 vol. (1921–28, reissued 1964); EMANUEL HIRSCH, *Lutherstudien,* 2 vol. (1954); RUDOLF HERMANN, *Gesammelte Studien zur Theologie Luthers und der Reformation* (1960); ERNST WOLF, *Peregrinatio,* 2nd ed., 2 vol. (1962); JOHANNES HECKEL, *Lex Charitatis,* 2nd ed. (1973); ERNST BIZER, *Fides ex auditu,* 3rd ed. (1966); OTTO HERMAN PESCH, *Die Theologie der Rechtfertigung bei Martin Luther und Thomas von Aquin* (1967, reprinted 1985); REINHARD SCHWARZ, *Fides, Spes, und Caritas beim Jungen Luther* (1962); and BERNHARD LOHSE, *Mönchtum und Reformation* (1963). Two psychological studies are PAUL J. REITER, *Martin Luthers Umwelt, Charakter und Psychose,* 2 vol. (1937–41); and ERIK H. ERIKSON, *Young Man Luther: A Study in Psychoanalysis and History* (1958, reissued 1993).

(Ed.)

Luxembourg

The Grand Duchy of Luxembourg is a tiny sovereign state of only 998 square miles (2,586 square kilometres) that is bordered by Belgium on the west and north, France on the south, and Germany on the northeast and east. Luxembourg has come under the control of many states and ruling houses in its long history, but it has been a separate, if not always autonomous, political unit since the 10th century. The ancient Saxon name of its capital city, Lucilinburhuc ("Little Fortress"), symbolized its strategic position as "the Gibraltar of the north," astride a major military route linking Germanic and Frankish territories.

Strategic location

Luxembourg is a point of contact between the Germanic- and Romance-language communities of Europe, and the grand duchy itself has three official languages: German, French, and Luxembourgian. The peoples of Luxembourg and their languages reflect the grand duchy's common interests and close historical relations with its neighbours. In the 20th century, Luxembourg became a founding member of several international economic organizations. Perhaps most importantly, the grand duchy was an original member of the Benelux Economic Union (1944), which linked its economic life with that of The Netherlands and of Belgium and would subsequently form the core of the European Community (EC).

This article is divided into the following sections:

Physical and human geography

THE LAND

Relief and soils. The northern third of Luxembourg, known as the Oesling (Ösling), comprises a corner of the Ardennes Mountains, which lie mainly in southern Belgium. It is a plateau that averages 1,500 feet (450 metres) in elevation and is composed of schists and sandstones. This forested highland region is incised by the deep valleys of a river network organized around the Sûre (or Sauer) River, which runs eastward through north-central Luxembourg before joining the Moselle (or Mosel) River on the border with Germany. The Oesling's forested hills and valleys support the ruins of numerous castles, which are a major attraction for the region's many tourists. The fertility of the relatively thin mountain soils of the region was greatly improved with the introduction in the 1890s of a basic-slag fertilizer, which is obtained as a by-product of the grand duchy's steel industry.

Main regions

The southern two-thirds of Luxembourg is known as the Bon Pays, or Gutland (French and German: "Good Land"). This region has a more varied topography and an average elevation of 800 feet. The Bon Pays is much more densely populated than the Oesling and contains the capital city, Luxembourg, as well as smaller industrial cities such as Esch-sur-Alzette. In the centre of the Bon Pays, the valley of the northward-flowing Alzette River forms an axis around which the nation's economic life is organized. Luxembourg city lies along the Alzette, which joins the Sûre farther north.

In the east-central part of the Bon Pays lies a great beech forest, the Müllerthal, as well as a sandstone area featuring an attractive ruiniform topography. The country's eastern border with Germany is formed (successively from north to south) by the Our, Sûre, and Moselle rivers. The slopes of the Moselle River valley, carved up in chalk and calcareous clay, are covered with vineyards and receive a substantial amount of sunshine, which has earned the area the name of "Little Riviera." Besides vineyards, the fertile soils of the Moselle and lower Sûre valleys also support rich pasturelands. Luxembourg's former iron mines are located in the extreme southwest, along the duchy's border with France.

Climate. Luxembourg has a mild climate, with considerable precipitation. The north is slightly colder and more humid than the south. The mean temperatures in Luxembourg city range from 33° F (0.7° C) in January to 63° F (17° C) in July, but in the Oesling both extremes are slightly lower. The Oesling receives more precipitation than the Bon Pays, but the greatest amount, about 40 inches (1,000 millimetres), and the least, about 27 inches, fall in the southwest and southeast, respectively. The sheltered valley of the Moselle River benefits from a gentler and sunnier climate than does the rest of the duchy.

Settlement patterns. Northern Luxembourg is sparsely populated compared to the heavily urbanized and industrialized south. The north's rural population is clustered in villages of thick-set stone houses with slate roofs. The urban network in the south is dominated by the capital city, Luxembourg, which rises in tiers, with the upper (and older) section of the city separated from the lower-lying suburbs by the gorges of the Alzette and Petrusse rivers. A new quarter housing many European organizations nestles in a picturesque site carved into the river valley's sandstone cliffs. The second-largest city in Luxembourg, Esch-sur-Alzette, lies in the extreme southwest and is a traditional iron-making centre. Its growth, like that of the neighbouring iron and steel centres of Pétange, Differdange, and Dudelange, has slowed since the shrinkage of those industries in western Europe in the late 20th century. The remainder of the nation's population lives in towns and villages of relatively small size. Many of Luxembourg's villages date from ancient Celtic and Roman times or originated in Germanic and Frankish villages after about AD 400. In addition, many medieval castle villages continue to thrive, centuries after the castles themselves fell into ruin.

THE PEOPLE

Luxembourg has been one of the historic crossroads of Europe, and myriad peoples have left their bloodlines as well as their cultural imprints on the grand duchy. The Celts,

the Belgic peoples known as the Treveri, the Ligurians and Romans from Italy, and especially the Franks were most influential. The dialect spoken by Luxembourg's native inhabitants is Luxembourgian, or Letzeburgesch, a Moselle-Franconian dialect of German that has been enriched by many French words and phrases. Most Luxembourgers speak French (used for most official purposes) and German (the lingua franca). There is a strong sense of national identity among Luxembourgers despite the prevalence of these foreign influences. Almost all of Luxembourg's native citizens are Roman Catholic, with a small number of Protestants, mainly Lutherans, and Jews.

National languages

Luxembourg has a higher proportion of foreigners living within its borders than does any other European country. This is chiefly the result of an extremely low birthrate among native Luxembourgers, which has led to a chronic labour shortage. Fully one-quarter of the total population is of foreign birth and consists mainly of Portuguese, Italians, and other southern Europeans, along with French, Belgians, and Germans. Among the foreign workers are many in the iron and steel industry, and numerous others work in foreign firms and international organizations located in the capital.

The 20th century has also witnessed a continual internal migration away from the countryside to urban areas, and the growth of Luxembourg's service sector at the expense of heavy industry has only accelerated this trend. Luxembourg city in particular continues to attract migrants from the rest of the country because of its vibrant banking and finance sector. The increasing concentration of the population in the southwest has led the government to try to locate some industries in rural areas. About two-thirds of Luxembourg's work force is engaged in trade, government, and other service occupations, while almost one-third of the work force is employed in industry and construction, and the rest in agriculture.

THE ECONOMY

Luxembourg's economy is notable for its close connections with the rest of Europe, since Luxembourg itself is too small to create a self-sustaining internal market. Luxembourg's prosperity was originally based on the iron and steel industry, which in the 1960s represented as much as 80 percent of the total value of exports. By the late 20th century, however, the nation's economic vigour stemmed chiefly from its involvement in international banking and financial services and in such noncommercial activities as hosting intra-European political activities. The result of this adaptability and cosmopolitanism is a very high standard of living; the Luxembourgers rank in the world second only to the Swiss in their standard of living and their per capita income.

Resources. Luxembourg's natural resources are quite modest. Its agriculture is not particularly prosperous, and its once-copious iron ore deposits had been exhausted by the 1980s. With the exception of water and timber, there are no energy resources. Indeed, Luxembourg has almost nothing that predisposes it to agricultural or industrial development. The roots of its economic growth lie in its use of capital and in the adaptability and ingenuity of its work force rather than in natural resources.

The town of Clervaux, in the Oesling, Lux.
E. Streichan/SuperStock

Industry. The production and export of iron and steel have long played major roles in Luxembourg's economy. Steel production was originally based on exploitation of the iron ore deposits extending from Lorraine into the southwestern corner of the grand duchy. This ore has a high phosphorus content, however, and it was not until the introduction of the basic Bessemer process in 1879 that the ore could be used for making steel. Thereafter Luxembourg's metallurgical industries grew and flourished. During the 1970s, however, the worldwide demand for steel slumped, causing the steel industry's portion of Luxembourg's gross domestic product to fall. In response to this crisis, the steel industry was restructured and merged into a single group called ARBED (Aciéries Réunies de Burbach-Eich-Dudelange), and further measures aimed at increasing efficiency enabled Luxembourg's steelmakers to maintain their profitability. With the overall decline of steel production, however, Luxembourg's economy has become more dependent on factories owned by American-based and other multinational companies operating in the country. These factories primarily produce motor-vehicle tires, chemicals, and fabricated metals.

Luxembourg had become an international financial centre and a home to more than 160 banks by the late 20th century. It owes this position to a number of factors, perhaps chief of which is the government's own farsighted policies. In 1929 the government began to encourage the registering in Luxembourg of holding companies; these large corporations can control a number of subsidiary companies but are heavily taxed in many countries of the world. The liberal tax climate produced by the new policy led many industrial and financial corporations to maintain offices, often as their European headquarters, in Luxembourg city. The main offices of the European Investment Bank are there, as are the representatives of many banking institutions from around the world who keep in contact with the European Community (EC). Luxembourg city is also one of the capitals of the EC and as such is home to the European Court of Justice and several major EC administrative offices.

Agriculture. The agricultural resources of Luxembourg are quite modest. With the exception of livestock products, surpluses are scarce, and marginal soils in many parts of the country hinder abundant harvests. Most farming is mixed and includes both animal raising and gardening. Livestock and their by-products account for the bulk of agricultural production, with cattle raising having gained in importance at the expense of pig and sheep raising. Wheat, barley, and other cereal grains are the next most important products, followed by root vegetables. More than three-quarters of the country's farms are smaller than 200 acres (50 hectares). The vineyards along the Moselle River produce some excellent wines.

International trade. Luxembourg's overall balance of payments is strongly positive, mostly because of the country's thriving financial sector. Most of the grand duchy's merchandise trade takes place with EC countries, and especially its three neighbours—Germany, Belgium, and France, which together receive about 60 percent of Luxembourg's exports and provide about 80 percent of its imports.

Energy. Luxembourg meets most of its energy needs with imports. Its only domestic source of power is the hydroelectricity obtained from several dams on its rivers.

Transportation. Luxembourg's internal road system is not extensive but is well maintained, and several highways link the country with its neighbours. A port at Mertert on the canalized Moselle River connects the grand duchy with the Rhine waterway system and provides it with an avenue for the international movement of goods.

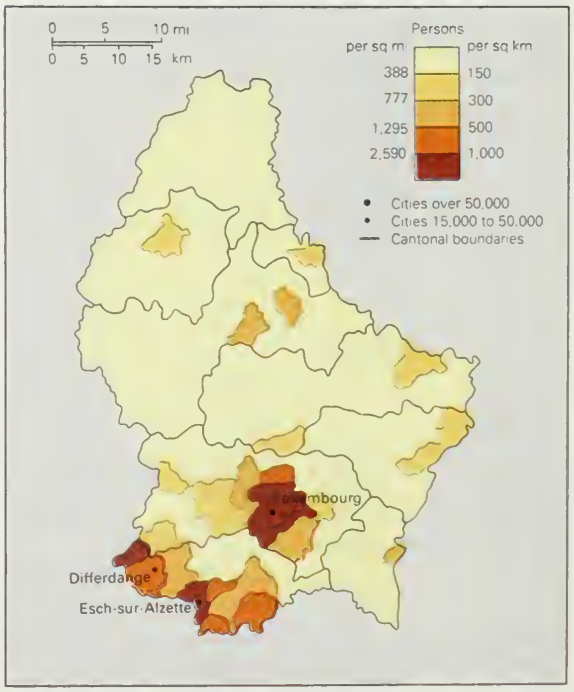
The government has operated the nation's railroads since World War II. They are modern, electrified, and mostly double-tracked. A major portion of international transportation to and from Luxembourg is by train, and the country is connected with its neighbours by a large number of lines. Findel Airport outside Luxembourg city has become a major European air terminal served by the lines of many countries. Luxair is the national airline.

Communications. Luxembourg's advanced telecommunications system provides it with close links both to EC countries and to other financial partners around the world, including Japan and the United States.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. The grand duchy is a constitutional monarchy with hereditary succession. Executive power authority lies with the grand duke, who appoints the prime minister. The powers of the grand duke are primarily formal, however. Actual executive power lies with the prime minister and his ministerial council, or Cabinet, who are responsible to the Chamber of Deputies. The members of this legislative assembly are elected by popular vote to five-year terms. Voting by all adult citizens, begun in 1919, is compulsory. Legislative elections have usually given rise to coalition governments formed alternatively by two of the three major parties: the Christian Social Party, the Socialist Workers' Party, and the Democratic Party. In addition, a Council of State named by the grand

Division of government responsibilities



Population density of Luxembourg.

duke functions as an advisory body. It is consulted on all draft legislation, advises the grand duke on administrative affairs, and serves as a supreme court in case of administrative disputes.

There are also three advisory bodies that are consulted before the passage of legislation affecting their particular area of the national life. The first of these consists of six confederations, three of which represent employers (commerce, guilds, and farmers) and three of which represent labour (workers, private employees, and civil servants). The second advisory group, the Social and Economic Council, has become a major committee for the examination of all projects. The third, the Immigration Council, advises the government on problems involving housing and the political rights of immigrants.

Justice is in the hands of magistrates appointed for life by the grand duke, the final appeal lying with the Superior Court of Justice. In the criminal court of assizes, six magistrates sit as jury as well as judge. Luxembourg is a member of the North Atlantic Treaty Organization (NATO) and has a small volunteer army. There is also a small paramilitary gendarmerie.

Luxembourg is divided administratively into three districts, each of which is headed by a commissioner appointed by the central government. Each district is in turn divided into cantons and subdivided into communes, or municipalities. Public works, health, and education are among the responsibilities of the communes, each of which is governed by an elected council and a mayor. These bodies also maintain liaison with the central government and act as its local agents.

Health and welfare. After World War I a broad system of social security and health services was introduced in Luxembourg to ensure maximum welfare protection to each citizen. Sickness benefits, in which patients pay only a small part of medical costs, as well as birth, family, and unemployment payments, are included in the plans. Housing conditions are generally comparable to those found in other western European countries. There has been some difficulty, however, in assimilating the many thousands of foreign workers and their families.

Education. Education is compulsory from age 6 to 15. The educational system offers a mix of primary and secondary schools run by state and local governments and by religious institutions. Considerable emphasis is laid on language studies. Instruction is initially given in German, and French is added in the second year. French completely replaces German in the classroom at the secondary level. There are no four-year universities in the grand duchy, so many young Luxembourgers obtain their higher education abroad. Luxembourg city does, however, have a campus that offers first-year university studies.

CULTURAL LIFE

The major cultural institution of Luxembourg is the Grand Ducal Institute, which has sections devoted to history, science, medicine, languages and folklore, arts and literature, and moral and political sciences. It functions as an active promoter of the arts, humanities, and general culture rather than as a conservator. The National Museum of History and Art has collections on the fine and industrial arts and on the history of Luxembourg. There is considerable public use of the National Library, the National Archives, and the Music Conservatory of the City of Luxembourg. The grand duchy also maintains cultural agreements with several European and other nations that provide it with the finest in the musical and theatrical arts. The Grand Orchestra of Radiotelevision Luxembourg is considered outstanding. There is an extensive market in Luxembourg city for works of painting and sculpture, both traditional and modern. The grand duchy's architectural heritage extends through practically the entire span of Europe's recorded history, from ancient Gallo-Roman villas to medieval castles, Gothic and Baroque churches, and contemporary buildings.

A small publishing industry exists, printing literary works in French, German, and Luxembourgian. The grand duchy's newspapers express diverse political points of view—conservative, liberal, socialist, and communist. Luxembourg's influence is felt far beyond its borders through the medium of Radiotelevision Luxembourg (RTL), a privately owned broadcasting company that transmits radio programs in five languages and television programs in two (French and German). RTL has a total European audience numbering as many as eight million persons. The government operates all postal and telegraph services in Luxembourg and has some control in the corporation that runs RTL.

Radiotelevision Luxembourg

For statistical data on the land and people of Luxembourg, see the *Britannica World Data* section in the BRITANNICA BOOK OF THE YEAR. (V.Bi./J.-P.E./J.M.G.)

History

ANCIENT AND MEDIEVAL PERIODS

The earliest human remains found in present-day Luxembourg date from about 5140 BC, but little is known about the people who first populated the area. Two Belgic tribes, the Treveri and Mediomatrici, inhabited the country from about 450 BC until the Roman conquest of 53 BC. The occupation of the country by the Franks in the 5th century AD marked the beginning of the Middle Ages in the locality. St. Willibrord played a very important role in the area's Christianization in the late 7th century. He founded the Benedictine abbey of Echternach, which became an important cultural centre for the region.

The area successively formed part of the Frankish kingdom of Austrasia, of the Holy Roman Empire under Charlemagne and Louis I the Pious, and then of the kingdom of Lotharingia. Luxembourg became an independent entity in 963, when Siegfried, Count de Ardennes, exchanged his lands for a small but strategically placed Roman castle lying along the Alzette River. This castle became the cradle of Luxembourg, whose name is itself derived from that of the castle, Lucilinburhuc ("Little Fortress"). Siegfried's successors enlarged their possessions by conquests, treaties, marriages, and inheritances. About 1060 Conrad, a descendant of Siegfried, became the first to take the title of count of Luxembourg. Conrad's great-granddaughter, Countess Ermesinde, was a notable ruler whose great-grandson, Henry IV, became Holy Roman emperor as Henry VII in 1308. This Luxembourg dynasty was continued on the imperial throne in the persons of Charles IV, Wenceslas, and Sigismund. In 1354 the emperor Charles IV made the county a duchy. In 1443 Elizabeth of Görlitz, duchess of Luxembourg and niece of the Holy Roman emperor Sigismund, was forced to cede the duchy to Philip III the Good, duke of Burgundy.

Origin of Luxembourg

HABSBURG AND FRENCH DOMINATION

Along with the rest of the Burgundian inheritance, the duchy of Luxembourg passed to the Habsburgs in 1477. The division of the Habsburg territories in 1555–56 following Emperor Charles V's abdication put the duchy in the possession of the Spanish Habsburgs. In the revolt of the Low Countries against Philip II of Spain, Luxembourg took no part; it was to remain with what is now Belgium as part of the Spanish Netherlands. (For more specific information about the period, see THE NETHERLANDS.)

The duchy was able to remain aloof from the Thirty Years' War (1618–48) for a time, but in 1635, when France became involved, a period of disaster began in Luxembourg, which was wracked by war, famine, and epidemics. Moreover, the war did not end for Luxembourg with the Peace of Westphalia in 1648, but only with the Treaty of the Pyrenees in 1659. In 1679 France under Louis XIV began to conquer parts of the duchy, and in 1684 the conquest was completed with the capture of Luxembourg city. France restored Luxembourg to Spain in 1697, however, under the terms of the Treaties of Rijswijk. At the conclusion of the War of the Spanish Succession, by the treaties of Utrecht and Rastatt (1713–14), Luxembourg (along with Belgium) passed from the Spanish to the Austrian Habsburgs.

In 1795, six years after the beginning of the French Revolution, Luxembourg came under the rule of the French again. The old duchy was divided among three *départements*, the constitution of the Directory was imposed,

and a modern state bureaucracy was introduced. The Luxembourg peasantry were hostile toward the French government's anticlerical measures, however, and the introduction of compulsory military service in France in 1798 provoked a rebellion (the Klëppelkrieg) in Luxembourg that was brutally suppressed.

PERSONAL UNION WITH THE NETHERLANDS

French domination ended with the fall of Napoleon in 1814, and the Allied powers decided the future of Luxembourg at the Congress of Vienna in 1815. The Congress raised Luxembourg to the status of a grand duchy and gave it to William I, prince of Orange-Nassau and king of the Netherlands. William obtained a Luxembourg that was considerably diminished, since those of its districts lying east of the Our, Sûre, and Moselle rivers had been ceded to Prussia. The status of the grand duchy during this period was complex: Luxembourg had the legal position of an independent state and was united with The Netherlands only because it was a personal possession of William I. But Luxembourg was also included within the German Confederation, and a Prussian military garrison was housed in the capital city.

The standard of living of Luxembourg's citizens deteriorated during this period. Under Austrian rule, and especially from 1735 on, the duchy had experienced an economic expansion. From 1816–17 on, however, William I ignored the duchy's sovereignty, treating Luxembourg as a conquered country and subjecting it to heavy taxes. Consequently, it was not surprising that Luxembourg supported the Belgian revolution against William in 1830, and, in October of that year, the Belgian government announced that the grand duchy was a part of Belgium, while William still claimed the duchy as his own. In 1831 the Great Powers (France, Britain, Prussia, Russia, and Austria) decided that Luxembourg had to remain in William I's possession and form part of the German Confederation. Moreover, the Great Powers allotted the French-speaking part of the duchy to Belgium (in which it became a province called Luxembourg), while William I was allowed to retain the Luxembourgian-speaking part. Belgium accepted this arrangement, but William I rejected it, only to subsequently accede to the arrangement in 1839. From that year until 1867, the duchy was administered autonomously from The Netherlands.

The rule of William I

INDEPENDENT LUXEMBOURG

William I negotiated a customs union for Luxembourg with Prussia, and his successor, William II, ratified this treaty in 1842. Against its own will, Luxembourg had thus entered into the Prussian-led Zollverein, or Customs Union, but the grand duchy soon realized the advantages of this economic union. Luxembourg subsequently developed from an agricultural country into an industrial one. Its road network was extended and improved, and two railway companies were begun that formed the basis for the national railway company founded in 1946.

The restricted constitution that William II enacted for Luxembourg in 1841 did not meet the political expectations of its citizens. The Revolution of 1848 in Paris had its influence on the grand duchy, and William II that year enacted a new and more liberal constitution, which was in turn replaced by another constitution in 1856. In 1866 the German Confederation was dissolved, and Luxembourg became an entirely sovereign nation, though the Prussian garrison remained in the capital. Napoleon III of France then tried to purchase the grand duchy from William III. The two rulers had already agreed on the sum of five million florins when William III backed out because the Prussian chancellor, Otto von Bismarck, disapproved of the sale. The Great Powers soon came to a compromise (London, May 11, 1867): Prussia had to withdraw its garrison from the capital, the fort would be dismantled, and Luxembourg would become an independent nation. The grand duchy's perpetual neutrality was guaranteed by the Great Powers, and its sovereignty was vested in the house of Nassau.

Independent Luxembourg

On the death of William III of The Netherlands in 1890 without a male heir, the grand duchy passed to Adolf, duke of Nassau (d. 1905), who was succeeded by his son William (d. 1912). Neither Adolf nor William interfered much in Luxembourg's government, but William's daughter, the grand duchess Marie Adélaïde, was more assertive and eventually became highly unpopular with the people. In 1914 the neutrality of Luxembourg was violated by Germany, which occupied the grand duchy until the Armistice of 1918. During the war, Marie Adélaïde had tolerated the illegal German occupation, for which she was criticized by the Allied powers after the liberation. Marie Adélaïde was forced to abdicate in favour of her sister Charlotte in 1919. In a referendum a few months later, the public voted overwhelmingly against the establishment of a republic and in favour of retaining Charlotte as grand duchess.

In December 1918 the Allied powers had forced Luxembourg to put an end to its customs union with Germany. For the grand duchy this meant the loss of its best customer (for cast iron and steel) as well as its main supplier of coal. Luxembourg urgently needed a new economic partner, and, though the people preferred an economic union with France, the grand duchy was forced to negotiate with Belgium, since France declared itself uninterested in such a union. The Belgium-Luxembourg Economic Union (BLEU) was established in 1921 and provided for a customs and monetary union between the two countries. The economic climate in Luxembourg remained rather dreary during the interwar period though.

In May 1940 the German army invaded and occupied Luxembourg for the second time; however, this time the government refused to collaborate and, together with the grand duchess, went into exile. Luxembourg was placed under German rule, and the French language was banned.

After Luxembourg's liberation in September 1944, it took part in the new international organizations being formed by the victorious Allies, including the United Nations. Luxembourg also joined the new Benelux Economic Union (1944) formed between Belgium, The Netherlands, and itself. By taking part in the Brussels Treaty of 1948 and in the formation of NATO in 1949, Luxembourg abandoned its perpetual neutrality. The country improved its economic position by obtaining a sound position within the European Coal and Steel Community (1952) and within the European Economic Community (1957). Prince Jean, Charlotte's son, was installed as lieutenant-representant of Charlotte in 1961, and he inherited the throne in 1964 upon his mother's abdication. (V.L.)

Role in European unity

For later developments in the history of Luxembourg, see the BRITANNICA BOOK OF THE YEAR.

Madagascar

The Republic of Madagascar (Malagasy: Repoblikan'i Madagasikara; French: République de Madagascar) lies off the southeastern coast of Africa. It occupies the fourth largest island in the world—after Greenland, New Guinea, and Borneo—with a surface area of 226,658 square miles (587,041 square kilometres). Located in the southwestern Indian Ocean, it is separated from the African coast by the 250-mile- (400-kilometre-) wide Mozambique Channel.

In spite of Madagascar's proximity to the continent, its population is primarily related not to African peoples but rather to those of Indonesia, more than 3,000 miles to the east. The Malagasy peoples, moreover, do not consider themselves to be Africans, but, because of the continuing bond with France that resulted from former colonial rule, the island has developed political, economic, and cultural links with the French-speaking countries of western Africa. French and Malagasy are the country's official languages.

Madagascar remains a geographic and historical paradox, linked in practice to Africa but identified in feeling with Indonesia, which is so far away as to have hardly any awareness of Madagascar or to maintain any contemporary ties of substance with it. The animal life and vegetation of the island are equally anomalous, differing greatly from that of nearby Africa and being, in many respects, unique.

Although the coastlands have been known to Europeans for more than 400 years and to Arabs for much longer, recent historical development has been more intense and concentrated in the central plateau, which contains the capital city of Antananarivo (formerly Tananarive). The road network and communications are generally better on the plateau, where the majority of the inhabitants have received some school education and are professing Christians, while in the coastal areas the majority follow traditional religions and generally have not attended school. (Ai.S.)

The article is divided into the following sections:

Physical and human geography

THE LAND

Relief. Madagascar consists of three parallel longitudinal zones—the central plateau, the coastal strip in the east, and the zone of low plateaus and plains in the west.

The plateau

Situated between 2,500 and 4,500 feet (800 and 1,400 metres) above sea level, the plateau has been uplifted and worn down several times and is tilted to the west. Three massifs are more than 8,500 feet high. The Tsaratanana region in the north is separated from the rest of the plateau by the Tsaratanana Massif, whose summit at an elevation of 9,436 feet (2,876 metres) is the highest point on the island. Ankaratra Massif in the centre is an enormous volcanic mass whose summit, Tsiafajavona, is 8,668 feet high. Ankaratra is a major watershed divide separating three main river basins. Farther south, Andringitra is a vast granite massif north of Tôlañaro (Faradofay); it rises to 8,720 feet at Boby Peak.

The plateau slopes more regularly toward the extreme southern plain, but its boundaries to the east and west are more abrupt. To the east it descends in a sharp fault, by vertical steps of 1,000 to 2,000 feet. This cliff, which is called the Great Cliff or Cliff of Angavo, is often impassable and is itself bordered by the Betsimisaraka Escarpment, a second and lower cliff to the east, which overhangs the coastal plain.

Behind the scarp face are the remains of ancient lakes, including one called Alaotra. To the south the two steep gradients meet and form the Mahafaly and the Androy plateaus, which overhang the sea in precipitous cliffs. Toward the west the descent is made in a series of steps. In places, however, the central plateau is bordered by an impassable escarpment, such as the Cliff of Bongolava in the west-central part of the island. To the extreme north the plateau is bordered by the low belt of the Ambohitra Mountains, which include a series of volcanic craters.

The coasts

The coastal strip has an average width of 30 miles. It is a narrow alluvial plain that terminates in a low coastline bordered with lagoons linked together by the Pangalanes (Ampangalana) Canal, which is some 400 miles long. To the south of Farafangana the coast becomes rocky, and in the southeast there occur many little bays. To the northeast is the deep Bay of Antongil (Antongila).

The western zone is between 60 and 125 miles wide. Its sedimentary layers slope toward the Mozambique Channel and produce a succession of hills. The inland (eastern) side of these steep hills dominates the hollows formed in the soft sediments of the interior, while the other side descends to the sea in rocky slopes. The coastline is straight, bordered by small dunes and fringed with mangroves. The currents in the Mozambique Channel have favoured the offshore deposit of alluvium and the growth of river deltas. On the northwestern coast there are a number of

estuaries and bays. This coast is bordered by coral reefs and volcanic islands, such as Nosy-Be (Nossi-Bé), which protects Ampasindava Bay. (Je.D.)

Drainage and soils. *Drainage.* The steep eastern face of the plateau is drained by numerous short, torrential rivers, which discharge either into the coastal lagoons or directly into the sea over waterfalls and rapids. They include the Mandrare, the Mananara, the Faraony, the Ivondro, and the Maningory. The more gently sloping western side of the plateau is crossed by longer and larger rivers, including the Onilahy, the Mangoky, the Tsiribihina, and the Betsiboka, which bring huge deposits of fertile alluvium down into the vast plains and many-channeled estuaries; the river mouths, while not completely blocked by this sediment, are studded with numerous sandbanks.

The volcanic lakes

There are many lakes of volcanic origin on the island, such as Lake Itasy. Alaotra is the last surviving lake of the eastern slope. Lake Tsimanampetsotsa, near the coast south of Toliara (formerly Tuléar), is a large body of saline water that has no outlet.

Soils. The central plateau and the eastern coast are mainly composed of gneiss, granite, quartz, and other crystalline rock formations. The gneiss decomposes into red murrum, laterite, and deeper and more fertile red earths, giving Madagascar its colloquial name of the Great Red Island. Fertile alluvial soils in the valleys support intensive cultivation. There also are scattered volcanic intrusions that produce fertile but easily erodible soils. Lake Alaotra is a large sedimentary pocket in the central plateau containing some of the island's most productive farmland. The western third of the island consists entirely of deposits of sedimentary rock, giving rise to soils of medium to low fertility.

Climate. The hot, wet season extends from November to April and the cooler, drier season from May to October. The climate is governed by the combined effects of the moisture-bearing southeast trade and northwest monsoon winds as they blow across the central plateau. The trade winds, which blow throughout the year, are strongest from May to October. The east coast is to the windward and receives a high annual rate of precipitation, reaching nearly 150 inches (3,800 millimetres) at Maroantsetra on the Bay of Antongil. As the winds cross the plateau, they lose much of their humidity, causing only drizzle and mists on the plateau itself and leaving the west in a dry rain shadow. The southwest in particular is almost desert, with the dryness aggravated by a cold offshore current.

The western rain shadow

The monsoon, bringing rain to the northwest coast of Madagascar and the plateau, is most noticeable during the hot, humid season. The wind blows obliquely onto the west coast, which receives a moderate amount of precipitation annually; the southwest, which is protected, remains arid. Annual rainfall drops from 83 inches on the northwestern island of Nosy-Be to 37 inches at Maintirano on the west coast to 14 inches at Toliara in the southwest. The plateau receives moderate rains, with 53 inches falling annually at Antananarivo and 48 inches at Fianarantsoa, which lies about 200 miles farther south.

July is the coolest month, with mean monthly temperatures around the island ranging from a low of about 50° F

(10° C) to a high of about 78° F (26° C), and December is the hottest month, with temperatures between 61° and 84° F (16° and 29° C). Temperatures generally decrease with elevation, being highest on the northwest coast and lowest on the plateau.

Tropical cyclones are an important climatic feature. They form far out over the Indian Ocean, especially from December to March, and approach the eastern coast, bringing torrential rains and destructive floods.

Plant and animal life. Much of the island was once covered with evergreen and deciduous forest, but little now remains except on the eastern escarpment and in scattered pockets in the west. The plateau is particularly denuded and suffers seriously from erosion. The forest has been cut in order to clear rice fields, to obtain fuel and building materials, and to export valuable timber, such as ebony, rosewood, and sandalwood. About seven-eighths of the island is covered with prairie grasses and bamboo or small thin trees. There also are screw pines, palms, and reeds on the coasts. In the arid south of the island grow thorn trees, giant cacti, dwarf baobab trees, pachypodium succulents, and other xerophytes (drought-resistant plants) that are peculiar to the island.

The grassland vegetation

Because of the island's isolation, many zoologically primitive primates have survived and evolved into unique forms. About 40 species of lemurs are indigenous to Madagascar. Several unique hedgehoglike insectivores have evolved, and there are many kinds and sizes of chameleons. Birds are numerous and include guinea fowls, partridges, pigeons, herons, ibis, flamingos, egrets, cuckoos, Asian robins, and several kinds of birds of prey. There are about 800 species of butterfly, many moths, and a variety of spiders. The only large or dangerous animals are the crocodiles, which occupy the rivers. The snakes, including the *do*, which is 10 to 13 feet in length, are harmless.

Inland waters contain tilapia (an edible perchlike fish), rainbow trout, and black bass. Marine fish and crustaceans abound on the coasts and in the lagoons, estuaries, and even in some upland streams. They include groupers, giltheads, tuna, sharks, sardines, whitings, crayfish, crabs, shrimps, mussels, and oysters. The coelacanth, referred to as a living fossil and once thought extinct for millions of years, inhabits offshore waters.

Settlement patterns. Despite the importance of intensive rice cultivation, the land is used primarily for pastoral purposes. Cattle are kept in all parts of the island. Fewer are found in the dense forest areas of the eastern escarpment, but elsewhere pastoralism predominates, most often coexisting with the cultivation of subsistence crops.

Rice cultivation

On the plateau, the valley floors and irrigable slopes are mainly used for growing rice. The forest peoples traditionally grew hill rice, after cutting and burning the forest; this practice continues, although it is discouraged by the government, which promotes the establishment of permanent irrigated rice fields.

The older villages of the Merina and Betsileo were often perched on hilltops and defended by huge ditches. Today, villages have been rebuilt on lower ground, and hamlets and homesteads are scattered over the landscape. On the plateau, cattle enclosures are built of stone walls; the landscape is also dotted with funerary monuments, which take the form of beautifully carved wooden posts.

Small towns began to develop at the administrative centres of the island's several kingdoms at least by the 18th century. The most populous cities are Antananarivo, in the central plateau; Mahajanga (formerly Majunga), on the northwest coast; Fianarantsoa, in the southern plateau; Toamasina (formerly Tamatave), on the east coast; Antsiranana, in the north; Toliara, in the southwest; and Antsirabe, south of Antananarivo, mainly a tourist centre.

Racial or economic separation is not noticeable in the older cities such as Antananarivo and Fianarantsoa, but the newer towns are often divided into socioeconomic sectors. Because of recent internal migration, most of the cities are composed of a mixture of ethnic groups.

THE PEOPLE

Population groups. Madagascar has been inhabited by human beings for the relatively short period of only about 2,000 years. Language and culture point unequivocally to Indonesian origins, but there is no empirical evidence of how, why, or by what route the first settlers came to the island. Studies of the winds and currents of the Indian Ocean indicate that the voyage from Indonesia could have been made. It is assumed that the original peopling of the island, however sparse, was accomplished by a single cultural group, probably as the result of a single voyage.

Indonesian origins

There is also widespread evidence from linguistics, archaeology, and tradition of influence from Afro-Arab settlers on the coasts before AD 1000. There is slighter evidence of an Indian influence in vocabulary, but there is no trace of Hinduism in Malagasy culture and of orthodox Islām only in later coastal settlements.

The inhabitants of Madagascar speak Malagasy, which, written in the Latin alphabet, is a standardized version of Merina, an Austronesian language. Although there are numerous local variations of Malagasy, they are all mutually intelligible. French is also widely spoken and is officially recognized. It is used as a medium of instruction, especially in the upper grade levels, as is Malagasy.

The population is divided into about 20 ethnic groups, the largest and most dominant of which is the Merina people, who are scattered throughout the island. The name Merina (Imerina) is said to mean Elevated People, deriving from the fact that they lived on the plateau. The second largest group is the Betsimisaraka (The Inseparable Multitude), who live generally in the east. The third most numerous group is the Betsileo (The Invincible Multitude), who inhabit the plateau around Fianarantsoa. Other important peoples are the Tsimihety (Those Who Do Not Cut Their Hair); the Sakalava (People of the Long Valley); the Antandroy (People of the Thorn Bush); the Tanala (People of the Forest); the Antaimoro (People of the Banks); and the Bara (a name of uncertain origin). Smaller groups are the Antanosy (People of the Island); the Antaifasy (People of the Sand); the Sihanaka (People of the Lake); the Antakarana (People of the Rocks); the Betanimena (People of the Red Soil), who are now largely absorbed by the Merina; the Bezanozano (Those with Many Braided Hair); and the Mahafaly (the Joyful People). These ethnic names do not stand for clear-cut cultural boundaries, for in many cases one group fades imperceptibly into another. Moreover, the conventional translations are by no means reliable and most of the names themselves are of somewhat recent origin, probably crystallized and rigidified by the exigencies of colonial administration more than by the realities of indigenous culture. In no sense are these groups to be regarded as "tribes," a concept now considered invalid, nor are they composed of clans, but rather, in most cases, of endogamous and often non-unilinear descent groups.

About half of the population has been converted to Christianity, which is about equally divided between Protestantism and Roman Catholicism. A sizable community of Muslims also is found in the northwest. The rest of the people continue to practice their traditional religion, which is based upon ancestor worship. The dead are buried in tombs and are believed to reward or punish the living. There is a supreme being called Zanahary (the Creator) or Andriamanitra (the Fragrant One). There is also a belief in local spirits, and a complex system of taboos constrains Malagasy life.

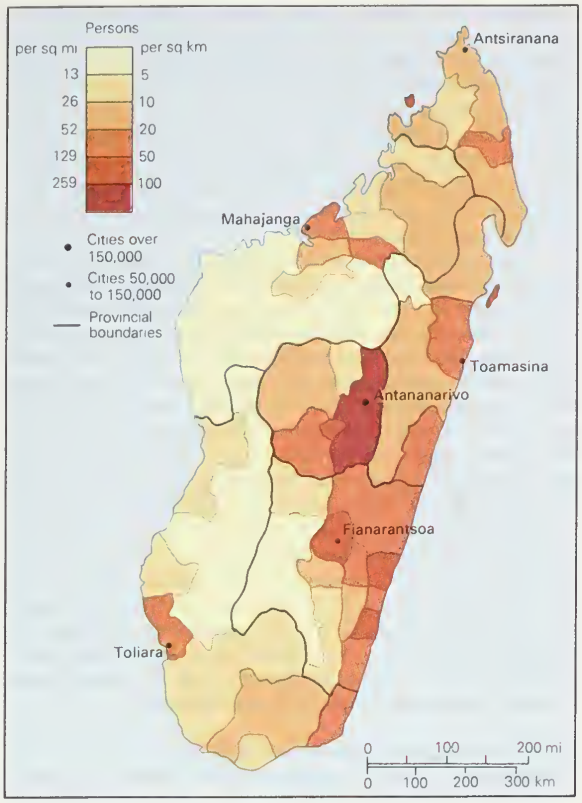
Traditional religion

Demography. More than 95 percent of the population is Malagasy. The major foreign communities are French, Comorian, Indian and Pakistani, and Chinese. Births greatly outnumber deaths, and the population is growing at a relatively rapid rate. Government policy, however, opposes any form of population control. One-half of the population, moreover, is under age 17, portending continued high growth rates well into the 21st century.

Emigration of the French, Comorians, Indians and Pakistanis, and Chinese in the late 20th century has significantly reduced their populations. There has been, however, no significant emigration of Malagasy peoples abroad.

The eastern part of the central plateau is the region of highest population density, and the eastern coastal plain has the second highest density. The eastern forest zone and the northeastern coast densities vary but rank as the

Population densities



Population density of Madagascar.

next most densely populated regions. Most of the western two-thirds of the country is sparsely inhabited.

The eastern half of the island contains almost all the major cities and towns. Antananarivo is the most populous city; perched on two precipitous mountain ridges, the old part of the city is dominated by the Manjakamiadana palace and has an extremely picturesque, almost medieval appearance.

THE ECONOMY

The control of Madagascar's economy by France, which had taken nearly half of the island's exports and supplied more than half of its imports, ended following the changes in government that occurred during the turbulent years 1972–75. Currency, banking, finance, loans, and economic planning had been influenced by accords with France and by French personnel in government, commerce, and technical assistance. After 1972–75 aid came from new sources, including the Soviet Union, the People's Republic of China, and North Korea, but most continued to come from France, other Western countries, and Japan.

Resources. The Great Red Island disappointed those who hoped to discover precious metals in large quantities. Considerable small-scale gold mining was conducted toward the end of the 19th century, by both French and Malagasy prospectors. There is a wide variety of semiprecious stones, but deposits are not of significant economic importance. Mineral deposits include chromite, which is found north of Antananarivo and in the southeast at Ranomena; ilmenite (titanium ore), found on the southeast coast at Tôlañaro, a source thought to represent the world's largest reserve of titanium; low-grade iron ore, found in scattered deposits in the southern half of the island; low-grade coal north of Toliara and inland from Besalampy; nickel near Fianarantsoa; and copper north of Ampanihy and near Ambilobe. There also are smaller deposits of zircon, monazite, bauxite, lead, graphite, quartzite, jasper, gold, uranothorianite, bentonite, kaolin, and alunite. The various gems include garnet, amethyst, tourmaline, beryl, and columbite.

Principal mineral deposits

The eastern evergreen forest and the scattered remnants of deciduous forest are valuable for their timber. Except for fish and crustaceans, the indigenous animal life is of little economic importance. Domestic animals include the humped zebu (cattle of Asiatic derivation, doubtless brought from Africa), of great religious importance; goats; fat-tailed sheep; dogs; poultry; and pigs.

Although there are many narrow valleys and magnificent waterfalls, especially on the eastern escarpment, only a small number of them have been harnessed for electric power generation. Hydroelectric power stations provide about two-thirds of the country's electricity requirements; the remainder is supplied by coal-burning thermal stations. Many mines and factories also generate their own electricity with diesel- or steam-powered generators. Bituminous shales have been discovered at Bemolanga, oil at Tsimiroro, and natural gas off the coast of Morondava. The development of these resources remains commercially questionable, however.

Agriculture, forestry, and fishing. Rice occupies the largest share of the total crop acreage. Many varieties of dry, wet, and irrigated rice are grown in the central plateau; dry rice is also grown in the eastern forests and wet rice in the lower river valleys and along the estuaries, mainly by populations migrated from overpopulated parts of the plateau. Costly imports are still required.

Slash-and-burn techniques (the temporary clearance of land for agriculture) are used in the escarpment forest and along the east coast. In the river valleys of the west, cultivation is permanent; irrigation techniques are heavily utilized.

Sugarcane is grown on plantations in the northwest, around Mahajanga, and on the east coast near Toamasina. Cassava (manioc) is a staple grown all over the island, and potatoes and yams are cultivated mainly in the highland region of Ankaratra. Bananas are produced commercially on the east coast, and corn (maize) is grown mainly on the central plateau, in the south, and in the west. Fruits include apples, grapefruits, avocado pears, plums, grapes, oranges, litchis, pineapples, guavas, pawpaws, passion fruits, and bananas. Robusta coffee is grown on the east coast and arabica coffee on the plateau. Other significant crops are beans, peanuts (groundnuts), *pois du cap* (lima beans), coconuts, pepper, vanilla, cacao, sisal, raffia, tobacco, copra, cotton, and castor beans.

Agricultural produce

Cattle (mainly zebu) are distributed throughout the island. The large numbers of pigs, sheep, goats, chickens, ducks, geese, and turkeys are found mainly on the plateau. The hoarding of cattle as a sign of wealth and for religious sacrifice has frustrated government efforts to increase the use of cattle for domestic meat consumption and for export.

A significant area of the forest is degraded (*i.e.*, regenerated after repeated burnings, with many original species lost and smaller, fewer, less valuable species prevalent); the rest is wet or dry tropical forest. Major reforestation efforts have been undertaken, but, with about 80 percent of domestic fuel needs supplied by wood and charcoal, the country's total forested area continues to decline drastically.

Fisheries are poorly developed and depend mostly on small traditional fishing communities on the west coast; production is badly adjusted to the island's needs and to the potential market. In the late 20th century, however, the industrialization of marine fishing was begun, and rivers, lakes, and irrigated rice fields were stocked with breeding fish. The inshore waters are fished, while the distant offshore waters are neglected; inland distribution of the fish caught is poor, except in main towns. The bulk of the catch is composed of fresh fish and crustaceans; some fish are dried. There is also considerable raising of fish in the irrigated rice fields, mainly for home consumption.

The fishing industry

Industry. Mining and quarrying are little developed. The most important products are graphite, mica, monazite, quartz, garnet, amethyst, salt, and chromite. Less valuable amounts of gold, tourmaline, citrine, beryl, ilmenite, columbite, zircon, and jasper are produced as well. Merina jewelers polish and set semiprecious stones at small workshops in most of the towns of the plateau.

The country's manufacturing consists mainly of rice mills and small industrial establishments. More than half of the manufacturing is located in and around Antananarivo. Products include wood, paper pulp, cotton cloth, fertilizer, oils, soap, sugar, cigarettes and tobacco, sisal

rope and mats, bricks, processed foods, and beverages. A small printing industry and several motor-vehicle assembly plants are also located there.

Finance and trade. The Malagasy franc replaced the CFA (Communauté Financière Africaine) franc in 1963, and in 1973 Madagascar officially left the Franc Zone. The Central Bank issues all currency.

The value of exports is derived mainly from coffee, cloves and clove oil, vanilla, sisal, raffia, sugar, rice, pepper, tobacco, peanuts, and petroleum products. Despite their variety, many of these, like coffee, cloves, vanilla, and sisal, are threatened by world overproduction or by the manufacture of synthetic substitutes. Imports include crude petroleum, chemical and metal products, machinery, vehicles, electrical equipment, cotton textiles, and essential foods. After 1972, trade with France fell sharply, although France remains Madagascar's main trading partner. Other important trading partners include the United States, Japan, and Italy.

Administration of the economy. Before 1972 the government had established producers' cooperatives, which collected and processed most of the rice crop (at prices that were bitterly resented by the peasants); state farms intended to increase the commercial production of rice, cattle, coffee, oil palms, cotton, and silk; a rural development program; and a national consumers' cooperative with retail shops located in most towns.

After a period of prolonged domestic turbulence from 1972 to 1975, a new emergent military regime replaced the already constrained free-trade economy with one whose goal was to achieve "a socialist paradise under divine protection" by the year 2000. Nationalization made state corporations out of foreign firms, transforming the five French banks into three state banks for agriculture, industry, and trade. In addition, foreign insurance companies were converted into two state insurance corporations, and state monopolies were formed for import-export trading and shipping and for the textile, cotton, and power industries, as well as for the new agencies created for the extension of irrigation.

Economic planning

The economy responded with a relentless decline. Exports fell, inflation rose, and debt expanded from $89 million in 1970 to $250 million in 1978 and $3.3 billion in 1988. Debt services took more than half of the country's export earnings, and imports nearly ceased for lack of foreign exchange. Industrial production fell to a quarter of the 1975 level, and foreign investment declined to almost nothing. Devaluation reduced the value of the Malagasy franc by 80 percent. Under these adverse conditions the country's infrastructure and social services deteriorated greatly. The rural population was reduced to subsistence levels, bartering with cattle and bags of paddy. By 1982 the country was technically bankrupt, forced to adopt a program of structural adjustment imposed by the International Monetary Fund and face a humiliating turnabout to reliberalize the economy. Abolition of the state monopolies was accepted, and any state enterprise that could not pay its way was threatened with privatization. Private business took years to regain any confidence, however.

Taxation is mainly indirect and is derived largely from various customs, import and export duties, and excise taxes. Direct taxes take the form of taxes on company income, registration fees, stamp duties, and personal taxes; the latter bear heavily on the peasants.

Most union members hold office jobs or work in industry. A popular and extensive trade union is the Union des Syndicats Autonomes de Madagascar, but the Sendika Kristianina Malagasy (Christian Confederation of Malagasy Trade Unions) claims more affiliated unions. The main employers' association is the Union des Syndicats d'Intérêt Économique de Madagascar.

Transportation. Transport facilities serve primarily the plateau and the east coast. Facilities are rudimentary on the western half of the island, although the country's best natural harbours are located there.

The majority of roads are unpaved. Roads down the eastern escarpment and across the western coastal strip, as well as minor roads everywhere, become impassable during the wet season. The main paved road runs south from Antananarivo to Fianarantsoa, where it branches southwest to Toliara, southeast to Tôlañaro via Ihosy, and east to Mananjary and Manakara. Paved roads run east from Antananarivo toward Toamasina, west to Analavory, and north to Mahajanga and Antsiranana.

Two railways connect the plateau with the east coast; they run from Antananarivo to Toamasina and from Fianarantsoa to Manakara. Plateau routes run from Antananarivo south to Antsirabe, to Fianarantsoa, and north to Ambatondrazaka.

Rail transportation

The main port is Toamasina, which has a fine deepwater harbour equipped with quay berths and directly linked to Antananarivo by rail, air service, and road. Mahajanga is second in importance but is accessible only to small ships of shallow draft; it has considerable dhow traffic with the Comoros. Antsiranana has one of the finest natural harbours in the world but is as yet too remote from the main centres of economic activity; it contains the former French naval base, arsenal, and dry dock and also has a small commercial port. The coastal lagoons and swamps of the Pangalanes Canal on the east coast, which are linked by artificial channels where necessary, provide a waterway that is 434 miles (698 kilometres) long.

Airfields are found throughout the island. The main international airport is at Ivato, near Antananarivo, and some international flights make secondary landings at Toamasina, Nosy-Be, and Mahajanga. Air Madagascar provides internal service; its international flights are supplemented by those of several foreign airlines.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. The Malagasy Republic became independent in 1960, having been an autonomous republic in the French Community from 1958 (see below *History*). The country was ruled from 1960 to 1972 through a bicameral legislature consisting of a national assembly, directly elected by universal adult suffrage, and a senate, one-third of which was nominated by the president and the rest of which was indirectly elected.

Between 1972 and 1975 Madagascar was under military rule. Radical political and economic reorganization was instituted in 1975, and a new constitution was implemented later that year for the renamed Democratic Republic of Madagascar. The constitution established a presidency; the Supreme Revolutionary Council, a body of members including the president, prime minister, military chiefs, some ministers, and other nominated leaders; a Cabinet, composed of the prime minister and other ministers; a unicameral legislature, the People's National Assembly, composed of deputies directly elected for five years; a Military Development Committee for advice on defense and economic policy; and a National Front for the Defense of the Revolution (Front National pour la Défense de la Révolution), grouping all parties willing to support the government and led by the Advance Guard of the Malagasy Revolution (Avant-garde de la Révolution Malgache) with its "Red Book" ("Boky Mena") manifesto. The government was fairly well-balanced ethnically, and the old polarization of coastal and plateau peoples was diminished, although the Merina continued to dominate the civil service, professions, and education.

"Red Book" manifesto

There was a many-layered local electoral system in which thousands of local village communities elected delegates to associations of village councils, which then sent delegates to district groupings, which, in turn, sent delegates to six provincial councils. Power was in the hands of party delegates at all levels, under military oversight, rather than with the former bureaucratic hierarchy that existed before the reorganization.

With the subsequent failure of the government's utopian policies and the devastation and virtual bankruptcy of the economy, the constitution was relaxed, again allowing for opposition parties, of which two emerged very powerful. Pressing for abolition of the Supreme Revolutionary Council and the Military Development Committee, the opposition has also sought another new constitution.

Justice. The former Merina state that ruled the island throughout the 19th century had an elaborate system of laws, courts, and justice. The present Malagasy legal sys-

tem, however, is based upon French codes and practices, and most judges and magistrates have had French training. There is a Constitutional High Court, an appellate court, criminal tribunals, and tribunals of first instance; there is also a criminal code, a code of criminal procedure, and a code of civil procedure. The customary law of the Merina and other ethnic groups is taken into account by state magistrates when judging marriage, family, land, and inheritance cases.

Customary law

The armed forces. The army played no direct political role in Madagascar until 1972, although the presence of French army units had bolstered the former government. The French troops were withdrawn in 1973, and the French naval base at Antsiranana was handed over to Madagascar in 1975. The Malagasy armed forces consist of an army, a navy, and an air force. There is also a large paramilitary force, as well as a secret police. Detachments of local police are stationed at the headquarters of each administrative division, as well as in Antananarivo. The whole force is under unified command and falls within the responsibility of the ministry of the interior.

Education. The educational system consists of primary and secondary schools, technical institutes, teacher-training colleges, and a university system. Enrollment at the University of Madagascar (founded in 1955) and its five regional branches has increased dramatically in the late 20th century. There has been an increased use of the Malagasy language in teaching, although some coastal peoples have objected because of the language's close relationship to the Merina people.

The level both of school attendance and of educational attainment is higher on the plateau than in the coastal areas. Protestant and Roman Catholic missions have been providing education since the 19th century, and the missions continue to educate a large proportion of the schoolchildren, although the government now maintains official schools at all levels and is attempting to phase out private education. In the main towns there are other privately run schools, catering to those unable to enter either government or mission schools. About two-thirds of Madagascar's population is literate, and the majority of illiterate persons are female.

The role of mission schools

Health and welfare. Malagasy doctors began to practice Western medicine in 1880; and a medical school was established in Antananarivo. The health system includes principal and secondary hospitals, dispensaries, and medical centres. Medical personnel include doctors, as well as pharmacists, dentists, midwives, social assistants, visiting nurses, and health assistants.

Hospitals and specialists are mainly in the towns, apart from some rural hospitals run by Christian missions. Health insurance and other social benefits are available mainly to better-paid workers and professionals among the employed population.

The extension of health services is largely credited for the steady population increase. Infant mortality remains high, but infant deaths from malaria, which is endemic all over the island, have been cut by half. Debilitating parasitic diseases, such as schistosomiasis, an infection of the bladder or intestines, remain serious and are hard to control since their breeding grounds are the irrigated rice fields and the streams that feed them. Venereal disease is also widespread, especially in its incipient form.

Housing. Houses are typically rectangular and crowned with steeply angled roofs. In the rural areas, most houses are made of either mud and wattle or woven matting supported by poles. In the eastern forest, they are built of interlaced split bamboo and are thatched with palm, while, in the south, overlapping upright wooden planks are used for the walls. In the plateau, rural housing is constructed of earth blocks and thatched roofing, while upper-income and most urban housing consists of two- or three-story homes—typically with kitchen at the top, living quarters in the middle, and storage below—all surrounded by wide balconies supported by brick columns and crowned with steep tiled roofs. This is the lofty Indonesian style of architecture, transformed by new techniques contributed by the missionaries. The original style survives in the house of Andrianampoinimerina (reigned 1787–1810) at Ambohimanga and reaches its apotheosis in the queen's palace built by Jean Laborde in the 19th century.

Indonesian style of architecture

The government-sponsored housing authority conducts research into design, materials, and production methods and is seeking to promote inexpensive urban housing, but the problem of overcrowding is expected to increase with continued urban growth. The existence of a well-established craft of house construction, however, may successfully alleviate housing pressures without resorting to imported materials or relying on foreign enterprise.

Social and economic divisions. Traditionally, society was divided into three castes—the nobles, the freemen, and the former slaves and their descendants. These social distinctions are no longer strict and are manifest only on ceremonial occasions, such as weddings and funerals. They do, however, form the basis of other economic and social distinctions. During the 19th century, the Merina elite conquered the island, established themselves as rulers, and adopted Protestant Christianity; in the late 1800s, some became Roman Catholics. Under French rule in the 20th century, the Merina retained their supremacy in education, business, and the professions, while the remainder of the population retained its sense of "difference" from the dominant peoples and some adopted Roman Catholicism.

Three traditional castes

A further distinction is made between the peoples of the plateau and those of the coast, who are called *côtiers*. The coastal peoples feel deprived of the education, power, and wealth that is concentrated on the plateau. Since independence, the government has been composed of *côtiers*, and a conscious effort has been made to keep the Merina elite of the plateau from power.

CULTURAL LIFE

The cultural milieu. The culture is basically Indonesian. Arabic and Islāmic contributions include an intricate system of divination, or *sikidy*, and calendrical features, such as the Arabic-derived names of the days of the week, which also apply to the markets held on those days. The coastal areas of the west, north, and south might be expected to show African cultural elements, but, apart from some Bantu words, these are often difficult to identify conclusively.

The state of the arts. The conquest of the plateau peoples by the French and their subsequent assimilation of Western values have deprived them of most of their traditional institutions. In music, however, Western dance and musical instruments have been adapted to Malagasy rhythms. The tube zither, the conch, and the cone drum are of Indonesian origin, while other types of drums and animal horns suggest African influence. Folk music has been retained, but much of the singing consists of Western church hymns and chants adapted to the distinctive Malagasy musical style.

Social and religious life on the plateau centres upon the church congregation, and the cultural emphasis on ancestral tombs is now largely expressed in Christian terms. More time, money, and care are spent on building tombs than houses. The dead are always brought back to their ancestral tombs, however long or far away they have spent their lives. Tombs are opened every few years, the remains taken out and carried in procession with much ceremony, then replaced after being rewrapped in new shrouds, which are still woven from locally produced silk, coloured with natural, herbal dyes. The male peasants wear cloth trousers with tunics reaching to the knees. Women wear cloth dresses but wrap a silk cloth under one arm and over the other shoulder, even when wearing Western fashions.

The cult of the dead

The coastal peoples have retained more of their traditional customs. Funeral practices are similar to those of the plateau, with local variations of detail. In the eastern forests men wear shorts rather than trousers, and many still wear the short tunic that is woven from raffia fibres. In the far south some older men wear a homespun silk cloth that is wrapped around the waist and between the legs, but most have adopted imported cotton clothes.

The Mahafaly have a remarkable wood-carving industry, and their tombs of coloured stones and carved wooden posts are the most beautiful on the island. The Betsileo also have a thriving wood-carving industry, making in-

Handicrafts

laid furniture of valuable hardwoods. They also produce ornamental cloths of very finely woven raffia and have become specialists in the production of coloured straw hats. Betsileo and Merina women have become experts in French-style embroidery, sewing, and dressmaking.

The Malagasy language is rich in proverbs, and there is now an extensive written literature including poetry, legend, history, and scholarly works, as well as contemporary themes. Literary production is aided by an excellent printing industry, for which the Merina have shown a flair since learning it from the London Missionary Society in the 1820s. The peoples of the southeast still preserve their manuscripts in Arabic script with great reverence; few can be more than 200 years old, although some may be copies of much earlier manuscripts.

Cultural institutions. The government encourages the blending of old and new cultural expressions, and a number of new seasonal festivals have been promoted, including the Festival of Rice, the Festival of the Trees, the Festival of the Party, and Independence Day. Towns, churches, schools, and private groups hold concerts or dances, and in the cities there are cultural associations based on the members' home districts.

The main libraries and museums, located in Antananarivo, include the National Library, the Municipal Library, and the National Archive. There are also the library of the Malagasy Academy, the university library, and the university museum. There are museum collections of Malagasy culture and archaeology; natural science collections include a zoo with animals specific to Madagascar.

The press and broadcasting. There are daily and other newspapers published in French and Malagasy, and a government gazette is also published. The island receives radio, television, and telephone service. (Ai.S.)

For statistical data on the land and people of Madagascar, see the *Britannica World Data* section in the BRITANNICA BOOK OF THE YEAR.

History

EARLY HISTORY

Archaeological investigations of this century indicate that human settlers reached Madagascar about AD 700. Although the huge island lies geographically close to Bantu-speaking Africa, its language, Malagasy, belongs to the distant Malayo-Polynesian language family. There are, nonetheless, a number of Bantu words in the language, as well as some phonetic and grammatical modifiers of Bantu origin. Bantu elements exist in every dialect of Malagasy and appear to have been established for some time.

As a people, the Malagasy represent a unique blend of Asian and African physical and cultural features found nowhere else in the world. Although on the whole Asian features predominate, African ancestry is prevalent and African influences in Malagasy material and nonmaterial culture are widespread. The most plausible theory for this circumstance is that the seafarers of the Malayo-Polynesian world who settled Madagascar initially arrived by way of eastern Africa and the Comoros after these areas had already been colonized by Bantu-speaking Africans. There is also some evidence that Bantu speakers inhabited portions of western Madagascar prior to the 17th century, only to eventually become completely assimilated into Malagasy culture. After the 14th century, important Afro-Arab influences entered Madagascar and spread through much of the island. Apart from the colonial French, settlers from overseas appear to have stopped coming to Madagascar by about 1600.

Original settlers

Madagascar before 1650. Much of Madagascar was populated by internal migration before the beginning of the 16th century, giving the theretofore empty lands their *tompontany* (original inhabitants, or "Masters of the Soil"). Yet politically the island remained fragmented. Most of the nearly 20 ethnic groups that make up the modern Malagasy population did not attain any form of "national" consciousness until new political ideas arrived from abroad in the 1500s and began to spread through the island. A host of written European accounts from the 16th and early 17th centuries fails to reveal any large state or empire, and few of the Malagasy oral traditions collected since the mid-19th century go back that far in time.

Still, small local states were found at many points along the coast visited by European ships. The capitals were almost always located near river mouths, territorial domains were invariably small, and rulers were independent of one another. Alliances and wars were usually short-lived affairs involving limited economic objectives and little loss of life, and they seldom led to any border adjustments. Economies were pastoral or agricultural, often a mixture of both, and there were no radical differences in wealth. In some areas the rulers appeared to be absolute, while in others elders and priests had the preponderant influence. In one area in southeastern Madagascar, later to become known as Fort-Dauphin (site of the French East India Company fort of that name), early Europeans believed they had found a Muslim state in existence among the Antanosy people of the region. It was ruled by a "Moorish king" and had an aristocracy with privileges deriving presumably from Islām. Their collective name was Zafindraminia, or descendants of Raminia, the ultimate great ancestor.

Small local states

In the first quarter of the 16th century, Portuguese navigators also reported a number of coastal towns in northern Madagascar that were architecturally similar to Kilwa, a once important entrepôt in what is today Tanzania. The towns belonged to an Afro-Arab commercial network in the western Indian Ocean which undoubtedly predated the 16th century. At the town of Vohemar, once the island's northeastern centre of international trade, the blend of Malagasy and Afro-Arab customs produced an arts and crafts tradition that was quite original.

Portuguese explorers who visited the Matitana River valley in southeastern Madagascar witnessed the arrival of a group of Afro-Arabs ("Moors from Malindi") between 1507 and 1513. Within one or two generations the descendants of this group had intermarried and merged with the local *tompontany* to form another group known as the Antemoro. By the 1630s the Antemoro had formed a theocratic state, which was the only state in Madagascar at the time to possess written texts. Using the Arabic alphabet, the texts were written in the Malagasy language and were both religious and secular in nature. Proximity to Islām became a major criterion among the Antemoro for the right to rule, and there is little doubt that the four Antemoro sacerdotal clans were far closer to the Muslim faith than were the Zafindraminia of the Fort-Dauphin area. In time, Antemoro holy men, traveling far and wide within Madagascar, came to influence other Malagasy in both religion and government.

Political evolution 1650 to 1810. Unknown to the early coastal visitors from Europe, new and historically pivotal dynasties also were beginning to form in southwestern and central Madagascar toward the mid-16th century. Two of them, the Maroserana in the southwest and the Andriana-Merina in central Madagascar, would go on to create vast empires, each with its own apex and decline, between about 1650 and 1896, the year the French annexed Madagascar. While the Maroserana were able to emplace their rulers over several south-central peoples, the most outstanding achievement of the dynasty was the creation of two states in western Madagascar, Menabé and Boina. These states later combined into the Sakalava empire, which controlled most of western Madagascar and several adjacent areas deep inland.

Sakalava empire

The Sakalava were originally a group of warriors who came into contact with the Maroserana before 1660, the year the Maroserana ruler, King Andriandahifotsy, founded Menabé. Ultimately, "Sakalava citizenship" was extended to hundreds of west-coast clans as the original Sakalava warriors and their descendants intermarried and merged with them. A sense of unity also came from religion, as the Maroserana royals, upon death, became the sacred ancestors of all Sakalava. The Sakalava empire was ultimately weakened by internal power struggles for the throne, by attempts to substitute Islām for the ancestral cult, and, after 1810, by wars with the Merina, a people of the central plateau already on the way to an empire.

The Betsimisaraka confederation, a quasi-state concur-

rent with the late Sakalava empire, was a brief but successful attempt in the 18th century to unite the coastal peoples of Madagascar's eastern littoral. Ruled by Ratsimilaho, son of an English pirate and a Malagasy princess, the viable confederation extended along more than 200 miles of coastline. After Ratsimilaho's death in 1750, the confederation began an abrupt, though prolonged, disintegration.

Merina kingdom

The Merina kingdom was founded toward the end of the 16th century in the swampy Ikopa valley on the central plateau. Antananarivo (Tananarive) became its capital. In the 18th century, Imerina was divided among four warring kings. One of them, Andrianampoinimerina, who reigned 1787–1810, reunited the kingdom about 1797. He gave it uniform laws and administration and sold slaves to the French on the coast, using the guns he got in return to conquer his neighbours, the Betsileo. Under Andrianampoinimerina, Merina society was divided into a ruling noble class (Andriana), a class of freemen (Hova), and a slave class (Andevo). At Andrianampoinimerina's death, he left his son a single political ambition: "The sea will be the boundary of my rice field" (*i.e.,* of his kingdom).

Early European contacts. Madagascar is mentioned in the writings of Marco Polo, but the first European known to have visited the island is Diogo Dias, a Portuguese navigator, in 1500. It was called the Isle of St. Lawrence by the Portuguese, who frequently raided Madagascar during the 16th century, attempting to destroy the incipient Muslim settlements there. Other European nations also moved in; in 1642 the French established Fort-Dauphin in the southeast and maintained it until 1674. One of their governors, Étienne de Flacourt, wrote the first substantial description of the island. In the late 17th and early 18th centuries, Madagascar was frequented by European pirates (among them Captain William Kidd) who preyed upon shipping in the Indian Ocean.

In the 18th century, the Mascarene Islands to the east were colonized by the French with the help of Malagasy slaves. Two attempts at fortified settlements failed, one at Fort-Dauphin by the Count de Modave, the other at the Bay of Antongil by Baron Benyowski; however, French trading settlements prospered, notably at Tamatave.

THE KINGDOM OF MADAGASCAR

Formation of the kingdom (1810–61). Andrianampoinimerina's son, Radama I (1810–28), allied himself with the British governor of the nearby island of Mauritius, Sir Robert Farquhar. In order to prevent reoccupation of the east coast by the French, Farquhar supported Radama's annexation of the area by supplying him with weapons and advisers and giving him the title "king of Madagascar." At the same time, Radama agreed to cooperate with Britain's new campaign to end the slave trade. In 1817 he captured the east coast town of Tamatave, from which he launched annual expeditions against the coastal populations. He eventually conquered almost the entire east coast, the northern part of the island, and most of the two large Sakalava kingdoms. Only the south and a part of the west remained independent. The French retained only the small island of Sainte Marie. In addition, Radama invited European workmen, and the London Missionary Society spread Christianity and influenced the adoption of a Latin alphabet for the Malagasy language. Radama died prematurely in 1828; he was succeeded by his widow, Ranavalona I, who reversed his policy of Europeanization. She expelled Christian missionaries and persecuted Malagasy converts. A few Europeans maintained external trade and local manufacture, but eventually they also were expelled. The British and French launched an expedition against Ranavalona but were repulsed at Tamatave in 1845. By the time of her death (1861), Madagascar was isolated from European influence.

Merina expansion

Outside influences (1861–95). Ranavalona was succeeded by her son, Radama II, who readmitted the foreigners. English Protestants and French Roman Catholics vied for supremacy, while businessmen obtained excessive concessions. This policy led to Radama's overthrow by the Merina oligarchy in 1863. The head of the army, Rainilaiarivony, a Hova, became prime minister and remained in power by marrying three queens in succession: Rasoherina, Ranavalona II, and Ranavalona III. He embarked on a program of modernization, and in 1869 he caused Protestantism to be adopted and suppressed the Malagasy religion. European-style ministries were created and governors set up in the provinces. Villages were supervised by former soldiers. Education was declared obligatory and placed under the direction of the Christian missions. A code of laws was worked out that combined ancient customs with Western practices such as monogamy.

The French began to extend their influence over the Sakalava, and the first "Franco-Merina" war (1883–85) ended with an ambiguous treaty: France was given a settlement at Diégo-Suarez and a resident at Antananarivo, but the institution of a protectorate was temporarily avoided. The succeeding period was marked by disorder and internal strife. In 1890 the British recognized Madagascar as a French protectorate, but Rainilaiarivony refused to submit to French suzerainty. In January 1895, French troops landed at Majunga, and on Sept. 30, 1895, they occupied Antananarivo. The prime minister was exiled. The queen signed a treaty recognizing the protectorate and was maintained on the throne as a figurehead.

The French invasion

THE FRENCH PERIOD

The colonial period (1896–1945). French occupation soon extended to the entire part of the island conquered by the Merina. But in Imerina itself, armed guerrilla bands (the Menalamba, or "red togas") resisted modernization and French rule. The French Parliament voted the annexation of the island on Aug. 6, 1896, and sent General Joseph-Simon Gallieni first as military commander, then as governor-general. Slavery was abolished. Gallieni put down the insurrection, subdued the oligarchy, and sent the queen into exile on Feb. 27, 1897. In 1898 the old Merina kingdom was pacified; Gallieni then undertook the difficult task of subjugating the independent peoples. Two insurrections, in the northwest (1898) and in the southeast (1904), were quickly put down and, when he left the island in 1905, unification had been achieved. The Merina governors had been replaced by French administrators with leaders taken from local peoples. The teaching of French in the schools was made compulsory. Customs duties favoured French products, though Malagasy enterprise was also encouraged. The Tamatave-Antananarivo railroad was begun, roads were built, and a modern health service was inaugurated.

The economic development of the island continued under Gallieni's successors. The railroad and its branch lines were completed in 1913. A second line, the Fianarantsoa-Manakara, was finished in 1935. Automobile roads increased after 1920, airlines after 1936. The cities and seaports were built up and equipped, and loans were contracted in France. Exports were confined to agricultural products and raw materials for industry. Rice, cassava (manioc), rubber, raffia, meat, and graphite predominated at first. Between World Wars I and II, coffee, vanilla, cloves, and tobacco, introduced by the Europeans and then taken up by native planters, became more important. Three-quarters of all trade was with France. Material aspects of life became Westernized, especially in the cities, and half the population became Christianized.

Malagasy nationalism

In 1915 a nationalist secret society, the Vy Vato Sakelika (VVS), was outlawed. In 1920 a teacher, Jean Ralaimongo, launched a campaign in the press to give the Malagasy "subjects" French citizenship and to make Madagascar a French *département.* When France failed to respond to the demand for assimilation, the movement turned toward nationalism. In 1940 Madagascar, though hesitant at first, rallied to the Vichy government. Then came a blockade, occupation by the British and South Africans (1942), and finally a return to Free France.

The French Union (1946–58). In the elections of 1945, two Malagasy nationalists were elected to the French parliament. The constitution of 1946, creating the French Union, made Madagascar an Overseas Territory of the French Republic, with representatives to the Paris assemblies and a local assembly at Antananarivo. Six provincial assemblies were created later. The political struggle erupted into violence on March 30, 1947, with a full-

The 1947–48 rebellion

scale insurrection in eastern Madagascar. The leaders of the Democratic Movement for Malagasy Renewal (Mouvement Démocratique de la Rénovation Malgache), including the three representatives to the French national assembly, were outlawed. While an official count of lives lost in the revolt records about 11,000 dead, it is certain that thousands more of the Malagasy populace perished from famine, cold, and psychological misery while hiding from both the French Army and the insurgents in the island's inhospitable tropical forests.

A period of political inactivity followed until the 1950s. After the "Overseas Territories Law" of 1956 gave Madagascar an executive elected by the local assembly, Vice Premier Philibert Tsiranana founded the Social Democratic Party (Parti Social Démocrate; PSD), which, though most of its members were non-Merina from the coastal areas, offered to cooperate with the Merina. In 1958 France agreed to let its overseas territories decide their own fate. In a referendum on September 28, Madagascar voted for autonomy within the French Community. On Oct. 14, 1958, the autonomous Malagasy Republic was proclaimed; Tsiranana headed the provisional government.

THE MALAGASY REPUBLIC

The opposition regrouped under the name of Congress Party for the Independence of Madagascar (Ankoton'ny Kongresy ny-Fahaleovantena Malagasy), which included both Protestant Merina dissidents and communists. Antananarivo was this party's stronghold; it also had some support in the provinces but, owing to the electoral system established by the PSD, held only three seats in the legislature.

The Tsiranana regime

The PSD also settled the provincial question: executive power in the local assemblies was vested in a minister delegated by the central government. Tsiranana was elected president of the republic, and he was instrumental in obtaining its independence on June 26, 1960. Tsiranana and the PSD remained in power until 1972. Under his regime, successive development plans were inspired, according to Tsiranana, by a "grass roots socialism," and were aimed at improving the lot of the peasantry. In foreign policy, the bond with France remained strong, and close relations were established with the United States, West Germany, Taiwan, South Africa, and other anticommunist powers.

Tsiranana was reelected in January 1972, but political and labour unrest, and his own poor health, led him to appoint Major General Gabriel Ramanantsoa as prime minister with full powers of government. A plebiscite on Oct. 8, 1972, confirmed Ramanantsoa as head of government; there was no longer a president after Tsiranana resigned on October 11. The new head of government initiated radically different foreign and domestic policies. Under new agreements with France, French military and naval forces were removed from the island, and all French citizens were to be treated as aliens. Ties were established with the Soviet Union and other communist nations, and the country was withdrawn from the Franc Zone. In 1973, a rural reorganization program—in which elected committees would sell produce to state-owned companies—was initiated, and the government began to take control of joint French-Malagasy organizations.

In the wake of political and social unrest, on Feb. 5, 1975, Ramanantsoa handed power over to a former minister of the interior, Colonel Richard Ratsimandrava. He assumed the titles of president and prime minister but was assassinated six days later. A military directorate was then established; it dissolved on June 15, after naming

The Ratsiraka regime

Lieutenant Commander Didier Ratsiraka president and head of the Revolutionary Council. A referendum on Dec. 21, 1975, approved Ratsiraka as president under a new constitution that set up the Democratic Republic of Madagascar. Ratsiraka, sworn in as president on Jan. 4, 1976, continued the policies begun by Ramanantsoa. He nationalized the banks, insurance companies, and the nation's mineral resources and solidified his nation's ties with the communist powers. The formation in 1976 of the National Front for the Defense of the Revolution—a coalition of formerly banned political parties headed by Ratsiraka—further increased the president's control of the government and of Madagascar's political life.

Ratsiraka was reelected without opposition in 1983. Under the banner of scientific socialism he further extended government control over the economy. Despite several loans from the International Monetary Fund to help keep the country's economy afloat, however, it declined drastically. In 1986, Ratsiraka reversed the country's course completely. Laws were altered across-the-board to allow for a free-market economy. In June 1990, France responded by forgiving Madagascar its huge debt of four billion French francs. Overseas investors began to show renewed interest in the country, particularly South Africa. In September 1990 a "new era of cooperation" began between Madagascar and South Africa with a meeting at Antananarivo between Ratsiraka and South African President F.W. de Klerk. Ratsiraka lost the controversial presidential elections held in December 2001. A recount eventually declared Marc Ravalomanana the winner. (H.J.D./R.K.K.)

KENT, *From Madagascar to the Malagasy Republic* (1962, reprinted 1976); and RAYMOND K. KENT (ed.), *Madagascar in History: Essays from the 1970s* (1979). (R.K.K.)

Madrid

Madrid is the capital of Spain, its largest city, and a national centre of arts and industry. With its surrounding province, also called Madrid, it forms one of the new autonomous regions of the post-Franco era. Its capital status reflects the centralizing policy of the 16th-century Spanish king Philip II and his successors. The choice of Madrid as capital, however, was also the result of Madrid's previous obscurity and neutrality, in that it lacked ties with an established, non-royal power, rather than of any strategic, geographic, or economic considerations. Indeed Madrid is deficient in other characteristics that might be thought to qualify it for a leading role. It is not on a major river, in the way that so many European cities are; the playwright Lope de Vega, referring to a magnificent bridge over the distinctly unimposing waters of the Manzanares, suggested either selling the bridge or buying another river. Madrid does not possess mineral deposits or other natural wealth, nor was it ever a destination of pilgrimages, although its patron saint, San Isidro, enjoys the all but unique distinction of having been married to another saint. Even the city's origins seem inappropriate for a national capital, since its earliest historical role was as the site of a small Moorish fortress on a rocky outcrop—part of the northern defenses of what was then the far more important city of Toledo, 40 miles (65 kilometres) to the southwest.

It was in 1607, a whole generation after Philip II took the court to Madrid in 1561, that Philip III officially made the city the national capital, a status it has retained ever since. Under the patronage of Philip and his successors, Madrid developed into a city of curious contrasts, preserving its old, overcrowded centre, around which developed palaces, convents, churches, and public buildings. This combination has created a quintessentially Spanish city, a true capital in character, with a sparkle and vitality all its own.

This article is divided into the following sections:

Physical and human geography

THE LANDSCAPE

The city site and climate. Madrid lies almost exactly at the geographical heart of the Iberian Peninsula. It is situated on an undulating plateau of sand and clay known as the Meseta (derived from the Spanish word *mesa,* or "table") at an altitude of 2,100 feet (635 metres) above sea level, making it one of the highest capitals in Europe. This location, together with the proximity of the Carpetovetónica Range, is partly responsible for the weather pattern of cold, crisp winters accompanied by sharp winds. Sudden variations of temperature are possible, but summers are consistently dry and hot, becoming especially oppressive in July and August, when temperatures sometimes rise above 100° F (37.8° C). Average temperatures range between 41° and 75° F (5° and 24° C), while average rainfall varies between a low of less than one-half inch (11 millimetres) in July up to about two inches in October, usually the rainiest month of the year. The temperate times of year are spring and fall, which are also the most attractive seasons for visitors.

Temperature variations

The city layout. Madrid is a city of contrasting styles, reflecting clearly the different periods in which change and development took place. The old centre, a maze of small streets around a few squares in the vicinity of the imposing Plaza Mayor, contrasts with the stately Neoclassical buildings and grand boulevards created by the most eminent architects of their day. Modern office buildings in the centre and swaths of apartment blocks around the outskirts attest to the styles and economic realities of present-day development. Much of Madrid gives the impression of being cramped. When Madrid was first made the capital, the king obliged the city's inhabitants to let a floor of their houses to ambassadors and visiting dignitaries, which prompted many people to build structures with only one floor or sometimes (in the so-called *casas a la malicia,* or "spite houses") having two floors but with a facade giving the impression of only one. Subsequent development of the city generated an enormous demand for land, particularly with the extensive construction of public buildings and convents. The last of Madrid's four sets of city walls was built in 1625 and was not demolished until 1860 (by which time the population of the city had quadrupled). The situation was not alleviated even when Napoleon's brother Joseph, who briefly interrupted the Bourbon line of kings, demolished the convents to create more open space. Joseph's nickname of "El Rey Plazuelas" ("King of the Small Plazas"; one of the few complimentary ones he was given) derived from the squares he created. They did little to appease the ecclesiastical authorities, whose alienation contributed to his downfall. One of the squares, the Plaza de Oriente, facing the palace of the same name, was cleared of 56 houses, a library, a church, and several convents.

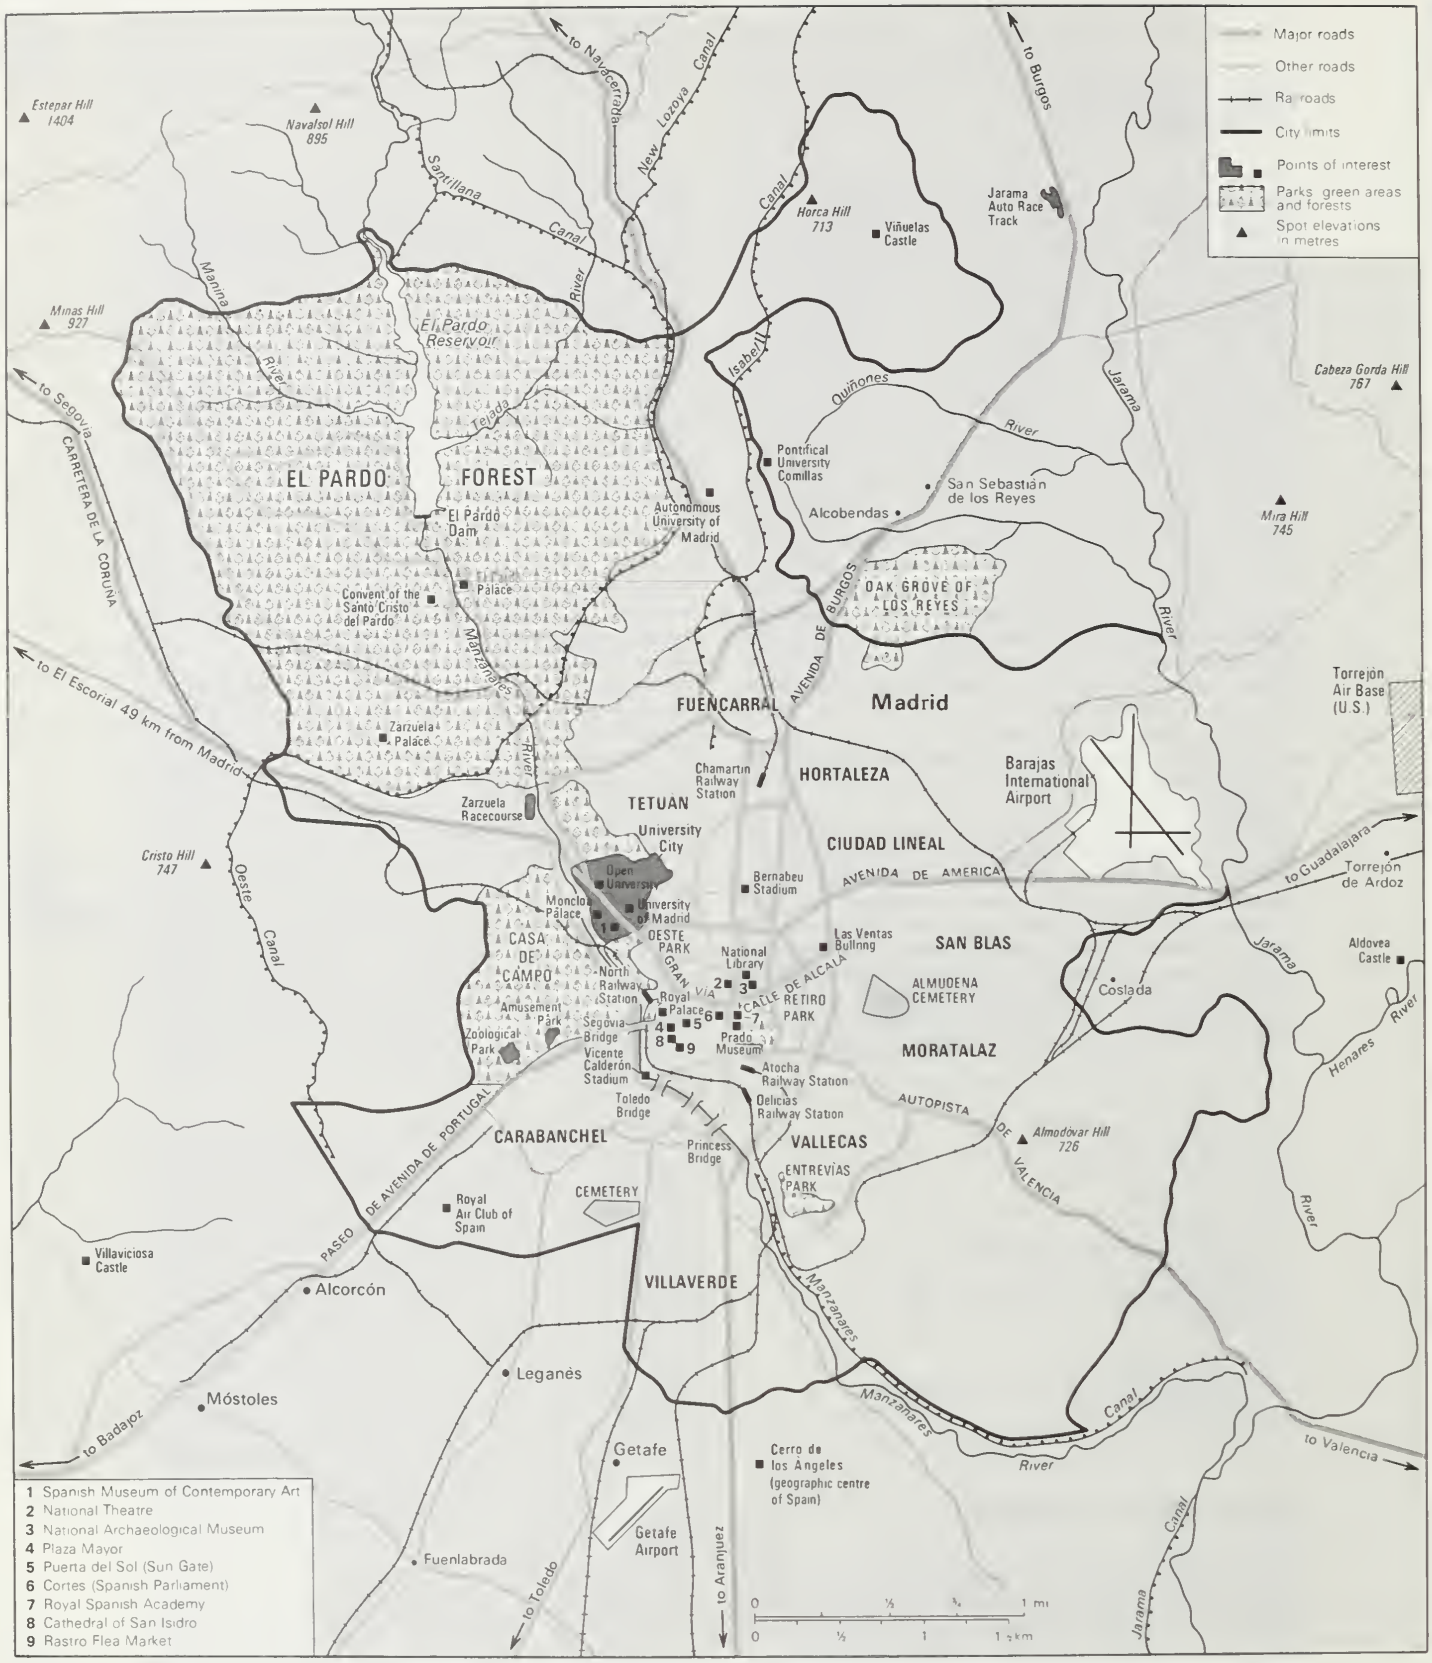
Creation of open space

"Los Madriles" ("the Madrids") is a traditional phrase that acknowledges the fact that each *barrio* (quarter) has developed its own style. There was also a geographical and social distinction among the *barrios altos, barrios centrales,* and *barrios bajos.* The last, spilling downhill from the Plaza Mayor along the Calle de Toledo toward the river, are still poor, albeit picturesque. Later development, also accommodating Madrid's poorer citizens, spread down toward the reclaimed marshland on both sides of the river, where low-cost housing is still to be found. Just over the brow of the hill is the Rastro, the popular flea market. Despite a number of urban development plans, Madrid did not spread into the open spaces around it, not even crossing the Manzanares River until 1948. By contrast, however, the city as a whole has some extensive parks, with more open space overall than Paris. Some, like El Pardo or Casa de Campo, are survivals of hunting parks; the Retiro, on the other hand, is the site of a former royal palace.

Madrid has not escaped the problems common to so many modern cities. Pollution can be intense, traffic a problem. Personal safety is not as certain as it once was in the days of the *serenos* (night watchmen). But the city has preserved the charm, character, and vivacity that give it and its inhabitants a style of their own—an important aspect of modern Spain, where each region seeks to express its own identity.

THE PEOPLE

The flow of migration to Madrid, attracted chiefly by the city's expanding industrial belt, has created a modern population representative of the entire Spanish nation. A traditional nickname for the Madrileños is *gatos* ("cats"),



Madrid.

originally coined in the Middle Ages as a reference to the ability of local troops to scale castle walls. It would be no less apt as a reference to the local life-style and the late hours kept by the city's modern inhabitants, although keeping late hours is also common in other parts of Spain, especially in the heat of summer. People eat late, theatres and cinemas begin performances late as a matter of course, and the siesta is by no means dead, although the introduction of modern business methods and the influx of foreign interests have tended to lead to the introduction of the *semana inglesa* (literally "English week"), doing away with the long midday break. The city offers a wealth of cultural events and entertainments. It is not a cosmopolitan city as such, and yet its cultivated people tend to be widely read, while the young are up-to-date with the latest pop music. There is no large foreign population, nor are there distinct ethnic groups, although the number of *casas regionales*—regional clubs catering to people who

Late-hour life-style

have come to work from all over the country—reflects the source of labour for Madrid's burgeoning industrial and commercial sectors. Since the early 1970s the Latin-American population has become more numerous as the historic flow of those migrating to the Americas to escape economic misery or political conflict has been reversed. Madrid is a city that, with its style and flair, absorbs and holds those who live there or know it. Its inhabitants have a reputation for being attached to it; in the words of a local proverb, "From Madrid to heaven, and in heaven a little window from which to see it."

THE ECONOMY

Industry, commerce, and finance. Being the centre for government, finance, and insurance is a factor that has for long contributed to the prosperity of the capital, not to mention activities such as tourism and the city's position as the nation's transportation hub. In the postwar period (which, of course, for Spaniards means post-1939—since that was when the Spanish Civil War ended, and since Spain was neutral in World War II) the city became an important manufacturing centre for the automotive and aircraft industries, and for electric and electronic equipment, and optics, the production of plastics and rubber, and consumer goods. Madrid, with Barcelona, dominates publishing in Spain.

Postwar industrial development

Transportation. The road and rail systems both converge on the capital from all corners of the country. A subway system, the Metro, serves Madrid with various lines that extend throughout the city. The international airport of Barajas lies about eight miles east of the city. A motorway (expressway) system encircles Madrid in a roughly pentagonal shape, coming to a point in the south. Other major motorways radiate from the encircling artery in all directions. There are numerous bus routes operated by municipal and private authorities; minibus service is also available. The road-building programs of the 1960s, when much was sacrificed to the convenience of automobile owners, have since been recognized as less than wholly beneficial. Some of the overpasses introduced to speed up traffic flow have since been dismantled.

ADMINISTRATION AND SOCIAL CONDITIONS

With the return of democracy to Spain in the late 1970s and the development of autonomous regional governments, more emphasis has been placed on local consultation and issues such as the future of the environment. In 1982 the city administration carried out a massive public opinion survey to find out what people really wanted at the neighbourhood level. The resulting General Ordinance Plan (Plan General de Ordenación) was an attempt to establish a long-term, full-scale scheme for future directed growth, aiming not only to modernize the infrastructure of essential services but also to improve the quality of life in the city. Despite the introduction of the autonomous regions, Madrid continues to be the focus of Spain's government. It is also a bishopric, headquarters of the army corps, and residence of the captain general of the first military region. The supreme court and government ministries are also located there, besides the Cortes (the Spanish parliament), which is housed in a 19th-century Neoclassical building. Characterized by the bronze lions (made from melted down Moorish cannon) flanking the entrance, it is one of the smallest parliament buildings in Europe. Local administration is under the direction of a mayor and city council.

The General Ordinance Plan

CULTURAL LIFE

Modern pressures have perhaps inhibited the extensive street life for which Madrid has been famous, although people still live very much in the streets, especially during the intense heat of summer when the café terraces fill and people stroll up and down in the evenings. Modern culture, in the form of film, theatre, and music, is extensively represented, as is to be expected in a city with several major universities and academies. But the cultural life for which Madrid was once noted, the *tertulias*, that is to say the informal conversational gatherings and informal societies, have all but faded, along with the elegant cafés that housed them. Madrid's literary traditions, its associations with Lope de Vega, Calderón, Cervantes, Quevedo, Pérez Galdós, Larra, Baroja, and Azorín, continue in the city's varied cultural life, as demonstrated by the fact that it is one of the major publishing centres for the Spanish-speaking world.

Modern Madrid has attractions at all levels. The 23,000-seat bullring, Las Ventas, is the largest in Spain and the place where the novice bullfighters have to display their skills in the *alternativa* (the occasion on which a matador kills his first bull) in order to become established. The season runs from March to October. There are two major football (soccer) teams, with the annual matches against the Barcelona teams among the high points of the year. Important matches are played in two stadia, the

Bullfighting tradition

Palacio Real and gardens, Madrid.

125,000-seat Santiago Bernabéu and the 70,000-seat Vicente Calderón. The *verbenas*, special fiestas held in each quarter in honour of its patron saint, are regular public events, especially in warm weather, with San Isidro (mid-May) taking pride of place. The *zarzuelas* (light opera of mildly satirical flavour, indulging in topical comment and set by tradition in Madrid) are commonly held in the open air at this time. There are, in fact, more than 40 parks and public gardens, the principal ones being the Retiro, Campo del Moro, Casa de Campo, and Oeste Park, not to mention the curious temple of Debod (an ancient Egyptian temple acquired by Spain at the time of the construction of the Aswān High Dam) near Rosales, with splendid panoramic views over the city.

Museums abound. Unusual ones include those for theatre, railways, and (understandably enough for Spain) *tauromaquia*, the bullfight. The city is richly endowed with artistic masterpieces: tapestries in the Casa de Cisneros (the mayor's residence) and the Royal Palace (Palacio Real); paintings by Bruegel and Titian in the convent of the Descalzas Reales; and Spanish and foreign masters in the Palacio de Liria, home of the dukes of Alba. The most famous collection is housed in the Prado, which displays the artworks collected by the Spanish monarchy over the ages and reflects the pattern of Spain's alliances. Charles V and Philip II were patrons of Venetian art; Philip IV was a great collector in the 17th century; and the accession of the Bourbon family led to an influx of French works. Spain's control of the Netherlands led to a solid Flemish section. El Casón del Buen Retiro is nearby and houses 19th- and 20th-century works, the most famous probably being Picasso's "Guernica." This painting in 1981 was sent to Spain from New York City in accordance with Picasso's directive that the painting be moved there only after democracy had returned to the country.

The Prado

Notable among an abundance of libraries are the prestigious National Library (Biblioteca Nacional) and the Library of the Royal Palace, acclaimed for its historic collection. Madrid is also famous for its secondhand bookshops, and the Feria del Libro (book fair), held in the spring, is a widely heralded event.

Madrid is Spain's foremost centre of higher education and includes several of the country's leading universities, among which are the Open University (Universidad Nacional de Educación a Distancia), the Complutensian University, and the Polytechnical University, all in University City, and to the north the Autonomous University.

History

The early period. The Arab town, or medina, grew around the alcazar (castle) on a promontory overlooking the Manzanares River. The name Majerit first appears in AD 932, when the Christian king Ramiro II of León razed the town's walls, but there are traces of earlier (even prehistoric) habitation. The Christian king Alfonso VI of Castile and León captured the town from the Muslims in 1083, and thereafter a number of kings of Castile spent time there. The parliament (Cortes) was called there as early as 1309. The alcazar was damaged in an earthquake in 1466 and the subsequent medieval palace was extended by various monarchs, notably Charles I and Philip II. In this period the town grew to the east up both sides of what are now the Calle Mayor and the Calle de Segovia, with the Moors (who continued to live there until after the Christian reconquest of Spain was completed in 1492) jammed into the southwest corner, which is still called the Moreria. The whole of the city at this time was only 500 by 900 yards in area. Some of the street patterns of the pre-16th century city remain, but few buildings; one that still stands is the much-restored Casa de los Lujanes, where it is believed the French king Francis I was once held prisoner. Charles I enjoyed hunting near Madrid, and it is said that the widening of the city gates to accommodate his carriages opened the cramped streets to heavier traffic, a process that was to increase when the court was properly established in the city. By 1598 the population of Madrid had reached 60,000, and by the time of the first extant plan of Madrid (Pedro Teixeira's in 1656) it had grown to be an imposing city of 100,000 people and 11,000 buildings.

Christian takeover

Under the Habsburg monarchs, the Madrid de los Austrias expanded even more rapidly. The foreign ministry (1634), the Casa de Cisneros, and the Segovia Bridge date from this time, as does the church of San Isidro el Real. (It is also, incidentally, still Madrid's temporary cathedral—Nuestra Señora de la Almudena, begun rather tardily in 1883, is still under construction.) Architects such as Juan de Herrera (who died in 1597) and Francisco de Mora contributed to the monumental quality of the city. But the most striking contribution of this period is generally considered to be the Plaza Mayor, designed by Juan Gómez de Mora and built between 1617 and 1619; it was modified after the great fire of 1790. Graceful in concept, it is surrounded by five-story houses with balconies and topped with steeples. Nine archways open onto the plaza at oblique angles from surrounding streets, and the continuous arcade at street level contains shops and restaurants. Bullfights (in those days conducted by noblemen on horseback), fireworks displays, and plays all took place there, as did the grim ceremonies of the Inquisition. Until 1765 public garrotings were also carried out there. The last bullfight to take place in the Plaza Mayor was in honour of the wedding of Isabella II in 1846.

Habsburg rule

Development under the Bourbon kings. No less impressive a landmark dates from the next great phase of the city's growth, under the Bourbons, whose side Madrid took against the Habsburgs in the War of the Spanish Succession (1701–14), although the city was briefly occupied by pro-Habsburg troops. The Royal Palace was begun by Philip V after the disastrous fire that destroyed the Alcazár on Christmas night, 1734. His grandiose plan, with 23 inner courts, was never realized, although the finished work did have 500 rooms. It was a fitting addition to the other major city features created under his patronage, the Royal Spanish Academy (Real Academia Española), the National Library, and the Royal Academy of History (Real Academia de Historia). The Royal Palace, with its elegant granite and limestone walls, contains a ceiling by Tiepolo in the throne room and, in the Armeria, one of the world's finest collections of armour, including the swords of the conquistadores Hernán Cortés and Francisco Pizarro. The last king of Spain actually to live there was Alfonso XIII, whose apartments have been preserved just as he left them when he abdicated in 1931. The royal family now resides in the more private and less ostentatious La Zarzuela Palace, set in its own grounds to the northwest of Madrid. A less important palace was also favoured by the Bourbon kings—the Palacio del Buen Retiro; its gardens, which were much admired for their French style, are still a much frequented open space.

Growth under the Bourbon kings

The greatest Bourbon builder was Charles III (1759–88), who is known as the mayor-king for his interest in the growth and development of the city and his many contributions to its skyline. This was the age of Enlightenment, and Charles tried to establish a harmony between leisure and science, culture and industry. His style was cosmopolitan, reflecting the tastes of the Europe of his time. With his concern for the appearance of the city, its gates, avenues, and trees, he anticipated the designs of modern city planners. He relied heavily in his schemes on the works of three Neoclassical architects, Francisco Sabatini, Ventura Rodríguez, and Juan de Villanueva. During this period the city continued to grow eastward to the present Plaza de la Independencia, which is the site of a monumental arch, the Puerta de Alcalá, built in 1778 and still a key landmark. Another famous landmark, the central post office, in the Puerta del Sol, also dates from this time. All distances in the country are still measured from the zero-kilometre stone beneath its wall. The square itself holds a firm place in people's affections; it is particularly popular on New Year's Eve when people go to hear the clock strike midnight and to eat the 12 grapes that supposedly ensure good luck in the following months. In earlier times the square was significant because of the stagecoaches that left from there to all parts of the peninsula. Its appeal made it the site of various innovations in urban amenities, from the first gas lamps in 1830 through the first mule

Charles III, the mayor-king

trams and first public urinal to the first electric streetlights and electric streetcars. Charles III would doubtless have approved of all these innovations. In his time he set up the Botanic Garden (which still exists), with a "physic" garden from which anybody could (and still can) collect medicinal herbs. He planned a natural history and science museum next to it but died before it could be completed.

Madrid was occupied by French troops during the Napoleonic Wars, and Napoleon's brother Joseph was installed on the throne. On May 2, 1808, there was a mass uprising against Joseph, leading to what the Spaniards term "la Guerra de la Independencia." Ferdinand VII, on his return in 1814 from imprisonment by Napoleon, bestowed the title of "heroic" upon the city. In 1819 the building intended by Charles III to house a natural history and science museum was completed. Into it Ferdinand moved artworks of the royal collection, until then scattered among various palaces. This was the start of what was to become one of the world's major art galleries, the Prado. The Madrid of this period can still be studied in close detail, thanks to the remarkable model constructed by León Gil Palacios in 1830. It was during this period that the city expanded to the north, under the direction of Joaquín Vizcaíno, a nobleman who was also mayor (as was customary at the time). He is also known as the man who introduced such innovations as street numbers for buildings, street lighting, and municipal refuse collection. The Paseo del Prado was extended by two new boulevards, the Paseo de los Recoletos and the Paseo de la Castellana. For years this area presented an almost rural atmosphere and featured imposing town houses with great gardens. Now it is the site of tall office blocks, apartment buildings, luxury hotels, and embassies, as well as the National Library, the National Archaeological Museum, the Queen Sofía Art Centre, and the Thyssen-Bornemisza Museum. One of the area's mansions (now a bank) belonged to the Marqués de Salamanca, who in 1872 also contributed to the drive northward by building 28 streets on a grid plan, starting from the Calle de Alcalá and parallel to the Paseo. Still bearing his name, this area remains one of the most elegant *barrios* in Madrid.

Modernization under the Plan Castro

Somewhat earlier, in 1860, the Plan Castro, also referred to as the Ensanche, or widening, had further expanded and modernized the city, adding convenience and meeting the economic and commercial needs of the time. It was the first comprehensive, forward-looking modern plan for Madrid. However, it was to be frustrated by population growth, land speculation, and the poor areas that sprang up outside the planned zones.

Modern Madrid. During the 20th century, Madrid grew dramatically and became a modern commercial and administrative centre. This transformation had begun by 1910, when a major new landmark appeared. The *barrio* of San Bernardo was bisected by a broad way running from the Calle de Alcalá downhill to the Plaza de España, where the city's first high-rise commercial buildings were erected. This, the Gran Vía, was designed to be the main street of the city, and it has a characteristic vitality, with cinemas, coffeehouses, shops, and banks.

With the advent of the Republic in 1931, radial and ring roads appeared, and the Paseo de la Castellana was extended even farther. The city suffered heavily in the Civil War, with two years of aerial and artillery bombardment and combat lines drawn up as close as University City. War damage to public buildings was repaired, and ambitious reconstruction plans were drawn up, but these were by and large unsuccessful in practice. The city spread outward, swallowing its own suburbs; between 1948 and 1951 Madrid's city limits were extended to cover a total of 205 square miles (531 square kilometres), about 10 times its previous area. A period of land speculation and uncontrolled urban sprawl followed. During the 1950s and '60s, the city expanded rapidly into the surrounding countryside. Industrial districts developed south and east of the historic centre, encircled by areas of ramshackle, low-rise squatter housing and poorly built high-rise public housing for the workers who streamed into the city. Meanwhile, elite suburban developments of single-family homes proliferated on Madrid's northern and western peripheries. High-rise office buildings spread north from the historic centre along the Paseo de la Castellana and displaced many of the elegant mansions that had lined the street.

Mid-20th-century expansion

During the 1980s and '90s, Madrid enjoyed renewed prosperity and rising living standards. New suburban developments of single-family and two-family houses appeared on the city's outskirts, even in the traditionally working-class south and east. At the same time, an extensive renovation program improved the quality of older working-class neighbourhoods and restored many aging buildings in the historic centre. Legislation passed toward the end of the 20th century protected many of the city's most prized structures and promoted the preservation of less-famous historic buildings. At the beginning of the 21st century, Madrid's planners worked to balance present-day prosperity with respect for the city's rich historic legacy.

Malta

An independent republic, Malta (Repubblika Ta' Malta) comprises a small but strategically important group of islands in the central Mediterranean Sea. Throughout a long and turbulent history, the archipelago has played a vital role in the struggles of a succession of powers for domination of the Mediterranean and in the interplay between emerging Europe and the older cultures of Africa and the Middle East. As a result, Maltese society was molded by centuries of foreign rule, with influences ranging from Arab to Norman to English.

There are five islands—Malta (the largest), Gozo, Comino, and uninhabited Kemmunett (Comminotto) and Filfla—lying some 58 miles (93 kilometres) south of Sicily, 180 miles (290 kilometres) north of Libya, and about 180 miles east of Tunisia, at the eastern end of that constricted portion of the Mediterranean Sea separating Italy from the African coast. The islands cover a combined land area of 122 square miles (316 square kilometres). Valletta is the capital, although Birkirkara is the largest city.

The article is divided into the following sections:

Physical and human geography

THE LAND

Relief. Malta Island measures about 17 miles at its longest distance from southeast to northwest and about 9 miles at its widest distance from east to west. The main physical characteristic of Malta is a well-defined escarpment that bisects it along the Victoria Lines Fault running along the whole breadth of the island from Point ir-Raħeb (west of Nadur Tower) to the coast northeast of Għargħur.

Limestone and coral

The highest areas are coralline limestone uplands that constitute a triangular plateau, Ta' Żuta (829 feet [253 metres]), to the west. The uplands are separated from the surrounding areas by blue clay slopes, while undercliff areas are found where the coralline plateau has fallen and forms a subordinate surface between the sea and the original shore. The total shoreline is 85 miles.

To the north the escarpment is occasionally abrupt and broken by deep embayments. To the south, however, the plateaus gradually descend from about 600–800 feet into undulating areas of globigerina (derived from marine protozoa) limestone less than 400 feet high. On the west are deeply incised valleys and undercliff areas, while on the east are several valleys that descend to the central plains.

The west coast of Malta presents a high, bold, and generally harbourless face. On the east, however, a tongue of high ground known as Mount Sceberras separates the bays of Marsamxett and Grand Harbour. These deepwater harbours contribute to the strategic importance of Malta. They are associated with nine seasonal creeks that include those of Sliema, Lazzaretto, Msida, and Newport. The northern shore is again bare and craggy, characterized by its coves and hills, which are separated by fertile lowlands.

In Gozo the landscape is characterized by a broken coralline plateau to the north and by low-lying globigerina limestone plains and hills to the south. The highest point, in the west, is 578 feet. The total shoreline is 27 miles.

Drainage and soils. Malta possesses favourable conditions for the percolation and underground storage of water. The impermeable blue clays provide two distinct water tables between the limestone formations. The principal source for the public supply of water has been the main sea-level water table. The absence of permanent streams or lakes and a considerable loss of rainfall, however, have made water supply a problem. This problem has been combated with an intensive reverse-osmosis desalination program. About 70 percent of Malta's daily water needs are supplied by desalination plants throughout the islands.

Shortage of fresh water

Maltese soils are mainly young or immature and thin. By law, when soils are removed from construction sites, they must be taken to agricultural areas, and level stretches in quarries are often covered with carted soil. Organic refuse from the towns is also used. Consequently, the soils are unusual and are partly a manufactured medium.

Climate. The climate is typically Mediterranean, with hot, dry summers, warm and sporadically wet autumns,

and short, cool winters with adequate rainfall. Nearly three-fourths of the total annual rainfall of about 20 inches (508 millimetres) falls between October and March; June, July, and August are normally quite dry.

The temperature is very stable, the annual mean being 64° F (18° C) and the monthly averages ranging from 54° F (12° C) to 88° F (31° C). Winds are strong and frequent; the most common are the cool northwesterly (the *majjistral*), the dry northeasterly (the *grigal,* or gregale), and the hot humid southeasterly (the *xlokk,* or sirocco). The relative humidity is consistently high and rarely falls below 40 percent.

Plant and animal life. While wild vegetation is sparse, there is an abundance of cultivated potatoes, sulla (a leguminous fodder crop), onions, tomatoes, and vines. The forest cover, though poor, features a wide variety of trees, including the carob, fig, and chaste. The Maltese government has initiated a major tree-planting program to improve forestation on the islands. The developed seashore vegetation includes golden and rock samphires, sea campion, spurge, saltwort, and marram grass.

Typical of the few native mammals are the hedgehog, the least weasel, the water and white-toothed shrews, and the pipistrelle and other bats. Rats, mice, and some rabbits also are found. Resident birds include the spectacled and Sardinian warblers, the Manx and Cory's shearwaters, and the blue rock thrush. Linnets, tree and Spanish sparrows, buntings, rock doves, and several species of owl also form breeding populations, while birds of passage include ospreys, rollers, swallows, cuckoos, bee-eaters, and vultures. Common insects are beetles, grasshoppers, flies, mosquitoes, moths, bees, wasps, cockroaches, ants, and several species of butterflies. Ladybirds migrate from Sicily.

Settlement patterns. Until the mid-19th century, the Maltese lived mainly in the relative seclusion of clustered villages and hamlets; the fragmentation of farmholdings accentuated the individuality of the farming community. The *zuntier,* or church square, was the traditional focus of village life. With the growth of the Dockyard complex in the latter part of the 1800s, new settlements appeared around Grand Harbour, and the Sliema metropolitan region developed in the 20th century into the most fashionable part of Malta. The advent of industrial estates near major villages somewhat stemmed the exodus from the rural areas. Higher living standards have given rise to residential developments all over the island; its central and northwest areas are now densely populated. Overbuilding has been a cause for serious concern, spawning legislation meant to contain the ecological threats thus posed.

Concern with overbuilding

Gozo conserves its own rural character. The architecture of the development at Ta' Ċenċ successfully blends with the island's natural beauty and is aesthetically stimulating. Comino is more rural still, with only a handful of residents, no cars, and two hotels.

THE PEOPLE

The islands' ethnic and linguistic composition reflects the heritage of many rulers. A European atmosphere predominates as a result of close association particularly with southern Europe. About 95 percent of the islanders are Maltese-born, and the remainder includes mostly persons of English and Italian descent. During the 20th century, the increasing rate of Anglo-Maltese marriages added a new dimension to the ethnic structure of the population.

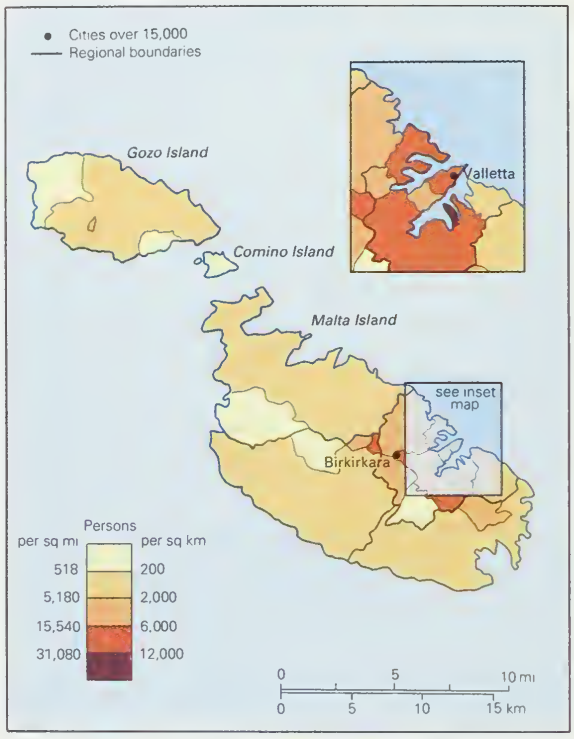
Maltese—the medium of daily conversation—is a distinct language that resulted from the interaction and fusion of North African Arabic and a Sicilian form of Italian. It is the only Semitic language that is officially written in Latin script; it became an official language of Malta in 1934. English, the other official language, is the medium

of instruction in the schools. Italian was the language of church and government until 1934 and is still understood by a sizable sector of the population.

Relations of state and church

Although Roman Catholicism is the state religion, there is full freedom for all religious beliefs. The islands are an independent province of the church, with two dioceses at Malta and Gozo and two bishops serving the cathedrals at Valletta and Rabat (Victoria). There are two Roman Catholic cathedrals, at Mdina and Valletta, and an Anglican cathedral, at Valletta. There is a mosque at Corradino Heights.

Malta has one of the highest population densities in the world. The population has somewhat stabilized, however, with a considerable decline in the birthrate since the 1950s. The death rate has remained fairly stable, having fallen only slightly, while the infant mortality rate has dropped significantly. Emigration, formerly encouraged and even financed by the government, has also tapered off; the primary destination of emigration is Australia. The majority of the country's immigrants are repatriates. The age structure of the population is fairly evenly distributed, and the life expectancy is about 74 years.



Population density of Malta.

THE ECONOMY

Malta's only exploited mineral resource is the globigerina limestone that is used as building stone, although the country has offshore reserves of petroleum. Its other assets are its deep harbours, an adaptable, skilled labour force, and a strategic position as both a fueling centre and, until March 1979, a military and naval base. The economy, therefore, has been somewhat artificial and until 1979 determined by the vicissitudes of war and peace in the Mediterranean. In the 1950s Britain began the retrenchment of its naval and military forces on Malta, a move that necessitated a drastic diversification of the economy. A series of five- and seven-year plans were supported by government grants, loans, and other fiscal incentives to encourage private investment.

Industry and tourism. Economic plans professed to build on a tripod basis of industry, agriculture, and tourism. In fact, however, industrial growth lagged behind these plans, resulting in the successful establishment of only a few multinational corporations (mainly producing textiles). From 1971 the government increasingly took over weak enterprises, sometimes closing them. Since 1987 new development has concentrated on manufacture of industrial components, including computer parts, instruments, and other high-tech goods, as well as a large variety of consumer products (toys, cosmetics, detergents, processed foods) and more traditional goods such as lace, silver filigree, pottery, glassware, and canework. Foreign investment in manufacturing is encouraged and facilitated by the Malta Development Corporation.

Tourism is a major source of income. The influx of tourists and some immigration spurred the building of hotels and housing, but there are questions about the islands' capacity to cater to an annual total of tourists greater than the country's population. Besides shipbuilding and transshipment services, the establishment of backup facilities for oil companies and of other outlets for traditional Maltese skills in cross-cultural dealings produced jobs and foreign currency earnings that boosted the Maltese currency, making it one of the strongest in the world.

Agriculture and fishing. Agricultural development is hampered by infertile soils and the lack of adequate water supplies, and large amounts of food and beverages are imported. Most farming is carried out on small terraced strips of land that preclude the introduction of large-scale mechanization. Consequently, agriculture continues to decline in terms of cultivated land. The farming labour force has grown increasingly older, female, and part-time, but agricultural production has risen gradually because of improved techniques in the cultivation of some crops, especially horticultural ones. The major crops are grains, vegetables, fruit (especially citrus), and fodder for domestic consumption and early potatoes and onions for export. Flowers, seeds, plants, and cuttings are exported as well. Cattle, pigs, sheep, poultry, and goats are also raised.

Agricultural production

Fishing is seasonal and not fully developed. The fishing boats are small, and the catch is affected by weather conditions. The fish population off the island is quite sparse and in the late 1980s began to be supplemented by agriculture. During the summer months, small lamps are used by fishermen (lampara fishing) to attract the fish, mainly the very popular lampuka, or dolphin (*Coryphaena hippuras*).

Finance. The Central Bank and the Malta Development Corporation were both founded in 1968. Also in that year, Malta joined the International Monetary Fund. The Malta Export Trade Corporation was founded in 1989. In 1971 the island entered into a special trade relationship with the European Communities (EC), a relationship that was subsequently revised with the aim of rendering it more favourable to Malta in its delicate stage of economic development. Malta is trying to secure full membership status in the EC.

Transportation. The road system connects all towns and villages and includes a coast road, a panoramic road, and a regional road, which connects Msida to the coast road via St. Andrews. Bus services radiating from Valletta provide inexpensive and frequent internal transportation. Taxis are abundant, and most families have a private automobile. There is no railway. Several daily sailings connect Malta and Gozo, and, in addition to a regular ferry and car-ferry service, Malta and Sicily are connected by fast commercial catamarans. Scheduled airlines, including the national airline (Air Malta, based at Luqa Airport), connect Malta with most European capitals as well as with Africa, especially North Africa, and the Middle East.

GOVERNMENT AND SOCIAL CONDITIONS

Government. The 1964 Independence Constitution, under which Malta was a constitutional monarchy and parliamentary state, was amended in 1974 to make Malta a republic within the Commonwealth. Its head of state is a president appointed by the Maltese Parliament, which is elected by universal adult suffrage for a term of five years and is basically derived from the British model. Local features include a single chamber with 69 members, while election is by proportional representation from 13 electoral divisions. An amendment adopted in 1987 guarantees a majority of seats to a party receiving more than 50 percent of the total votes in the general election. The two major parties are the Nationalist Party and the Malta Labour Party. The president acts on the advice of the Cabinet, which consists of the prime minister and other ministers (some assisted by parliamentary secretaries) and

is collectively responsible to Parliament. There is no municipal government in the islands.

The judicial system

Maltese law, which was codified mainly during the period from 1854 to 1873, is largely based on the Napoleonic Code and Napoleonic law. Procedural common law and some commercial and maritime affairs are regulated by English principles, but judiciary precedent is not binding. Maltese is the language of the courts. Civil and criminal jurisdiction is almost exclusively vested in the Superior Court and the Court of Magistrates. The chief justice and judges of the Superior Court are appointed by the president on the advice of the prime minister, and their duties are apportioned throughout the court system. The magistrates, who are appointed in the same way, sit in the lower courts.

Between 1964 and 1972, Malta's main defense dispositions were those contained in a 1964 Anglo-Maltese defense agreement, with the United Kingdom guaranteeing mutual assistance. Since then, through a constitutional amendment, Malta has followed a policy of neutrality and nonalignment and maintains its own regular armed forces.

Education. The Labour government radically altered the education system, which was previously structured on British models and strongly influenced by the Roman Catholic church. Compulsory education was extended to include all children from the ages of 6 to 16. An attempt at establishing an extreme form of the "comprehensive" system was abandoned; streaming (the grouping of students by age and intellectual ability) and examinations were at first discarded but later reintroduced; purely technical institutes were not compelled to follow the program. At the tertiary level, a student-worker scheme was introduced in 1978, students working for six months and studying for six months, thereby linking admission to institutions of higher learning to the availability of employment. This system was largely revoked by the Education Act of 1987, and admission to institutions of higher learning is now based completely on competence.

The University of Malta, founded as a Jesuit college in 1592 and established as a state institution in 1769, was refounded in 1988. It offers courses in most disciplines and has a prestigious medical school. Its modern campus at Tal-Qroqq also houses the International Maritime Law Institute and the Mediterranean Academy of Diplomatic Studies. The historic Old University building in Valletta is now the seat of the university-linked Foundation for International Studies and its associated bodies, the International Environment Institute, the Mediterranean Institute, and the Euro-Mediterranean Centre on Marine Contamination Hazards (created by the Council of Europe). Malta is also the site of the Regional Marine Pollution Emergency Response Centre for the Mediterranean Sea, operated jointly by the International Maritime Organization (IMO) and the United Nations Environment Programme (UNEP).

Health and welfare. A scheme to integrate health services, essentially consisting of free hospital care and some domestic assistance, was introduced after 1971. Certain measures deemed to be necessary preliminaries to a wider-ranging national health scheme gave rise to conflict with the local medical association, and heavy reliance was then placed on foreign doctors. Since 1988 Malta has been the seat of the United Nations International Institute on Aging, and thus special attention is given to geriatrics.

In 1956 social insurance was introduced to cover employees more than 14 years of age and self-employed or unemployed persons between 19 years and pension age. A comprehensive contributory insurance scheme was introduced in 1971, integrating a variety of earlier legislation. The plan included a pension amounting to two-thirds of an individual's salary at the time of retirement. The first step toward comprehensive national health insurance was taken in 1979 with the introduction of free hospitalization.

CULTURAL LIFE

Folk traditions and festivals

Malta's cultural influences stem largely from its history of foreign domination and the predominance of the Roman Catholic church. Folk traditions have evolved mainly around the festa to celebrate the patron saint of a village, marked by processions and fireworks. Good Friday also is celebrated with colourful processions in several villages. *Imnarja,* the Feast of St. Peter and St. Paul, which takes place on June 29, is the principal folk festival; it is highlighted by folksinging (*għana*) contests and fried-rabbit picnics at Buskett. The annual Carnival is celebrated at Valletta with vigorous dancing displays that include the Parata, a sword dance commemorating the Maltese victory over the Turks in 1565, and Il-Maltija, the Maltese national dance. Soccer is the most popular sport in Malta, and Ta' Qali National Stadium is the site of important local and international matches.

Apart from its unique Neolithic ruins near Raħal Ġdid (Paola, Paula, or Pawla) and Tarxien, Malta contains important examples of its flourishing architectural school of the 17th and 18th centuries. It was essentially Classical with a balanced overlay of Baroque decorations. The Italian artists Caravaggio and Mattia Preti spent several years in Malta, the latter's most important paintings embellishing many of Malta's churches.

The arts

In the 20th century, a vernacular architecture was developed by Richard England and others. The composer Charles Camilleri introduced folk themes into his works, while Maltese literature was enriched by the poetry of the national bard, Dun Karm. An interesting theatrical upsurge led by John Schranz paralleled the emergence of Francis Ebejer as a brilliant playwright. Alfred Chircop and Luciano Micallef have gained prominence with their abstract paintings, while Gabriel Caruana has excelled in ceramics.

Valletta is the centre of many of Malta's cultural institutions: the National Museum of Archaeology, the National Museum of Fine Arts, the War Museum, the Manoel Theatre (one of Europe's oldest theatres still in operation), and the Foundation for International Studies. The National Library of Malta dates from the late 18th century and houses a large collection as well as the archives of the Knights Hospitalers. The Folk Museum and the Museum of Political History are located at Vittoriosa. Until the early 1990s, Maltese radio and television stations had been operated exclusively by the Malta Broadcasting Authority, but a change in legislation has opened the way for privately operated broadcasting stations. There are two daily newspapers in Maltese and one in English.

For statistical data on the land and people of Malta, see the *Britannica World Data* section in the BRITANNICA BOOK OF THE YEAR.

History

The earliest archaeological remains date from about 3800 BC. Neolithic farmers lived in caves like those at Dalam (near Birżebbuġa) or villages like Skorba (near Nadur Tower) and produced pottery that seems related to that of contemporary eastern Sicily. An elaborate cult of the dead of Stone Age or Copper Age culture evolved about 2400 BC. Initially centring around rock-cut collective tombs such as those at Ġgantija (near Xagħra) and Ħaġar Qim (near Żurrieq), it culminated—probably through contacts with the cultures of the Cyclades and Mycenae—in the unique underground burial chamber (hypogeum) at Ħal Saflieni (near Raħal Ġdid). This culture came to a sudden end about 2000 BC, possibly as a result of invasions. The culture that replaced it, of southern Italian flavour, is evidenced today only by fragmentary remains. Bronze Age tools and weapons have been found at Borġ in-Nadur (near Birżebbuġa) and Tarxien Cemetery (near Raħal Ġdid), while Iron Age relics from about 1200 to 800 BC include cart ruts at Binġemma (near Nadur Tower).

Domination by Carthage and Rome

Between the 8th and 6th centuries BC, contact was made with Semitic cultures. Evidence is scanty, however, and a few inscriptions found on Malta constitute the only indication of a Phoenician presence. There is more substantial proof of the Carthaginian presence in the 6th century BC; coins, inscriptions, and several Punic-type rock tombs have been found. It is certain that in 218 BC Malta came under Roman political control. Originally part of the praetorship of Sicily, the islands were subsequently given the status of municipium and were thus allowed to coin their own money, send ambassadors to Rome, and

control domestic affairs. According to tradition, St. Paul was shipwrecked in Malta in AD 60 and began to convert the inhabitants. The Maltese have been Christians uninterruptedly since that time.

With the division of the Roman Empire, in AD 395, Malta was given to the eastern portion dominated by Constantinople. Until the 15th century, it followed the more immediate fortunes of nearby Sicily, being ruled successively by Arabs (who left a strong effect on the language), Normans (who advanced the legal and governmental structures), and a succession of feudal lords. In 1530, however, it was ceded to the Order of the Hospital of St. John of Jerusalem (the Knights Hospitalers), a religious and military order of the Roman Catholic church. Malta became a fortress and, under the Knights' grand master, Jean de La Valette, successfully withstood the Ottoman siege of 1565. The new capital city of Valletta became a town of splendid palaces and unparalleled fortifications. Growing in power and wealth—owing mainly to their maritime adventures against the Turks—the Knights left the island an architectural and artistic legacy. Although there was little economic and social contact between them and the Maltese, they managed to imprint their cosmopolitan character on Malta and its inhabitants.

In 1798 Napoleon Bonaparte captured the island, but the French presence was short-lived, and the Treaty of Amiens returned the island to the Knights in 1802. The Maltese protested and acknowledged Great Britain's sovereignty, subject to certain conditions incorporated in a Declaration of Rights. The constitutional change was ratified by the Treaty of Paris in 1814.

British rule

Malta's political status under Britain underwent a series of vicissitudes in which constitutions were successively granted, suspended, and revoked. British demands for Malta's military facilities dominated the economy, and the Dockyard became the colony's economic mainstay.

The island flourished during the Crimean War and was favourably affected by the opening of the Suez Canal in 1869. Self-government was granted in 1921 on a dyarchical basis whereby Britain shared power and responsibility with Maltese ministers who were elected by the legislature. But the battle over the relative roles of the English, Italian, and Maltese languages took its toll, and in 1936 the islands reverted to a strictly colonial regime in which full power rested in the hands of the governor. During World War II, the islands repelled the Axis powers against severe odds, having been one of the most heavily bombed targets of that conflict. As a result, it was awarded the George Cross, Britain's highest civilian decoration. Self-government was granted in 1947, revoked in 1959, and then restored in 1962. Malta finally achieved independence within the Commonwealth on Sept. 21, 1964. It became a republic on Dec. 13, 1974.

The withdrawal of British military and naval personnel from its famous Dockyard—associated with the achievement of independence from the United Kingdom in 1964—created economic and political problems for Malta. From 1964 to 1971, Malta was governed by the Nationalist Party, whose attitude was firm alignment with the West. In 1971, however, when the Malta Labour Party came to power, its policy was nonalignment and special friendship with China and Libya. In 1979 the total closure of the British base and the end of the British alliance were celebrated by the Maltese government as the arrival of "real" independence; however, the existence of serious problems, especially with regard to the guarantee of full and productive employment and the deepening division between local political parties, was acknowledged. The Nationalists were returned to power in 1987 with a policy of seeking full membership in the European Community and transforming the economy into a modern, technologically oriented structure. Malta's growing international importance was acknowledged when it was chosen as the site of the first summit meeting between Soviet President Mikhail Gorbachev and U.S. President George Bush in 1989. For later developments in the history of Malta, see the BRITANNICA BOOK OF THE YEAR.

BIBLIOGRAPHY

Geography. *General works:* WALTER KÜMMERLY *et al.*, *Malta: Isles of the Middle Sea* (1965); and HARRY LUKE, *Malta: An Account and an Appreciation*, 2nd ed. rev. and enlarged (1960), are illustrated descriptive works with maps. Focus on local landscape is found in ROBIN BRYANS, *Malta and Gozo* (1966); HARRISON LEWIS, *A Guide to the Remote Paths and Lanes of Ancient Malta* (1974); and DOUGLAS LOCKHART and SUE ASHTON, *Landscapes of Malta, Gozo, and Comino* (1989). BODO NEHRING, *Die Maltesischen Inseln* (1966), provides a more scholarly geographic survey. Travelers' guides, some repeatedly revised in well-known publishers' series, include BRYAN BALLS and RICHARD COX, *Traveller's Guide to Malta: A Concise Guide to the Mediterranean Islands of Malta, Gozo, and Comino*, 4th ed. (1981); INGE SEVERIN, *See Malta & Gozo: A Complete Guide with Maps and Gazetteer*, rev. ed. (1984); and PETER MCGREGOR EADIE, *Malta and Gozo*, 3rd ed. (1990).

People: Minor Islands of the Mediterranean, Gozo, Malta (1981) is a UNESCO survey of the settlement patterns in the region. JEREMY BOISSEVAIN, *Hal-Farrug: A Village in Malta* (1969, reissued as *A Village in Malta*, 1980), offers a study of social life and customs. The role of religion is explored in JEREMY BOISSEVAIN, *Saint and Fireworks: Religion and Politics in Rural Malta* (1965); and MARIO VASSALLO, *From Lordship to Stewardship: Religion and Social Change in Malta* (1979).

Government and social conditions: PAUL CASSAR, *Medical History of Malta* (1964), is a detailed survey of the development of the essential social service. BARRY YORK, *Malta: A Non-Aligned Democracy in Mediterranean* (1987), offers a short overview of modern politics; and, for an equally brief look at the civil rights, see *Human Rights in Malta* (1985), a report of the International Helsinki Federation for Human Rights.

Economy: Surveys of the economic conditions are presented in M.M. METWALLY, *Structure and Performance of the Maltese Economy* (1977); and R. COHEN, M. MINOGUE, and J. CRAIG, *Small Island Economies* (1983). SALVINO BUSUTTIL, *Devaluation in Malta* (1968), examines the currency question in the period of independence. JOHN C. GRECH, *Threads of Dependence* (1978), explores the problems of dependency on foreign technology. LINO BRIGUGLIO, *The Maltese Economy: A Macroeconomic Analysis* (1988); and MICHAEL FRENDO and JOSEF BONNICI, *Malta in the European Community: Some Economic & Commercial Perspectives* (1989), are later analyses.

Cultural life and institutions: On the architecture, see LEONARD MAHONEY, *A History of Maltese Architecture: From Ancient Times up to 1800* (1988); J. QUENTIN HUGHES, *The Building of Malta During the Period of the Knights of St. John of Jerusalem, 1530–1795*, rev. ed. (1967, reissued 1986); and CHARLES KNEVITT, *Connections: The Architecture of Richard England, 1964–84* (1984). Other arts are discussed in RICHARD ENGLAND (ed.), *Contemporary Art in Malta* (1973), including essays on music, painting, and drama; DANIEL MASSA (ed.), *Individual and Community in Commonwealth Literature* (1979); OLIVER FRIGGIERI, *Storia della letteratura maltese* (1986), an Italian translation from the Maltese of an analysis of Maltese poetry; and, on painting, MARIO BUHAGIAR, *The Iconography of the Maltese Islands, 1400–1900* (1988).

History. General historical surveys are presented in ERIC GERADA-AZZOPARDI, *Malta: An Island Republic* (1979); BRIAN BLOUET, *The Story of Malta*, 3rd rev. ed. (1981); and MARIO BUHAGIAR (ed.), *Proceedings of History Week 1983* (1984). For the earliest periods, see J.D. EVANS, *The Prehistoric Antiquities of the Maltese Islands* (1971). The Middle Ages are studied in ANTHONY T. LUTTRELL (ed.), *Medieval Malta: Studies on Malta Before the Knights* (1975); ERNLE BRADFORD, *The Great Siege: Malta 1565* (1961, reissued 1979); ROSE G. KINGSLEY, *The Order of St. John of Jerusalem: Past and Present* (1918, reprinted 1978); with the history continued in RODERICK CAVALIERO, *The Last of the Crusaders: The Knights of St. John and Malta in the Eighteenth Century* (1960). The modern period is explored in HENRY FRENDO, *Party Politics in a Fortress Colony: The Maltese Experience* (1979); R. DE GIORGIO, *A City by an Order* (1985); ERNLE BRADFORD, *Siege: Malta to 1940–1943* (1985); GEORGE HOGAN, *Malta: The Triumphant Years, 1940–43* (1978); CHARLES A. JELLISON, *Besieged: The World War II Ordeal of Malta, 1940–1942* (1984); DENNIS AUSTIN, *Malta and the End of the Empire* (1971); J.J. CREMONA, *An Outline of the Constitutional Development of Malta Under British Rule* (1963); EDITH DOBIE, *Malta's Road to Independence* (1967); and HENRY FRENDO, *Malta's Quest for Independence: Reflections on the Course of Maltese History* (1989). Mammals

The class Mammalia is a group of vertebrate animals, collectively known as mammals, in which the young are nourished with milk from special secreting glands (mammae) of the mother. In addition to these characteristic milk glands, mammals are distinguished by several other unique features. Hair is a typical mammalian feature, although in many whales it has secondarily disappeared except in the fetal stage. The mammalian lower jaw is hinged directly to the skull, instead of through a separate bone (the quadrate) as in all other vertebrates. A chain of three tiny bones transmits sound waves across the middle ear. A muscular diaphragm separates the heart and the lungs from the abdominal cavity. Only the left aortic arch of the primitive fourth pair persists (in birds the right arch persists; in reptiles, amphibians, and fishes both arches are retained). Mature red blood cells in all mammals lack a nucleus; all other vertebrates have nucleated red blood cells.

Except for the monotremes (echidnas and duck-billed platypuses), which lay eggs, all mammals are viviparous (*i.e.*, bear live young). In the placental mammals (including man) the young are carried within the mother's womb, reaching a relatively advanced stage of development before being born. In the marsupials (kangaroos, opossums, and allies) the newborn, incompletely developed at birth, continue to develop outside the womb, attaching themselves to the female's body in the area of her mammary glands. Some marsupials have a pouchlike structure or fold, the marsupium, that shelters the suckling young.

The class Mammalia is worldwide in distribution. It has been said that mammals have a wider distribution and are more adaptable than any other single class of animals, with the exception of certain less complex forms such as the arachnids and insects. This versatility in exploiting the Earth is attributed in large part to the ability of mammals to regulate their body temperatures and internal environment both in excessive heat and aridity and in severe cold.

(Ed.)

THE CLASS MAMMALIA

General features

The evolution of the Mammalia has produced tremendous diversity in form and habits. Living kinds range in size from tiny shrews, weighing but a few grams, to the largest of all animals that has ever lived, the blue or sulphur-bottom whale, which reaches a length of more than 30 metres (100 feet) and a weight of 136,000 kilograms (150 tons). Every major habitat has been invaded by mammals that swim, fly, run, burrow, glide, or climb.

There are approximately 4,000 species of living mammals, arranged in about 120 families and 20 orders. The rodents (order Rodentia) are the most numerous of existing mammals, both in number of species and number of individuals, and are one of the most diverse of living lineages. In contrast, the order Tubulidentata is represented by a single living species, the aardvark. The Proboscidea (elephants) and Perissodactyla (horses, rhinoceroses, and allies) are examples of orders in which far greater diversity occurred in mid- and late-Tertiary times (from about 3,000,000 to about 30,000,000 years ago) than today.

The tropical continental areas of the world around are the places of greatest present-day diversity of mammals, although members of the order occur on (or in seas adjacent to) all major land masses and on many oceanic islands (the latter principally, but by no means exclusively, reached by bats). Major regional faunas can be identified; these resulted in large part from evolution in comparative isolation of stocks of early mammals that reached these areas. South America (Neotropics), for example, was separated from North America (Nearctic) from Paleocene through much of Pliocene times (about 2,500,000 to 65,000,000 years ago) by inundation of the Panamanian Portal and adjacent areas in Middle America. Evolution of mammalian groups that had reached South America before the break between the continents, or some that "island-hopped" in after the break, proceeded quite independently from that of relatives that remained in North America. Some of the latter became extinct as the result of competition with more advanced groups, whereas those in South America flourished, some radiating to the extent that they have successfully competed with invaders since the rejoining of the two continents. Australia provides a parallel case of early isolation and adaptive radiation of mammals (monotremes, marsupials) thus isolated, but differs in that it was not later connected to any other land mass. The more advanced mammals of the infraclass Eutheria that reached Australia (rodents, bats) did

Radiation in South America

so, evidently by "island-hopping," long after the adaptive radiation of the early isolates.

In contrast, North America and Eurasia (Palearctic) are separate land masses but have closely related faunas, the result of connections several times in the Pleistocene and earlier across the Bering Strait. Their faunas frequently are thought of as representing not two distinct units, but one, related to a degree that a single name, Holarctic, is applied to it.

IMPORTANCE TO MAN

Wild and domesticated mammals are so interlocked with man's political and social history that it is impractical to attempt to assess the relationship in precise economic terms. Throughout his cultural evolution, for example, man has been dependent on other mammals for a significant portion of his food and clothing. Domestication of mammals helped to provide a source of protein for ever-increasing human populations and provided means of transportation and heavy work as well. Today, domesticated strains of the house mouse, European rabbit, guinea pig, hamster, gerbil and other species provide much-needed laboratory subjects for the study of human-related physiology, psychology, and a variety of diseases from dental caries to cancer. Recent emphasis on the study of nonhuman primates (monkeys and apes) has opened broad, new areas of research relevant to man's welfare. The care of domestic and captive mammals is, of course, the basis for the practice of veterinary medicine.

Some primitive peoples still depend on wild mammals as a major source of food, and many different kinds (from fruit bats and armadillos to whales) regularly are captured and eaten. On the other hand, the hunting, primarily for sport, of various rodents, lagomorphs, carnivores, and ungulates supports a multibillion-dollar enterprise. In the United States alone, for example, it is estimated that more than 2,000,000 deer are harvested annually by licensed hunters.

Influence on exploration

Geopolitically, the quest for marine mammals was responsible for the charting of a number of areas in both Arctic and Antarctic regions. The presence of terrestrial fur bearers, particularly beaver and several species of mustelid carnivores (*e.g.*, marten and fisher), was one of the principal motivations for the opening of the American West, Alaska, and the Siberian taiga. Sale of wild-taken furs still is an important industry in both the Old and New Worlds, but ranch-raised animals such as the mink, fox, and chinchilla now have become an important part of the fur industry, which directly and indirectly accounts for many millions of dollars in revenue each year in North America alone.

Aside from pelts and meat, special parts of some mammals regularly have been sought for their special attributes. The horns of rhinoceroses are used in concocting potions in the Orient; ivory from elephants and walruses is highly prized; and ambergris, a substance regurgitated by sperm whales, has been widely used as a base for perfumes (although now mostly replaced by synthetic substitutes).

Some mammals are directly detrimental to man and his activities. Murid rodents (house rats and mice of Old World origin) now occur in virtually all of the world's urban areas and each year cause substantial damage and economic loss. In some rural areas, herbivorous mammals eat or trample planted crops and compete with livestock for food, and native carnivores prey on domestic herds. These and other situations have led man to spend large sums annually to control populations of "undesirable" wild mammals, a practice long deplored by conservationists. Mammals are important reservoirs or agents of transmission of a variety of diseases that afflict man, such as plague, tularemia, yellow fever, rabies, leptospirosis, hemorrhagic fever, and Rocky Mountain spotted fever. The annual "economic debt" resulting from mammal-borne diseases of man and his domestic stock is incalculable.

Many large mammals that competed directly with man for food or space, or were specially sought by him for some reason, have been extirpated entirely or exist today only in parks and zoos; others are in danger of extinction, and their plight is receiving increased attention by a number of conservation agencies. Perhaps at least some can be saved. One of the most noteworthy cases of direct extirpation by man is the Steller's sea cow (*Hydrodamalis gigas*). These large (up to 12 metres, or 40 feet, long), inoffensive, marine mammals evidently lived in Recent times only along the coasts and shallow bays of the Commander Islands in the Bering Sea. Discovered in 1741, they were easily killed by Russian sealers and traders for food, their meat being highly prized, and the last known live individual was taken in 1768.

Extinction of Steller's sea cow

Of final note is the esthetic value of wild mammals and the relatively recent predilection of man to expend both considerable energy and resources to study and, if possible, conserve vanishing species, to set aside natural areas where native floral and faunal elements can exist in an otherwise highly agriculturalized or industrialized society, and to establish modern zoological parks and gardens. Such outdoor "laboratories" attract millions of visitors annually and will provide means by which present and future generations of humans can appreciate and study, in small measure at least, other kinds of mammals.

NATURAL HISTORY

The hallmarks of the mammalian level of organization are advanced reproduction and parental care, behavioral flexibility, and endothermy (the physiological maintenance of a relatively constant body temperature independent of that of the environment, allowing a high level of activity). Within the class, ecological diversity has resulted from adaptive specialization in food-getting, habitat preferences, and locomotion.

Throughout the past 70,000,000 years, the mammals have been the dominant animals in terrestrial ecosystems and important in nonterrestrial communities as well. The earliest mammals were small, active, predacious, and terrestrial or semiarboreal. From this primitive stock the mammals have radiated into a wide spectrum of adaptive modes against the background of the diverse environment of the Cenozoic (the last 65,000,000 years). Branches of the ancestral terrestrial stock early exploited the protection and productivity of the trees, whereas other lineages added further dimensions to the mammalian spectrum by adapting to life beneath the ground, in the air, and in marine and freshwater habitats.

Reproduction. In reproductively mature female mammals an interaction of hormones from the pituitary gland and the ovaries produces a phenomenon known as the estrous cycle. Estrus, or "heat," typically coincides with ovulation, and during this time the female is receptive to the male. Estrus is preceded by proestrus, during which ovarian follicles mature under the influence of a follicle-stimulating hormone from the anterior pituitary. The follicular cells produce estrogen, a hormone that stimulates proliferation of the uterine lining, or endometrium. Following ovulation, in late estrus, the ruptured ovarian follicle forms a temporary endocrine gland known as the corpus luteum. Another hormone, progesterone, secreted by the corpus luteum, causes the endometrium to become quiescent and ready for implantation of the developing egg (blastocyst), should fertilization occur. In members of the infraclass Eutheria (known as placental mammals) the placenta, as well as transmitting nourishment to the embryo, has an endocrine function, producing hormones that maintain the endometrium throughout gestation.

If fertilization and implantation do not occur, a phase termed metestrus ensues, in which the reproductive tract assumes its normal condition. Metestrus may be followed by anestrus, a nonreproductive period characterized by quiescence or involution of the reproductive tract. On the other hand, anestrus may be followed by a brief quiescent period (diestrus) and another preparatory proestrus phase. Mammals that breed only once a year are termed monestrous, and exhibit a long anestrus; those that breed more than once a year are termed polyestrous. In many polyestrous species the estrous cycle ceases during gestation and lactation (milk production), but some rodents have a postpartum estrus, mating immediately after giving birth.

The menstrual cycle of higher primates is derived from the estrous cycle, but differs from it in that when pro-

gesterone secretion from the corpus luteum ceases, in the absence of fertilization, the uterine lining is sloughed. In anthropoids other than man a distinct period of "heat" occurs around the time of ovulation.

Egg-laying by monotremes

Monotremes lay shelled eggs, but the ovarian cycle is similar to that of other mammals. The eggs are predominantly yolk (telolecithal), like those of reptiles and birds. Young monotremes are altricial (*i.e.*, in a relatively early stage of development and dependent upon the parent), reaching sexual maturity in about one year. (For additional information see below in *Monotremata*, subhead *Life cycle and reproduction*.)

The reproduction of marsupials differs from that of placentals in that the uterine wall is not specialized for the implantation of the embryos. The period of intrauterine development varies from about eight to 40 days. After this period the young migrate from the vagina to attach to the teats for further development. The pouch, or marsupium, is variously structured. Many species, such as kangaroos and opossums, have a single, well-developed pouch; in some phalangerids the pouch is compartmented, with a single teat in each compartment. The South American caenolestids or rat opossums have no marsupium. The young of most marsupials are dependent on maternal care for considerable periods, 13 to 14 weeks in *Didelphis*. Young koalas are carried in the pouch for nearly eight months, kangaroos to 10 months. (See below in *Marsupialia*, subheads *Life cycle* and *Reproductive adaptations*.)

Reproductive patterns in placental mammals are diverse, but in all cases a secretory phase is present in the uterine cycle and the endometrium is maintained by secretions of progesterone from the corpus luteum. The blastocyst emplants in the uterine wall. Villi are embedded in the lining of the uterus. The resulting complex of embryonic and maternal tissues is a true placenta. The uterine lining may be shed with the fetal membranes as "afterbirth" (a condition called deciduate) or may be resorbed by the female (nondeciduate). Placentae have been classified on the basis of the relationship between maternal and embryonic tissues. In the simplest nondeciduate placental arrangement the chorionic villi are in contact with uterine epithelium (the inner surface layer). In the "intimate deciduous" types, seen in primates, bats, insectivores, and rodents, the capillary endothelium (the layer containing minute blood vessels) of the uterine wall breaks down, and chorionic epithelium is in direct contact with maternal blood. In advanced stages of pregnancy in rabbits even the chorionic epithelium is eroded and the embryonic endothelium contacts the maternal blood supply. In no case, however, is there actual exchange of blood between mother and fetus; nutrients and gases must still pass through the walls of the fetal blood vessels.

The period of intrauterine development, or gestation, varies widely among eutherians, generally depending on the size of the animal, but influenced by the number of young per litter and the condition of young at birth. The gestation period of the domestic hamster (*Mesocricetus auratus*) is about two weeks, whereas that of the blue whale is 11 months and of the African elephant 21 to 22 months.

At birth the young may be well developed and able to move about at once (precocial) or they may be blind, hairless, and essentially helpless (altricial). In general, precocial young are born after a relatively long gestation period and in a small litter. Hares and many large grazing mammals bear precocial offspring. Rabbits, carnivores, and most rodents bear altricial young.

After birth young mammals are nourished by milk secreted by the mammary glands of the female. The development of milk-producing tissue in the female mammae is triggered by conception, and the stimulation of suckling the newborn prompts copious lactation. In therians (marsupials and placentals) the glands open through specialized nipples. The newborn young of marsupials are unable to suckle and milk is "pumped" to the young by the mother.

Composition of milk

Milk consists of fat, protein (especially casein), and lactose (milk sugar), as well as vitamins and salts. The actual composition of milk of mammals varies widely among species. The milk of whales and seals is some 12 times as rich in fats and four times as rich in protein as that of domestic cows but contains almost no sugar. Milk has meant an efficient energy source for the rapid growth of young mammals; the weight at birth of some marine mammals doubles in five days.

Behaviour. *Social behaviour.* The dependence of the young mammal on its mother for nourishment has made possible a period of training. Such training permits the nongenetic transfer of information between generations. The ability of young mammals to learn from the experience of their elders has allowed a behavioral plasticity unknown in any other group of organisms and has been a primary reason for the success of the mammals. The possibility of training is one of the factors that has made an increase in neural complexity selectively adaptive. Increased associational potential and memory extends the possibility of learning from experience, and the individual can make adaptive behavioral responses to environmental change. Individual response to short-term change is far more efficient than genetic response.

Some kinds of mammals are solitary, except for brief periods when the female is in estrus. In other species, however, social groups are present. Such groups may be reproductive, defensive, or may serve both functions. In those cases that have been studied in detail a more-or-less strict hierarchy of dominance prevails. Within the social group, maintenance of the hierarchy may depend on physical combat between individuals, but in many cases stereotyped patterns of behaviour evolve to displace actual combat, conserving energy, while maintaining the social structure.

Sexual dimorphism (a pronounced difference between sexes) frequently is extreme in social mammals. In large part this is because dominant males tend to be those that are largest or best armed. Dominant males also tend to have priority in mating, or may even have exclusive responsibility for mating within a "harem." Rapid evolution of secondary sexual characteristics can take place in a species with such a social structure even though the reproductive potential may be low.

A complex behaviour termed "play" frequently occurs between siblings, between members of an age class, or between parent and offspring. Play extends the period of maternal training and is especially important in social species, providing an opportunity to learn behaviour appropriate to the maintenance of dominance.

Territoriality. That area covered by an individual in his general activity is frequently termed the home range. A territory is a part of the home range defended against other members of the same species. As a generalization it may be said that territoriality is more important in the behaviour of birds than of mammals, but data for the latter are available primarily for diurnal species. The phenomenon of territoriality may be more widespread than is supposed. Frequently territories of mammals are "marked," either with urine or with secretions of specialized glands, as in lemurs, a form of territorial labelling less evident to humans than the singing or visual displays of birds. Many mammals that do not maintain territories per se nevertheless will not permit unlimited crowding and will fight to maintain individual distance. Such mechanisms result in more economical spacing of individuals over the available habitat.

Ecology. *Response to environmental cycles.* Mammals may react to environmental extremes by acclimatization, compensatory behaviour, or physiological specialization. Physiological responses to adverse conditions include torpidity, hibernation (in winter), and estivation (in summer). Torpidity may occur in the daily cycle or during unfavourable weather; short-term torpidity generally is economical only for small mammals that can cool and warm rapidly. The body temperature of most temperate-zone bats drops near that of the ambient air whenever the animal sleeps. The winter dormancy of bears at high latitudes is an analogous phenomenon and cannot be considered true hibernation.

Hibernation

True hibernation involves physiological regulation to minimize the expenditure of energy. The body temperature is lowered and breathing may be slowed to as low

as 1 percent of the rate in an active individual. There is a corresponding slowing of circulation and typically a reduction in the peripheral blood supply. When the body temperature nears the freezing point, spontaneous arousal occurs, although other kinds of stimuli generally elicit only a very slow response. In mammals that exhibit winter dormancy (such as bears, skunks, and raccoons), arousal may be quite rapid. Hibernation has evidently originated independently in a number of mammalian lines, and the comparative physiology of this complex phenomenon is only now beginning to be understood (see BEHAVIOUR, ANIMAL: *Dormancy*).

Inactivity in response to adverse summer conditions (heat, drought, lack of food) is termed estivation. Estivation in some species is simply prolonged rest, usually in a favourable microhabitat; other estivating mammals regulate the metabolism, although the effects are typically not so pronounced as in hibernation.

Behavioral response to adverse conditions may involve the selection or construction of a suitable microhabitat (such as the cool, moist burrows of desert rodents).

Migrations

Migration is a second kind of behavioral response. The most obvious kind of mammalian migration is latitudinal. Many temperate-zone bats, for example, undertake extensive migrations, although other bat species hibernate near the summer foraging grounds in caves or other equable shelters during severe weather when insects are not available. Caribou (*Rangifer tarandus*) migrate from the tundra to the forest edge in search of suitable winter range, and a number of cetaceans and pinnipeds undertake long migrations from polar waters to more temperate latitudes. Gray whales (*Eschrichtius robustus*), for example, migrate southward to calving grounds along the coasts of South Korea and Baja California from summer feeding grounds in the Okhotsk, Bering, and Chukchi seas. Of comparable extent is the dispersive feeding migration of the northern fur seal (*Callorhinus ursinus*).

Migrations of lesser extent include the altitudinal movements of some ungulates, the American elk or wapiti (*Cervus canadensis*) and bighorn sheep (*Ovis canadensis*), for example, and the local migrations of certain bats from summer roosts to hibernacula. Most migratory patterns of mammals are part of a recurrent annual cycle, but the irruptive emigrations of lemmings and snowshoe hares are largely acyclic responses to population pressure on food supplies.

Populations. A population consists of individuals of three "ecological ages"—prereproductive, reproductive, and postreproductive. The structure and dynamics of a population depend, among other things, on the relative lengths of these ages, the rate of recruitment of individuals (either by birth or by immigration), and the rate of emigration or death. The reproductive potential of some rodents (particularly muroids) is well known; some mice are reproductively mature at four weeks of age, have gestation periods of three weeks or less, and may experience postpartum estrus, with the result that pregnancy and lactation may overlap. Litter size, moreover, may average four or more, and breeding may occur throughout the year in favourable localities. The reproductive potential of a species is, of course, a theoretical maximum that is rarely met inasmuch as, among other reasons, a given female typically does not reproduce throughout the year. Growth of a population depends on the survival of individuals to reproductive age. The absolute age at sexual maturity ranges from less than four weeks in some rodents to some 15 years in the African elephant (*Loxodonta africana*).

Postreproductive individuals are rare in most mammalian populations. Survival through more than a single reproductive season is probably uncommon in many small kinds, such as mice and shrews. Larger species typically have longer life spans than do smaller kinds, but some bats are known, on the basis of banding records, to live nearly 20 years. Many species show greater longevity in captivity than in the wild. Captive spiny anteaters (*Tachyglossus*) are reported to have lived more than 50 years. Horses have been reported to live more than 60 years, and the oldest known elephant lived to be 81. Man has greater potential longevity than any other known species.

Locomotion. Specialization in habitat preference has been accompanied by locomotor adaptations. Convergent evolution within a given adaptive mode has contributed to the ecological similarity of regional mammalian faunas. Terrestrial mammals have a number of modes of progression. The primitive mammalian stock was doubtless ambulatory and plantigrade, walking with the digits, metacarpals, and metatarsals (bones of the midfoot), and parts of the ankle and wrist in contact with the ground. The limbs of ambulatory mammals are typically mobile, capable of considerable rotation.

Mammals modified for running are termed cursorial. The stance of cursorial species may be digitigrade (the complete digits contacting the ground, as in dogs) or unguligrade (only tips of digits contacting the ground, as in horses). In advanced groups, limb movement consists of a single forward and backward direction.

Saltatory (leaping) locomotion, sometimes called "ricochetal," has arisen in several unrelated groups and typically is found in mammals of open habitats. Jumping mammals (some marsupials, lagomorphs, and several independent lineages of rodents) typically have elongate, plantigrade hind feet, reduced forelimbs, and long tails.

Mammals of several orders have attained great size and have converged on specializations for "graviportal" (ponderous) locomotion. Such kinds have no digit reduction and deploy the digits in a circle around the axis of the limb for maximum support, like the pedestal of a column.

The bats are the only truly flying mammals. Only with active flight have the resources of the aerial habitat been successfully exploited. Mammals of several kinds (dermopterans, marsupials, rodents) are adapted for gliding. A gliding habit is frequently accompanied by scansorial (climbing) locomotion. Many nongliders, such as tree squirrels, are also scansorial.

Well-adapted arboreal mammals frequently are plantigrade, five-toed, and equipped with highly mobile limbs. Many New World monkeys have a prehensile tail, which is used as a "fifth hand." Gibbons have reduced the primitive, opposable anthropoid thumb as a specialization for brachiation, or "arm-walking," in which the animal hangs from branches and moves by a series of long swings. The highly arboreal tarsiers have expanded pads on the digits to improve the grasp, and many other arboreal kinds have claws (sloths) or well-developed nails.

Aquatic habits

Several groups of mammals have independently assumed aquatic habits. In some cases, semi-aquatic or aquatic mammals are relatively unmodified representatives of otherwise terrestrial groups (for example, otters, muskrats, water shrews). Other kinds have undergone profound modification for natatorial locomotion and a pelagic habit. Pinniped carnivores (walruses and seals) give birth to their young on land, but cetaceans are completely helpless out of water, on which they depend for mechanical support and thermal insulation.

Food habits. The earliest mammals, like their reptilian forebears, were active predators. From such a basal stock there has been a complex radiation of trophic adaptations. Modern mammals occupy a wide spectrum of feeding niches. In most terrestrial and some aquatic communities, carnivorous mammals are at the top of the food pyramid. There are also mammalian primary consumers in most ecosystems. The voracious shrews, smallest of mammals, sometimes prey on vertebrates larger than themselves. They may eat twice their weight in food each day to maintain their active metabolism and compensate for heat loss caused by an unfavourable surface-to-volume ratio. The largest of vertebrates, the blue whale, feeds on krill, minute planktonic crustaceans.

Within a given lineage, the adaptive radiation in food habits may be broad. Some of the Carnivora have become omnivorous (raccoons, bears) or largely herbivorous (giant panda). Marsupials exhibit a great variety of feeding types, and in Australia marsupials have radiated to fill ecological niches highly analogous to those of placental mammals elsewhere; there are marsupial "moles," "anteaters," "mice," "rats," "cats," and "wolves." Some bandicoots have ecological roles similar to those of rabbits, and wombats are semifossorial (*i.e.*, partially burrowing) herbivores

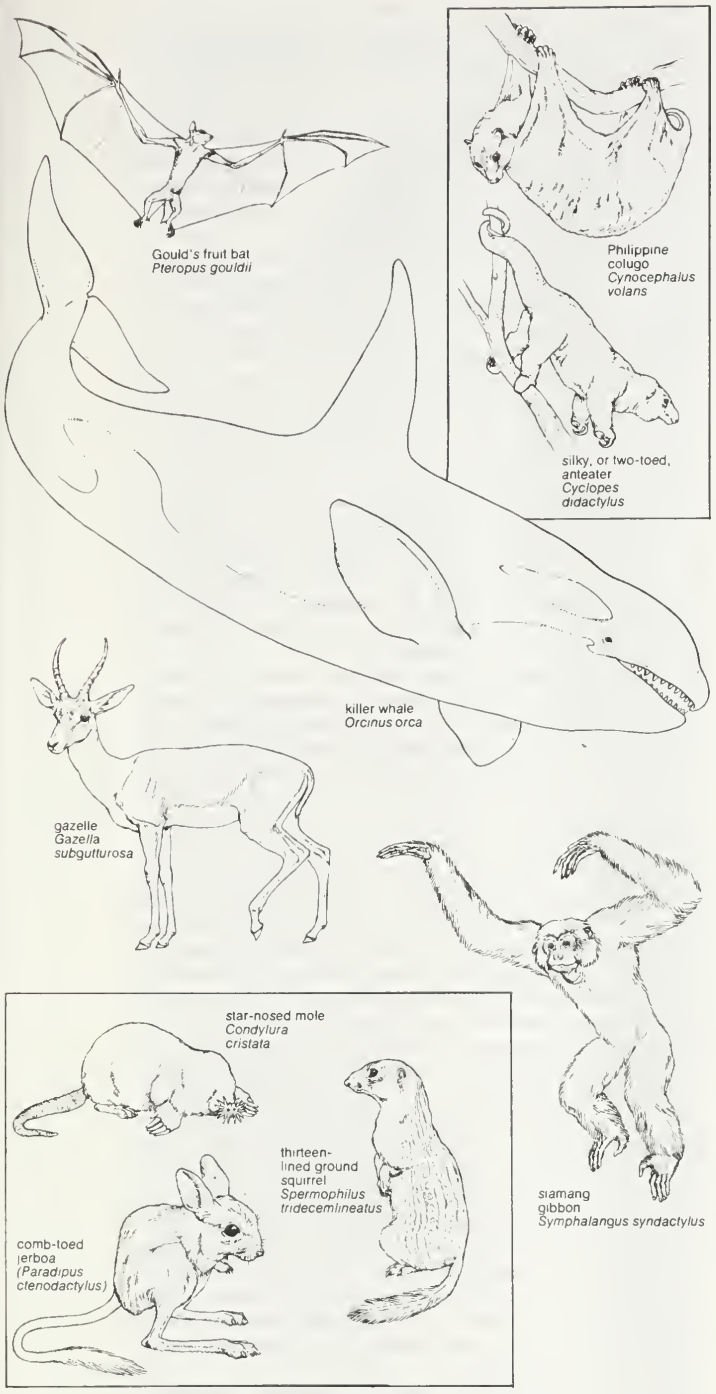

Figure 1: Range of body plans in mammals.

Drawing by R. Keane based on photographs courtesy of (Gould's fruit bat) J. Warham, (Philippine colugo) J.N. Hamlet, (silky, or two-toed anteater) New York Zoological Society, (comb-toed jerboa) Zeitschrift fur Saugetierkunde

analogous to marmots. In Australia the niche of large grazers and browsers is filled by a variety of kangaroos and wallabies.

Radiation of bats

Within the bats there has also been a remarkable adaptive radiation in food habits. Early in the history of the order there evidently was a divergence into insectivorous and frugivorous lines. The frugivorous line (Megachiroptera) has generally maintained its fruit-eating habit, although some have become rather specialized nectar-feeders. The Microchiroptera have been less conservative and have undergone considerable divergence in feeding habits. A majority of living microchiropterans are insectivorous, but members of two different families have become fish eaters. Within the large neotropical family Phyllostomatidae there are groups specialized to feed on fruit, nectar, insects, and small vertebrates (including other bats). Aberrant members of the family are the vampire bats (desmodontines) with a specialized dentition to aid the blood-lapping habit.

FORM AND FUNCTION

The skin and hair. The skin of mammals is constructed of two layers, a superficial nonvascular epidermis and an inner layer, the dermis or corium. The two layers interdigitate in dermal papillae (fingerlike projections), ridges of sensitive vascular dermis projecting into the epidermis. The outermost layers of the epidermis are cornified (*i.e.*, impregnated with various tough proteins) and enucleate (lacking cell nuclei). The epidermis is composed of flattened (squamous) cells in layers and is the interface between the individual and the environment. Its primary function is defensive, and it is cornified to resist abrasion. The surface of the skin is coated with lipids and organic salts, the so-called "acid mantle," thought to have antifungal and antibacterial properties. Deep in the epidermis is an electronegative layer, a further deterrent to foreign organic or ionic agents.

The dermis lies beneath the epidermis and nourishes it. The cutaneous circulation of the dermis is variously developed in mammals but it is typically extensive, out of proportion to the nutritional needs of the tissue. The major role of the cutaneous circulation is to moderate body temperature and blood pressure by forming a peripheral shunt, an alternate route for the blood. Also in the dermis are sensory nerve endings to alert the individual to pressure (touch), heat, cold, and pain. In general, skin bearing hairs has few or no specialized sensory endings, but hairless skin, such as the lips and fingertips of man, has specialized endings. The sensation of touch on hairy skin in man depends on stimulation of the nerve fibres of the hairs.

Hair is derived from an invagination (pocketing) of the epidermis termed a follicle. Collectively, the hair is called the pelage. The individual hair is a rod of keratinized cells that may be cylindrical or more-or-less flattened. Keratin is a protein also found in claws and nails. The inner medulla of the hair is hollow and contains air; in the outer cortex layer there are frequently pigment granules. Associated with the hair follicle are nerve endings and a muscle, the arrector pili. The latter allows the erection of individual hairs to alter the insulative qualities of the pelage. The follicle also gives rise to sebaceous glands that produce sebum, a substance that lubricates the hair.

Types of hair

Most mammals have three distinct kinds of hairs. Guard hairs protect the rest of the pelage from abrasion and frequently from moisture, and usually lend a characteristic colour pattern. The thicker underfur is primarily insulative and may differ in colour from the guard hairs. The third common hair-type is the vibrissa, or whisker, a stiff, typically elongate, hair that functions in tactile sensation. Hairs may be further modified to form rigid quills. The "horn" of the rhinoceros is composed of a fibrous keratin material derived from hair. Examples of keratinized derivatives of the integument other than hair are horns, hooves, nails, claws, and baleen.

Even though the primary function of the skin is defensive, it has been modified in mammals to serve such diverse functions as thermoregulation and nourishment of young. Secretions of sweat glands promote cooling due to evaporation at the surface of the body, and mammary glands are thought to be derived from sweat glands.

In certain groups (primates in particular) the skin of the face is under intricate muscular control and movements of the skin express and communicate "emotion." In many mammals the colour and pattern of the pelage is important in communicative behaviour. Patterns may be dymantic (startling, such as the mane of the male lion or hamadryas baboon), sematic (warning, such as the bold pattern of skunks), or cryptic (concealing), perhaps the most common adaptation of pelage colour.

Hair has been secondarily lost or considerably reduced in some kinds of mammals. In adult cetaceans insulation is provided by thick subcutaneous fat deposits, or blubber, with hair limited to a few stiff vibrissae about the mouth. The naked skin of whales is one of a number of features that contribute to the remarkably advanced hydrodynamics of locomotion in the group. Some fossorial mammals also tend toward reduction of the hair. This is shown most strikingly by the sand rats (*Heterocephalus*) of northeast

Africa, but considerable loss of hair has also occurred in some species of pocket gophers (Geomyidae). Hair may also be lost on restricted areas of the skin, as from the face in many monkeys, or the buttocks of mandrills, and may be sparse on elephants and such highly modified kinds as pangolins and armadillos.

Indeterminate (continuous) growth, as seen in the hair of the head in man, is rare among mammals. Hairs with determinate growth are subject to wear and must be replaced periodically—a process termed molt. The first coat of a young mammal is referred to as the juvenal pelage, which typically is of fine texture like the underfur of adults and is replaced by a postjuvenile molt. Juvenal pelage is succeeded by the subadult pelage, which in some species is not markedly distinct from that of the adult, or directly by adult pelage. Once this pelage is acquired molting continues to recur at intervals, often annually or semi-annually, sometimes more frequently. The pattern of molt typically is orderly, but varies widely between species. Some mammals apparently molt continuously, with a few hairs replaced at a time throughout the year.

Dentition. Specialization in food habits has led to profound dental changes. The primitive mammalian tooth had high, sharp cusps and served to tear flesh or crush chitinous material (primarily the exoskeletons of terrestrial arthropods, such as insects). Herbivores tend to have specialized cheek teeth with complex occlusal (contact) patterns and various ways of expanding the crown and circumventing the problem of wear. Omnivorous mammals, such as bears, pigs, and man, tend to have molars with low, rounded cusps, termed "bunodont."

Anteating

A prime example of convergence in conjunction with dietary specialization is seen in those mammals adapted to feeding on social insects (generally termed myrmecophagy, "anteating"). This habit has led to remarkably similar morphology in such diverse groups as the monotreme echidnas (Tachyglossidae), one dasyurid marsupial (Myrmecobiinae), some edentates (Myrmecophagidae) the aardvark, and pangolins (Pholidota). Trends frequently associated with myrmecophagy include: strong claws, an elongate, terete skull, a vermiform, extensible tongue, marked reduction in the mandible, and loss or extreme simplification of the dentition.

Specialized herbivores evolved early in mammalian history. The earliest (and with the longest evolutionary history) were the multituberculates. Evolutionary convergence in teeth (*i.e.,* resemblances not due to common ancestry) has occurred widely in herbivorous groups; most have incisors modified for nipping or gnawing, have lost teeth with the resultant development of a gap (diastema) in the tooth row, and exhibit some molarization (expansion and flattening) of premolars to expand the grinding surface of the cheek teeth. Rootless incisors or cheek teeth have evolved frequently, an open pulp cavity allowing continual growth throughout life. Herbivorous specializations have evolved independently in multituberculates, rodents, lagomorphs, primates, and in the wide radiation of ungulate and subungulate orders.

Skeleton. The mammalian skeletal system shows a number of advances over that of lower vertebrates. The mode of ossification of the long bones is characteristic. In lower vertebrates each long bone has a single centre of ossification, the diaphysis, and replacement of cartilage by bone proceeds from the centre toward the ends, which may remain cartilaginous, even in adults. In mammals secondary centres of ossification, the epiphyses, develop at the ends of the bones. Growth of bones occurs in zones of cartilage between diaphysis and epiphyses. Mammalian skeletal growth is termed determinate, for once the actively growing zone of cartilage is obliterated, growth in length ceases. As in all bony vertebrates, of course, there is continual renewal of bone throughout life. The advantage of epiphyseal ossification lies in the fact that the bones have strong articular surfaces before the skeleton is mature. In general, the skeleton of the adult mammal has less structural cartilage than does that of a reptile.

The skeletal system of mammals and other vertebrates is broadly divisible functionally into axial and appendicular portions. The axial skeleton consists of the braincase (cranium) and the backbone and ribs, and serves primarily to protect the central nervous system. The limbs and their girdles constitute the appendicular skeleton. In addition, there are skeletal elements derived from the gill arches of primitive vertebrates, collectively termed the visceral skeleton. Visceral elements in the mammalian skeleton include the jaws, the hyoid apparatus supporting the tongue, and the auditory ossicles of the middle ear. The postcranial axial skeleton in mammals generally has remained rather conservative during the course of evolution. The vast majority of mammals have seven cervical (neck) vertebrae; exceptions are sloths, with six or nine cervicals, and the Sirenia with six. The anterior two cervical vertebrae are differentiated as atlas and axis. Specialized articulations of these two bones allow complex movements of the head on the trunk. Thoracic vertebrae bear ribs and are variable in number. The anterior ribs converge toward the ventral midline to articulate with the sternum, or breastbone, forming a semirigid thoracic "basket" for the protection of heart and lungs. Posterior to the thoracic region are the lumbar vertebrae, ranging from two to 21 in number (most frequently four to seven). Mammals have no lumbar ribs. There are usually three to five sacral vertebrae, but some edentates have as many as 13. Sacral vertebrae fuse to form the sacrum, to which the pelvic girdle is attached. Caudal (tail) vertebrae range in number from five (fused elements of the coccyx of man) to 50.

The basic structure of the vertebral column is comparable throughout the Mammalia, although in many instances modifications have occurred in specialized locomotor modes to gain particular mechanical advantages. The vertebral column and associated muscles of many mammals is structurally analogous to a cantilever girder.

The skull

The skull is composite in origin and complex in function. Functionally the bones of the head are separable into the braincase and the jaws. In general, it is the head of the animal that meets the environment. The skull protects the brain and sense capsules, houses the teeth and tongue, and the entrance to the pharynx. Thus the head functions in sensory reception, food acquisition, defense, respiration, and (in higher groups) communication. To serve these functions, bony elements have been recruited from the visceral skeleton, the endochondral skeleton, and from the dermal skeleton of lower vertebrates.

The skull of mammals differs markedly from that of reptiles because of the great expansion of the brain. The sphenoid bones that form the reptilian braincase form only the floor of the braincase in mammals. The side is formed in part by the alisphenoid bone, derived from the epipterygoid, a part of the reptilian palate. Dermal elements, the frontals and parietals, have come to lie deep to (beneath) the muscles of the jaw to form the dorsum of the braincase. Reptilian dermal roofing bones, lying superficial to the muscles of the jaw, are represented in mammals only by the jugal bone of the zygomatic arch, which lies under the eye.

In mammals, a secondary palate is formed by processes of the maxillary bones and the palatines, with the pterygoid bones reduced in importance. The secondary palate separates the nasal passages from the oral cavity and allows continuous breathing while chewing or suckling.

Other specializations of the mammalian skull include paired occipital condyles (the articulating surfaces at the neck) and an expanded nasal chamber with complexly folded turbinal bones, providing a large area for detection of odours. Eutherians have evolved bony protection for the middle ear, the auditory bulla. The development of this structure varies, although an annular (ring-shaped) tympanic bone is always present.

Bones of the ear

The bones of the mammalian middle ear are a diagnostic feature of the class. The three auditory ossicles form a series of levers that serve mechanically to increase the amplitude of sound waves reaching the tympanic membrane, or eardrum, produced as disturbances of the air. The innermost bone is the stapes, or "stirrup bone." It rests against the oval window of the inner ear. The stapes is homologous with the entire stapedial structure of reptiles, which, in turn, was derived from the hyomandibular arch of primitive vertebrates. The incus, or "anvil," ar-

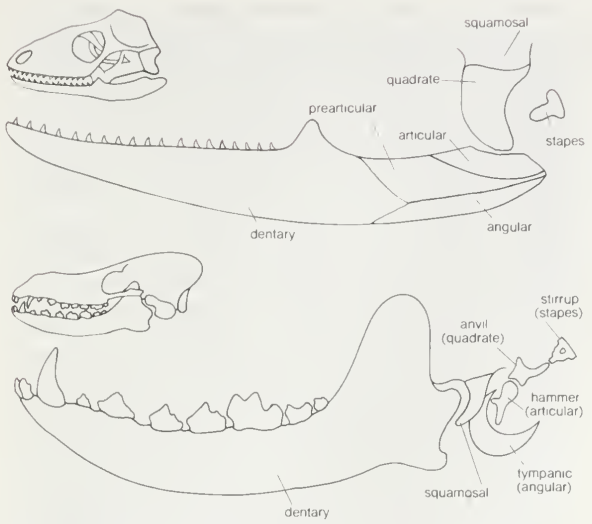

Figure 2: Comparison of lower jaw and ear region in the skull of (top) a reptile and (bottom) a mammal.

ticulates with the stapes. The incus was derived from the quadrate bone, which is involved in the jaw articulation in reptiles. The malleus, or "hammer," rests against the tympanic membrane and articulates with the incus. The malleus is the homologue of the reptilian articular bone. The mechanical efficiency of the middle ear has thus been increased by the incorporation of two bones of the reptilian jaw assemblage. In mammals the lower jaw is a single bone, the dentary, which articulates with the squamosal of the skull.

The limbs and girdles have been greatly modified with locomotor adaptations. The ancestral mammal had well-developed limbs and was five-toed. In each limb there were two distal (outer) elements (radius and ulna in the forelimb; tibia and fibula in the hindlimb) and a single proximal (inner or upper) element (humerus; femur). There were nine bones in the wrist, the carpals; and seven bones in the ankle, the tarsals. The phalangeal formula (the number of phalangeal bones in each digit, numbered from inside outward) is 2-3-3-3-3 in primitive mammals; in primitive reptiles it is 2-3-4-5-3. Modifications in mammalian limbs have involved reduction, loss, or fusion of bones. Loss of the clavicle from the shoulder girdle, reduction in the number of toes, and modifications of tarsal and carpal bones are typical correlates of cursorial locomotion. Scansorial and arboreal groups tend to maintain or emphasize the primitive divergence of the thumb and hallux (the inner toe on the hindfoot). Some details of limb modifications are included in the synopsis of the orders of mammals (see below *Annotated classification*).

Centres of ossification sometimes develop in nonbony connective tissue. Such bones are termed heterotopic or sesamoid elements. The kneecap (patella) is such a bone. Another important bone of this sort, found in many kinds of mammals, is the baculum, or os penis, which occurs as a stiffening rod in the penis of such groups as carnivores, many bats, rodents, some insectivores, and many primates. The os clitoridis is a homologous structure found in females.

Muscles. The muscular system of mammals is generally comparable to that of reptiles. With changes in locomotion, the proportions and specific functions of muscular elements have been altered, but the relationships of these muscles remain essentially the same. Exceptions to this generalization are the muscles of the skin and of the jaw.

The panniculus carnosus is a sheath of dermal (skin) muscle, developed in many mammals, which allows the movement of the skin independent of the movement of deeper muscle masses. Such movement functions in such mundane activities as the twitching of the skin to foil insect pests and in some species also is important in shivering, a characteristic heat-producing response to thermal stress. The dermal musculature of the facial region is particularly well developed in primates and carnivores, but occurs in other groups as well. Facial mobility allows expression that may be of importance in the behavioral maintenance of interspecific social structure.

Muscles of the jaw

The temporalis muscle is the major adductor (closer) of the reptilian jaw. In mammals the temporalis is divided into a deep temporalis proper and a more superficial masseter muscle. The temporalis attaches to the coronoid process of the mandible (lower jaw) and the temporal bone of the skull. The masseter passes from the angular process of the mandible to the zygomatic arch. The masseter allows an anteroposterior (forward-backward) movement of the jaw and is highly developed in mammals, such as rodents, in which grinding is the important function of the dentition.

Viscera. *Digestive system.* The alimentary canal is highly specialized in many kinds of mammals. In general, specializations of the gut accompany herbivorous habits. The intestines of herbivores are typically elongate and the stomach may also be specialized. Subdivision of the gut allows areas of differing physiological environments for the activities of different sorts of enzymes and symbiotic bacteria (which aid the animal by breaking down certain "indigestible" compounds). In ruminant artiodactyls the stomach has up to four chambers, each with a particular function in the processing of vegetable material. A cecum is common in many herbivores. The cecum is a blind sac at the distal end of the small intestine where complex compounds like cellulose are acted upon by symbiotic bacteria. The vermiform appendix is a diverticulum of the cecum. The appendix is rich in lymphoid tissue and in many mammals is concerned with defense against toxic bacterial products.

Hares and rabbits, the sewellel or "mountain beaver" (*Aplodontia rufa*), and some insectivores exhibit a phenomenon, known as reingestion, in which at intervals specialized fecal pellets are produced, which are taken in the mouth and passed through the alimentary canal a second time. Where known to be present, this pattern seems to be obligatory. Reingestion is poorly understood, but it is generally supposed that the process allows the animal to absorb in the upper gut vitamins produced by the microflora of the lower gut but not absorbable there.

Excretory system. The mammalian kidney is constructed of a large number of functional units called nephrons. Each nephron consists of a distal tubule, a medial section termed the loop of Henle, a proximal tubule, and a renal corpuscle. The renal corpuscle is a knot of capillaries, called a glomerulus, surrounded by a sheath, Bowman's capsule. The renal corpuscle is a pressure filter, relying on blood pressure to remove water, ions, and small organic molecules from the blood. Some of the material removed is waste, but some is of value to the organism. The filtrate is sorted by the tubules, and water and needed solutes are reabsorbed. Reabsorption is both passive (osmotic) and active (based on ion transport systems). The distal convoluted tubules drain into collecting tubules which, in turn, empty into the calyces, or branches, of the renal pelvis, the expanded end of the ureter. The pressure-pump nephron of mammals is so efficient that the renal portal system of lower vertebrates has been completely lost. Mammalian kidneys show considerable variety in structure, relative to the environmental demands on a given species. In particular, desert rodents have long loops of Henle and are able to reabsorb much water and to excrete a highly concentrated urine. Urea is the end product of protein metabolism in mammals, and excretion is therefore called ureotelic.

Action of the kidney

Reproductive system. The testes of mammals descend from the abdominal cavity to lie in a compartmented pouch termed the scrotum. In some species the testes are permanently scrotal and the scrotum is sealed off from the general abdominal cavity. In others the testes migrate to the scrotum only during the breeding season. It is thought that the temperature of the abdominal cavity is too high to allow spermatogenesis; the scrotum allows cooling of the testes.

The transport of spermatozoa is comparable to that in reptiles, relying on ducts derived from urinary ducts of earlier vertebrates. Mammalian specialities are the bulbourethral (or Cowper's) glands, the prostate gland, and

the seminal vesicle or vesicular gland. Each of these glands adds secretions to the spermatozoa to form semen, which passes from the body via a canal (urethra) in the highly vascular, erectile penis. The tip of the penis, the glans, may have a complex morphology and has been used as a taxonomic character in some groups. The penis may be retracted into a sheath along the abdomen or may be pendulous, as in bats and many primates.

Types of uterus

The structure of the female reproductive tract is variable. Four uterine types are generally recognized among placentals, based on the relationship of the uterine horns (branches). A duplex uterus characterizes rodents and rabbits; the uterine horns are completely separated and have separate cervices opening into the vagina. Carnivores have

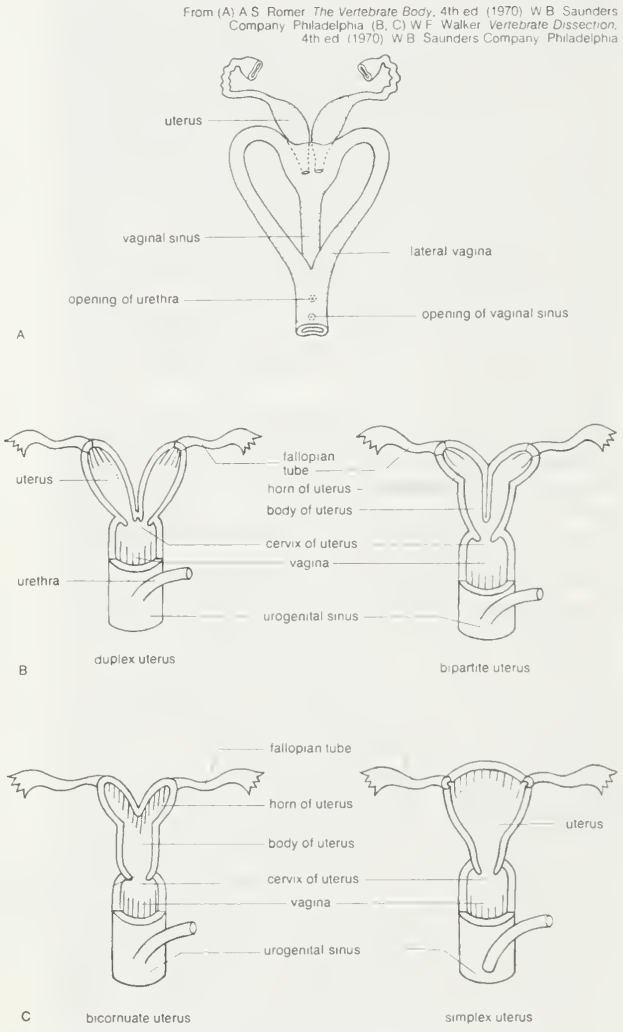

Figure 3: *Female reproductive systems.*
(A) Duplex uterus with median vaginal tube (kangaroo).
(B, C) Placental uteri.

a bipartite uterus, in which the horns are largely separate but enter the vagina by a single cervix. In the bicornate uterus, typical of many ungulates, the horns are distinct for less than half their length; the lower part of the uterus is a common chamber, the body. Higher primates have a simplex uterus in which all separation between the horns is lacking, forming a single chamber.

The female reproductive tract of marsupials is termed didelphous; the vagina is paired, as are oviducts and uteri. In primitive marsupials there are paired vaginae lateral to the ureters. In more advanced groups, such as kangaroos, the lateral vaginae persist and conduct the migration of spermatozoa, but a medial "pseud-vagina" functions as the birth canal.

Monotremes have paired uteri and oviducts, which empty into a urogenital sinus (cavity) as do fluid wastes. The sinus passes into the cloaca, a common receptacle for reproductive and excretory products.

Circulatory system. In mammals as in birds, right and left ventricles of the heart are completely separated, so that pulmonary (lung) and systemic (body) circulations are completely independent. Oxygenated blood arrives in the left atrium from the lungs and passes to the left ventricle, whence it is forced through the aorta to the systemic circulation. Deoxygenated blood from the tissues returns to the right atrium via a large vein, the vena cava, and is pumped to the pulmonary capillary bed through the pulmonary artery.

Among vertebrates, contraction of the heart is myogenic; rhythm is inherent in all cardiac muscle, but in myogenic hearts the pacemaker is derived from cardiac tissue. The pacemaker in mammals (and also in birds) is an oblong mass of specialized cells called the sinoatrial node, located in the right atrium near the junction with the venae cavae. A wave of excitation spreads from this node to the atrioventricular node, which is located in the right atrium near the base of the interatrial septum. From this point excitation is conducted along the atrioventricular bundle (bundle of His) and enters the main mass of cardiac tissue along fine branches, the Purkinje fibres. Homeostatic control of the heart by neuroendocrine or other agents is mediated through the intrinsic control network of the heart.

Blood leaves the left ventricle through the aorta. The mammalian aorta is an unpaired structure derived from the left fourth aortic arch of the primitive vertebrate. Birds, on the other hand, retain the right fourth arch.

Characteristics of the blood

The circulatory system forms a complex communication and distribution network to all physiologically active tissues of the body. A constant, copious supply of oxygen is required to sustain the active, endothermous physiology of the higher vertebrates. The efficiency of the four-chambered heart is important to this function. Oxygen is transported by specialized red blood cells, or erythrocytes, as in all vertebrates. Packaging the oxygen-bearing pigment hemoglobin in erythrocytes keeps the viscosity of the blood minimal and thereby allows efficient circulation while limiting the mechanical load on the heart. The mammalian erythrocyte is a highly evolved structure; its discoid, biconcave shape allows maximal surface area per unit volume. When mature and functional, mammalian red blood cells are enucleate.

Respiratory system. Closely coupled with the circulatory system is the ventilatory (breathing) apparatus, the lungs and associated structures. Ventilation in mammals is unique. The lungs themselves are less efficient than those of birds, for air movement consists of an ebb and flow, rather than a one-way circuit, so a residuum of air remains that cannot be expired. Ventilation in mammals is by means of a negative pressure pump made possible by the development of a definitive thoracic cavity with the evolution of the diaphragm.

The diaphragm is a unique, composite structure consisting of (1) the transverse septum (a wall that primitively separates the heart from the general viscera); (2) pleuroperitoneal folds from the body wall; (3) mesenteric folds; and (4) axial muscles inserting on a central tendon, or diaphragmatic aponeurosis.

The lungs lie in separate, airtight compartments called pleural cavities, separated by the mediastinum. As the size of the pleural cavity is increased the lung is expanded and air flows in passively. Enlargement of the pleural cavity is produced by contraction of the diaphragm or by elevation of the ribs. The relaxed diaphragm domes upward, but when contracted it stretches flat. Expiration is an active movement brought about by contraction of abdominal muscles against the viscera.

Air typically enters the respiratory passages through the nostrils where it may be warmed and moistened. It passes above the bony palate and the soft palate and enters the pharynx. In the pharynx the passages for air and food cross. Air enters the trachea, which divides at the level of the lungs into primary bronchi. A characteristic feature of the trachea of many mammals is the larynx. Vocal cords stretch across the larynx and are vibrated by forced expiration to produce sound. The laryngeal apparatus may be greatly modified for the production of complex vocalizations. In some groups, for example, howler monkeys

(*Alouatta*), the hyoid apparatus is incorporated into the sound-producing organ, as a resonating chamber.

Nervous and endocrine systems. The nervous system and the system of endocrine glands are closely related to one another in their function, for both serve to coordinate activity. The endocrine glands of mammals generally have more complex regulatory functions than do those of lower vertebrates. This is particularly true of the pituitary gland, which supplies hormones that regulate the reproductive cycle. Follicle stimulating hormone (FSH) initiates the maturation of the ovarian follicle. Luteinizing hormone (LH) mediates the formation of the corpus luteum from the follicle following ovulation. Prolactin, also a product of the anterior pituitary, stimulates the secretion of milk.

Control of the pituitary glands is partially by means of neurohumours from the hypothalamus, a part of the forebrain in contact with the pituitary gland by nervous and circulatory pathways. The hypothalamus is of the utmost importance in mammals, for it integrates stimuli from both internal and external environments, channelling signals to higher centres or into autonomic pathways.

The brain

The cerebellum of vertebrates is at the anterior end of the hindbrain. Its function is to coordinate motor activities and to maintain posture. In most mammals the cerebellum is highly developed and its surface may be convoluted to increase its area. The data with which the cerebellum works arrive from proprioceptors ("self-sensors") in the muscles and from the membranous labyrinth of the inner ear, the latter giving information on position and movements of the head.

In the vertebrate ancestors of the mammals the cerebral hemispheres were centres for the reception of olfactory stimuli. Vertebrate evolution has favoured an increasing importance of these lobes in the integration of stimuli. Their great development in mammals as centres of association is responsible for the "creative" behaviour of members of the class; *i.e.*, the ability to learn, to adapt as individuals to short-term environmental change through appropriate responses on the basis of previous experience. In vertebrate evolution the gray matter of the cerebrum has moved from a primitive internal position in the hemispheres to a superficial position. The superficial gray matter is termed the pallium. The paleopallium of amphibians has become the olfactory lobes of the higher vertebrates; the dorsolateral surface, or archipallium, the mammalian hippocampus. The great neural advance of the mammals lies in the elaboration of the neopallium, which makes up the bulk of the cerebrum. The neopallium is an association centre, the dominant centre of neural function, and is involved in so-called "intelligent" response. By contrast, the highest centre in the avian brain is the corpus striatum, an evolutionary product of the basal nuclei of the amphibian brain. The bulk of the complex behaviour of birds is instinctive. The surface of the neopallium tends in some mammals to be greatly expanded by convoluting, forming folds (gyri) between deep grooves (sulci).

Evolution and classification

THE EVOLUTION OF THE MAMMALIAN CONDITION

Mammals were derived in the Triassic Period from members of the reptilian order Therapsida. The therapsids, members of the subclass Synapsida (sometimes called the mammal-like reptiles), generally were unimpressive in relation to other reptiles of their time. Synapsids were present in the Carboniferous Period (about 280,000,000 to 345,000,000 years ago) and are one of the earliest known reptilian groups. They were the dominant reptiles of Permian times (about 225,000,000 to 280,000,000 years ago), and although they were primarily predacious in habit, the adaptive radiation included herbivorous species as well. In the Mesozoic (about 225,000,000 to 65,000,000 years ago), the importance of the synapsids was generally assumed by the archosaurs or "ruling reptiles," the therapsids, in general, being small, active carnivores. Therapsids tended to evolve a specialized heterodont dentition and to improve the mechanics of locomotion by bringing the plane of action of the limbs close to the trunk. A secondary palate was developed and the temporal musculature was expanded.

Figure 4: Reconstruction of *Lycaenops*, a Late Permian mammal-like reptile.

Drawing by R. Keane based on A.S. Romer, *The Vertebrate Story*, copyright 1959, the University of Chicago Press

The several features that separate modern reptiles from modern mammals doubtless evolved at different rates. Many attributes of mammals are correlated with their highly active habit; for example, efficient double circulation with a completely four-chambered heart, anucleate and biconcave erythrocytes, the diaphragm, and the secondary palate (which separates passages for food and air and allows breathing during mastication or suckling). Hair for insulation is a correlate of endothermy, the physiological maintenance of individual temperature independent of environmental temperature, and endothermy allows high levels of sustained activity. The unique characteristics of mammals thus would seem to have evolved as a complex interrelated system.

Because the characteristics that separate reptiles and mammals evolved at different rates and in response to a variety of interrelated conditions, at any point in the period of transition from reptiles to mammals there were forms that combined various characteristics of both groups. Such a pattern of evolution is termed "mosaic" and is a common phenomenon in those transitions marking the origin of major new adaptive types. To simplify definitions and to allow the strict delimitation of the Mammalia, some authors have suggested basing the boundary on a single character, the articulation of the jaw between the dentary and squamosal bones and the attendant movement of accessory jaw bones to the middle ear as auditory ossicles. The use of a single osteological character allows the placement in a logical classification of numerous fossil species, other mammalian characters of which, such as the degree of endothermy and nursing of young and the condition of the internal organs, probably never will be evaluated. It must be recognized, however, that were the advanced therapsids alive, taxonomists would be hard-put to decide which to place in the Reptilia and which in the Mammalia.

Mosaic evolution

CLASSIFICATION

Distinguishing taxonomic features. The higher classification of the Mammalia is based on consideration of a broad array of characters. Traditionally, evidence from comparative anatomy was of predominant importance, but more recently information from such disciplines as physiology, serology, and genetics has proved useful in considering relationships. Comparative study of living organisms is supplemented by the findings of paleontology. Study of the fossil record adds a historical dimension to knowledge of mammalian relationships. In some cases, the horses for example, the fossil record has been adequate to allow lineages to be traced in great detail.

Relative to that of other major vertebrate groups, the fossil record of mammals is good. Fossilization depends upon a great many factors, most important among which are the structure of the organism, its habitat, and conditions at the time of death. The most common remains of mammals are teeth and the associated bones of the jaw and skull. Enamel covering the typical mammalian tooth is composed of prismatic rods of crystalline apatite and is the hardest tissue in the mammalian body. It is highly resistant to chemical and physical weathering. Because of the abundance of teeth in deposits of fossil mammals, dental characteristics have been stressed in the interpretation of mammalian phylogeny and relationships. Dental

features are particularly well suited for this important role in classification because they reflect the broad radiation of mammalian feeding specializations from the primitive predaceous habit.

Annotated classification. The following classification has wide acceptance.

CLASS MAMMALIA

Vertebrate animals with the lower jaw formed by a single bone (dentary), articulating directly with the squamosal bone of the skull; dentition generally heterodont, thecodont, and diphyodont; body covered with hair derived from epidermis; young nourished by milk from mammary glands. For additional characteristics of the class, see *Form and function*, above. Groups preceded by a dagger mark (†) below are extinct.

Subclass Prototheria

Mammals in which principal cusps of molars form an anteroposterior row and much of the side of the braincase is formed by the periotic bone rather than by the alisphenoid. Primitive characters include uncoiled cochlea of the inner ear and absence of spine on the scapula (shoulder blade).

†*Infraclass Eotheria*

Fossil only; Upper Triassic to Lower Cretaceous of Eurasia and North America. Upper molars with internal and external cingula (shelves at base of crown), lower molars with internal cingulum only.

†*Order Triconodonta* (triconodonts). Fossil only; Northern Hemisphere; Upper Triassic to Lower Cretaceous. Probably carnivorous, the teeth well differentiated; molars typically with 3 prominent cusps; dentary bone lacking angular process.

†*Order Docodonta* (docodonts). Known only from fossil teeth and jaws from Upper Jurassic of Europe. Molars expanded, with transverse median furrow; angular process of mandible directed ventrally rather than posteriorly ("pseudangular").

Infraclass Ornithodelphia

Order Monotremata (monotremes). Pleistocene to Recent of Australia and New Guinea; possible record in Miocene of Australia family (Ectopodontidae). Reproduction by shelled eggs, incubated by female; no organized nipple, the milk flowing from mammary ducts onto the fur of the abdomen; cloaca present; adults toothless, rostrum covered with horny beak. Total length to 80 cm (31.5 in.). Examples: duck-billed platypus, and echidnas or spiny anteaters.

†*Infraclass Allotheria*

†*Order Multituberculata* (multituberculates). Fossil only; Upper Jurassic to lower Eocene of North America and Eurasia. The earliest herbivorous mammals; specializations of teeth and jaws superficially rodent-like; molars elongate, with two or three longitudinal rows of cusps; lower premolars tending to become serrated shearing blades. Size larger than typical Mesozoic mammals, to about that of a woodchuck.

Subclass Theria

†*Infraclass Trituberculata*

†*Order Symmetrodonta* (symmetrodonts). Fossil only; Upper Jurassic to Lower Cretaceous of Eurasia and North America. Molars with 3 prominent cusps arranged in symmetrical triangles; lower molars without posterior talonid basin ("heel").

†*Order Pantotheria* (pantotheres). Fossil only; Middle Jurassic to Lower Cretaceous of North America and Europe. Molars with 3 prominent anterior cusps (trigonid), asymmetrical; posterior basin (talonid) of lower molars developed, as in higher mammals.

Infraclass Metatheria

Order Marsupialia (marsupials). Upper Cretaceous to Recent of North and South America, Europe, Australia. Placenta formed from yolk sac (simple chorio-allantoic placenta in bandicoots), the young born in a relatively undeveloped state after brief gestation, developing further attached to mammae in marsupium (pouch) or along marsupial fold; female reproductive tract bifid, uterus and vagina double, penis bifurcate, posterior to scrotum. Angular process of mandible inflected; auditory bullae (when present) formed from alisphenoid bone and thus not homologous with bullae of eutherians. Epipubis ("marsupial bone") present; length of head and body varying from about 10 cm (4 in.; small opossums) to more than 160 cm (63 in.; kangaroos). Examples: opossums, kangaroos, wallabies, bandicoots, wombats, phalangers, koala.

Infraclass Eutheria (placental mammals)

Order Insectivora (insectivores). Upper Cretaceous to Recent, worldwide except Australia, polar regions, and many oceanic islands. A diverse group of mammals sharing certain primitive characteristics but highly specialized in several adaptive modes; dentition generally heterodont, rooted, variously modified; molars usually tuberculosectorial. Stance plantigrade to semiplantigrade; habit fossorial, terrestrial, arboreal, semiaquatic; insectivorous to omnivorous. Braincase low, rising but little above plane of rostrum; snout generally long, pointed, modified for olfaction and touch; zygomatic arch complete or incomplete. Length of head and body, 5 cm (2 in.; smallest shrews) to 45 cm (18 in.; largest hedgehogs). Shrews of the genera *Microsorex*, *Sorex*, and *Suncus* are the smallest of living mammals. Examples: shrews, moles, hedgehogs, tenrecs, solenodon.

Order Macroscelidea (elephant shrews). Lower Oligocene to Recent of Africa. Anteromost incisors widely spaced (incisor series forming a straight, anteroposterior row); posterior incisors caniniform; upper canine premolariform, bicuspid; posterior premolars molariform, last premolar largest tooth in dental series; molars quadrate, reduced in size or absent posteriorly; auditory bullae well developed. Stance plantigrade, hind feet elongate, modified for hopping gait; tail elongate. Length of head and body of living species, 12 to 20 cm (5–8 in.); tail 12 to 18 cm (5–7 in.; treated in section on *Insectivora*).

Order Dermoptera (colugos or "flying lemurs"). Upper Paleocene to lower Eocene of North America (Plagiomenidae). Recent of Southeast Asia (Cynocephalidae). In living species, upper incisors reduced, lower incisors procumbent, spatulate, pectinate (comb-like), molars low-crowned, used for shearing the vegetable diet. The most specialized and efficient of mammalian gliders; the patagium (gliding membrane) extends from the neck to phalanges of hand, to phalanges of foot, to tip of tail; total length of head and body, 34–45 cm (13–18 in.).

†*Order Tillodontia* (tillodonts). Fossil only; upper Paleocene to middle Eocene of Northern Hemisphere. Omnivorous or herbivorous; incisors rootless, enlarged, molars low-crowned; perhaps superficially bearlike in appearance; total length to approximately 120 cm (47 in.).

†*Order Taeniodonta* (taeniodonts). Fossil only; lower Paleocene to upper Eocene of North America, middle Eocene of Asia. Large, browsing herbivores; outer incisors rodent-like, inner incisors lost; canines well developed; cheek teeth simple, rootless pegs; length of skull to about 35 cm (14 in.).

Order Chiroptera (bats). Middle Eocene to Recent in tropical and temperate regions; volant, the wings consisting of a fold of skin (patagium) supported by elongated bones of the second through fifth digits; thumb clawed in suborder Microchiroptera, thumb and index finger clawed in Megachiroptera; hind limbs variously specialized but generally weak. Incisors generally reduced, canines prominent, cheek teeth rather primitive, with prominent ectoloph. Length of head and body from about 3 to 40 cm (1.2–16 in.); wing span to about 120 cm (47 in.).

Order Primates (primates). Late Cretaceous to Recent of Eurasia, Africa, North and South America. A diverse group of generalized, generally omnivorous mammals, modified for arboreality (some secondarily terrestrial). Dentition little specialized; a pair of incisors lost above and below, canines prominent, sexually dimorphic in some species; premolars usually bicuspid, sometimes caniniform; molars typically low-crowned, tuberculosectorial to bunodont. Limbs and girdles adapted for flexibility with little loss or fusion of elements; clavicle present; digits 1 (hallux and pollex) divergent, tending to become opposable; stance plantigrade. Olfaction de-emphasized in favour of vision, and snout reduced; eyes rotated forward allowing trend toward stereoscopic vision; in more advanced groups cerebrum expanded to cover cerebellum, braincase expanded. Length of head and body (including extended hind limbs), 15 cm (6 in.; pygmy marmosets, tarsiers) to more than 200 cm (79 in.; *Homo*). Examples: lemurs, lorises, Old World and New World monkeys, marmosets, great apes, man.

Order Edentata (edentates). Lower Eocene to Recent of North and South America. Anterior teeth lost and cheek teeth reduced to simple rootless pegs without enamel, or (in anteaters) lost altogether. Secondary articulations (xenarthrous processes) present between vertebrae in addition to zygapophyses (the usual articulating surfaces); cervical vertebrae 6 to 9, in some cases fused; acromion and coracoid processes of scapula enlarged, often joining to form bony ring; claws generally stout. Several groups walk on the sides of feet and structure may be modified accordingly. Brain small, skull low, zygomatic arch usually incomplete. Total length of fossil edentates to 300 cm (118 in.); living species to 185 cm (73 in.; giant anteaters). Examples: sloths, armadillos, anteaters.

Order Pholidota (pangolins). Oligocene to Recent of Eurasia and Africa; possible North America representatives (Paleanodontidae) upper Paleocene to lower Oligocene. Body covered with heavy, overlapping scales with hairs only at bases of scales; tail prehensile in some species. Myrmecophagous (anteating); skull elongate, braincase low; lower jaw reduced to thin shaft

of bone; feet 5-toed but only 3 toes of forefeet strongly clawed. Total length 75 to 170 cm (30–67 in.).

Order Tubulidentata (aardvark). Miocene to Recent of Africa, Pliocene of Eurasia; possible representatives in Eocene and Oligocene of Europe. Teeth reduced to 4 or 5 simple pegs in each jaw of adults, without enamel, the dentine intersected by numerous tubules (hence the ordinal name). Four toes on forefeet, 5 behind, each bearing a strong, stout, hooflike "nail." Skull elongate and tubular; tongue vermiform; mandible not so reduced as in other "anteaters." Legs powerful, skeleton generally primitive but tibia and fibula fused. One species; total length to 200 cm (79 in.).

Order Lagomorpha (lagomorphs). Upper Paleocene to Recent of Eurasia, North America, Africa, northern South America. Dentition superficially rodent-like, but with 2 pairs of upper incisors (a small pair situated behind the larger functional pair); canine and anterior premolars lost, forming prominent diastema (gap); cheek teeth high-crowned, rootless, 6 above and 5 below (more than in any rodent), and not occluding directly, so that mastication is a lateral movement; maxillary bone fenestrate (*i.e.,* with holes). Fibula articulating with calcaneum; infraorbital canal small. Scrotum anterior to penis. Total length, 15 cm (6 in.; pikas) to 70 cm (28 in.; hares). Examples: hares, rabbits, pikas.

Order Rodentia (rodents). Lower Eocene to Recent, worldwide except Antarctica and some oceanic islands. Single pair of rootless incisors above and below; canines and anterior premolars lost forming prominent diastema; never more than 2 premolars above and 1 below; cheek teeth frequently rootless, hypsodont; cusp patterns variable, cheek teeth ranging from pegs to massive teeth with highly complex occlusal patterns. Powerful jaw musculature developed in connection with grinding dentition; angular process of mandible well developed for muscle attachment. Postorbital bar absent; infraorbital foramen variously modified, in advanced groups passing portions of masseter muscle; postcranial skeleton relatively unspecialized. Forelimbs flexible, digits clawed, little reduction in number on forefeet, some specialization of hindfeet and reduction of digits associated with saltation; stance plantigrade or semiplantigrade. Total length of living species, 10 cm (4 in.; pygmy mice, some pocket mice) to 125 cm (49 in.; capybara). Examples: mice and rats, squirrels, porcupines, beaver.

†*Order Creodonta* (creodonts). Fossil only; Middle Cretaceous to upper Oligocene of North America, Eurasia, Africa. Primitive carnivorous mammals; canines well developed; cheek teeth specialized for shearing, but carnassial pair farther back in tooth row than in Carnivora. Auditory bullae unossified. Distal phalanges channelled for insertion of claws; no fusion of scaphoid, lunar, and centrale bones of wrist. More than 50 genera, in about 5 families. Size to that of bear or larger.

Order Carnivora (carnivores). Middle Paleocene to Recent on all continents (probably accompanied early man to Australia). Teeth variously modified, sectorial to bunodont, but the carnassial (shearing) pair of teeth always consisting of the last upper premolar over the first lower molar; dentition simplified in advanced pinnipeds (seals), nearly homodont, with no carnassials. Auditory bullae ossified in advanced forms. Terminal phalanges not channelled for insertion of claws; scaphoid, lunar, centrale bones of wrist fused. Carnivorous, omnivorous, herbivorous. Total head and body length 15 to 370 cm (6–146 in.). Examples: cats, dogs, bears, weasels, civets, hyenas, raccoons, seals, sea lions, walruses.

†*Order Archaeoceti* (archaeocetes, zeuglodonts). Fossil only; lower Eocene to middle Miocene of North Africa, Europe, North America. Primitive whale-like marine mammals, dentition not highly modified; anterior teeth simple, peglike; cheek teeth sectorial as in early carnivores; teeth not exceeding basic placental number (44); nostrils placed well back on elongate snout; skull not "telescoped" as in modern whales; hind limbs vestigial by upper Eocene; body elongate, some serpentine; total length to more than 2,000 cm (65 ft).

Order Odontoceti (toothed whales). Upper Eocene to Recent in all oceans and occasionally in freshwater. Dentition generally simple, undifferentiated (homodont), exceeding the primitive placental number (to 300 teeth in some porpoises) or secondarily reduced (to a single tooth in *Monodon,* the narwhal); nostrils located on top of head, above and between eyes, forming single "blowhole"; skull asymmetrical, markedly "telescoped," with reduction of frontals and parietals and concomitant extensive posterior expansion of maxillaries and premaxillaries. Relative to Archaeoceti, body shorter, stouter, total length 150 cm (59 in.; small porpoises) to about 1,900 cm (62 ft; male sperm whales). Examples: dolphins, porpoises, narwhal, sperm whales.

Order Mysticeti (baleen or "whalebone" whales). Upper Eocene to Recent in all oceans. Teeth absent; "whalebone" (baleen) present, consisting of ridged "curtains" of keratin extending from roof of mouth, used to strain krill (zooplankton); mouth cavernous, esophagus constricted to maximum diameter of about 20 cm; mandibular symphysis lacking; skull symmetrical, markedly "telescoped," with anterior expansion of occipitals; nostrils moved posteriorly, "blowhole" double, anterior to orbits (eyes). Total length from 600 cm (236 in.; pygmy right whale) to more than 3,000 cm (98 ft; blue or sulfur-bottom whale); the blue whale, weighing to 136,000 kilograms (150 tons), is the largest of all known vertebrates, living or extinct. Examples: rorquals (including blue whale), gray whales, bowheads, right whales.

†*Order Condylarthra* (condylarths). Fossil only; Upper Cretaceous to lower Oligocene of Eurasia, North and South America. Probably the basal stock from which most later ungulate groups evolved; directly descended from primitive placentals, and characteristics diverse. Tendency toward rounded molar cusps of equal height (bunodonty), formation of diastema, reduction of canine teeth, assumption of digitigrade stance and "experimentation" with hooves (ungules). About 90 genera and 7 families: some species at least as large as modern bears.

†*Order Pyrotheria* (pyrotheres). Fossil only; Eocene and Oligocene of South America. Incisors enlarged, tusklike; diastema prominent; cheek teeth low-crowned and with transverse crests; nostrils on top of heavy skull, suggesting development of fleshy proboscis. About 4 genera known; as in many other ungulate groups, trend to large size (to that of elephants); length of skull to 60 cm (24 in.).

†*Order Xenungulata* (xenungulates). Known only from a few fragmentary fossils from upper Paleocene of South America. Generally poorly known, but molars with tendency toward converging transverse crests as in Dinocerata of Northern Hemisphere; postcranial remains scanty but build obviously massive. Size to that of a modern rhinoceros.

†*Order Pantodonta* (pantodonts). Fossil only; Paleocene to Oligocene of North America and Asia. A varied group of herbivores, prominent in the Paleocene. Cheek teeth low-crowned, with transverse crests variously arranged, canines small or greatly developed. About a dozen genera; total length approximately 100 to 450 cm (39–177 in.).

†*Order Dinocerata* (uintatheres). Fossil only; Paleocene and Eocene of North America and Eocene of Asia. Skull low, later representatives with bony projections on nasal, maxillary, and frontal bones. Upper incisors absent, lower incisors reduced, saber-like upper canines (evidently only in males); upper molars unique, with 2 transverse crests forming a "V." Limbs graviportal (massive); about 8 genera; size to that of large rhinoceros.

Order Proboscidea (elephants and allies). Upper Eocene to Recent in Eurasia, Africa, North and South America. Earliest known representatives characterized by low-crown molars with two transverse lophs, diastema resulting from loss of outer lower incisor, canine and first premolar, and formation of upper and lower tusks by modification of incisors. Nasal opening toward top of skull, indicating that a fleshy proboscis ("trunk") was present, but perhaps of modest size; early proboscideans relatively long-bodied and short-limbed, superficially tapir-like. Middle and later Cenozoic times saw wide radiation from basal stock; about 2 dozen fossil genera known. Two living genera (*Elephas,* the Indian elephant; *Loxodonta,* the African elephant) with high and truncate skull; massive tusks; short mandible; peculiar cheek tooth arrangement in which a single, high-crowned, lophodont tooth is exposed in each half of the jaw at any one time, and replacement occurs continually from behind; long proboscis; graviportal limbs and girdles; length of head and body to 640 cm (252 in.).

Order Sirenia ("sea cows," dugongs, and manatees). Middle Eocene to Recent of Africa, Asia, North and South America. In living species: hind limbs lacking, pelvis vestigial; front limbs modified into flippers; tail flattened, expanded; body fusiform, neck indistinct, anterior teeth reduced, replaced by horny plates used in cropping estuarine vegetation; molars of living dugongs bunodont, premolars lost; cheek teeth of manatees bilophodont, increased to 20 or more in each jaw, with 6 in each jaw at a given time and worn teeth replaced from behind as in modern proboscideans. Total length to 450 cm (177 in.).

†*Order Desmostylia* (desmostylians). Known only as fossils from lower Miocene to lower Pliocene in shallow marine deposits of North Pacific Ocean. Skull massive, low, elongate; anterior teeth modified as tusks, 1 pair (canines) above, 2 pairs (canines and incisors) below; cheek teeth peculiar, cusps forming cylinders of enamel and replaced in a continual forward movement as in elephants and manatees; limbs and girdles massive; appearance perhaps superficially hippopotamus-like; total length to about 250 cm (98 in.).

†*Order Embrithopoda* (embrithopods). Known only from fos-

sils from lower Oligocene of North Africa. Limbs 5-toed, progression graviportal; superficially rhinoceros-like, large paired horns on nasal bones and smaller horns on frontals (*i.e.*, behind the larger pair). Incisors not enlarged as in other subungulates; cheek teeth high-crowned; total length to about 330 cm (130 in.).

Order Hyracoidea (hyracoids). Lower Miocene to Recent of Africa and southwestern Asia. Most generalized of subungulates, although postorbital bar present and permanent dentition reduced; last upper incisors and canine lost, forming diastema; remaining incisors rootless; molars high-crowned. Superficially rabbit- or rodent-like; herbivorous, living on rock slopes or semiarboreal. Total length of fossil species to about 200 cm (79 in.); living members 30 to 65 cm (12–26 in.). Living examples: hyrax species.

†*Order Notoungulata* (notoungulates). Known only as fossils; upper Paleocene to Pleistocene of South America and Paleocene and Eocene of North America and Asia. Varied assemblage, united by dental peculiarities; accessory cusps in central valley of upper molars; lower molars with crescentric ridges, the entoconid lying within the arc of the larger posterior crescent; usually no diastema or reduction in dentition; cheek teeth tending to become rootless, high-crowned, lophodont. Tendency for reduction of toes from 5 to 3; total length approximately 30 to 300 cm (12–118 in.).

†*Order Astrapotheria* (astrapotheres). Known only as fossils; upper Paleocene to upper Miocene of South America. Upper incisors lost, canine enlarged, rootless; lower incisors and canine enlarged; diastema prominent; premolars reduced; molars greatly enlarged. Forelimbs stout, feet digitigrade, hind-limbs relatively weakly developed, semiplantigrade. Skull truncate; position and character of nasal opening suggests presence of fleshy proboscis; absence of upper incisors suggests that heavy lower incisors may have opposed a modified upper lip to allow cropping of vegetation. Total length to about 280 cm (110 in.).

†*Order Litopterna* (litopterns). Known only as fossils; upper Paleocene to Pleistocene of South America. Hoofed herbivores with tendency toward reduced toes; from 5 to 3 or even 1. Dentition usually complete (or with some loss of incisors); no diastema; cheek teeth low-crowned, selenodont; tendency for molarization of premolars. Size to that of small horse.

Order Perissodactyla (perissodactyls). Lower Eocene to Recent; North America, Eurasia, Africa. Incisors variously modified, canines lost or specialized, diastema nearly always present, with loss of first premolars above and then below; molars primitively bunodont, becoming progressively more lophodont, hypsodont; molarization of premolars common at later stages. Hornlike projections on skull not uncommon. Trends toward lengthening of limbs, with limitation of motion to forward and backward. Feet mesaxonic (*i.e.*, with axis through toe III), reduction typically to 3 digits and later to a single digit; digits mostly hooved, but those of chalicotheres clawed. Range in body size from that of small dog (Eocene horses) to that of largest of known land mammals, *Baluchitherium*, an Oligocene rhinocerotid of Asia, nearly 600 cm (236 in.) in height at the shoulder. Examples: titanotheres, chalicotheres, tapirs, rhinoceroses, horses.

Order Artiodactyla (artiodactyls). Lower Eocene to Recent; worldwide except Australia. Dentition complete, bonodont (as in pigs) or variously reduced; incisors often reduced and upper incisors lost, vegetation cropped with lower incisors opposing gums of premaxilla; canine and first premolars frequently lost, forming prominent diastema; remaining premolars simple, not completely molariform; cheek teeth primitively low-crowned, bunodont, becoming hypsodont, selenodont (cusps expanding into crescents) in more advanced forms. Unguligrade, foot paraxonic (*i.e.*, the axis between digits III and IV); digit I lost first; digits II and V frequently rudimentary (dew claws), but more prominent in pigs and hippopotamuses; in advanced types metapodials III and IV fused to form cannon bone, adding extra functional joint to limb; astragalus distinctive, the articular surface a double pulley allowing efficient flexion and extension of hindlimb but precluding lateral movement. Parietal bones of skull reduced, frontal bones expanded, frequently bearing antlers or horns. Height at shoulder, 25 cm (10 in.) in small antelope to 370 cm (146 in.) giraffe. Examples: pigs, cattle, sheep, goats, antelope, pronghorn, giraffe.

Critical appraisal. Three subclasses of Mammalia generally have been recognized for many years: Prototheria, the monotremes; Allotheria, the extinct multituberculates; and Theria, including marsupials and placentals as well as the extinct symmetrodonts and pantotheres. However, a number of Mesozoic groups could not be placed satisfactorily in any of these subclasses as defined. Evidence on the formation of the braincase in nontherian mammals has suggested that the primitive taxa may in fact constitute a more coherent group than was once supposed. All nontherian mammals are thus placed in a single subclass, Prototheria; infra-ordinal status is proposed for monotremes, triconodonts and symmetrodonts, and multituberculates.

Monotremes and multituberculates. Monotremes and multituberculates represent highly modified offshoots of the earliest mammalian stock. The fossil record of undoubted monotremes is limited to the Pleistocene. Surely the group is an ancient one and, although living representatives are highly specialized, represents the grade of evolution of the reptilian-mammalian transition. Their primitive organization is underscored in the relatively unspecialized brain, retention of the oviparous habit and a cloaca, incomplete homeothermy, and reptile-like frontal and pterygoid bones.

The multituberculates also were derived from the earliest mammalian stock. They were adapted early to a herbivorous diet and developed gnawing incisors and elongate, grinding cheek teeth. The fossil record of the multituberculates, from Upper Jurassic to lower Eocene, is longer than that for any other mammalian order. The extinction of multituberculates in the Early Cenozoic may have been due to competition from placental herbivores, in particular the early rodents.

Marsupials. The split between marsupials and placentals has yet to be identified with any certainty. *Pappotherium* of the Lower Cretaceous of Texas was thought for a time to represent a common ancestor of the therian infra-classes, but more recently it has been discovered that recognizable didelphoid marsupials were contemporaneous with the pappotheriids.

The earliest records of marsupials are from North America but the great adaptive radiation of this group occurred in South America and Australia. Mostly free of competition from placentals on Cenozoic island continents, marsupials converged in many cases with the specializations of placentals elsewhere. Australia has been isolated from other major land masses throughout the Cenozoic and South America was an island from Paleocene to Pliocene. Invasions by placentals in later Cenozoic times reduced the once flourishing South America marsupial fauna to the remnant extant today. The South American and Australian radiations were independent, although both assemblages had a common source in generalized didelphoid (opossum-like) groups and evolved in parallel fashion in a number of instances. In general, higher categories in the classification of marsupials are not coordinate with those of the Eutheria. Some families of marsupials, for example, encompass a range of diversity comparable to that in eutherian orders.

Insectivores and colugos. Modern insectivores are divisible into several subgroups. The lipotyphlans include modern shrews, moles, and hedgehogs. The molars of hedgehogs are quadritubercular; those of shrews and moles are complicated by the development of a W-shaped external ridge or ectoloph. Lipotyphlans maintain the primitive insectivorous habits of their Mesozoic forebears. Zalambdodonts are represented by the peculiar selenodonts of the Greater Antilles, the tenrecs of Madagascar and West Africa, and the chrysochlorids—Cape golden moles—of southern Africa. The zalambdodonts may or may not represent a natural group. Their early history is obscure. All have V-shaped upper molars.

Tree shrews (tupaiids) of Southeast Asia are the sole survivors of a third insectivore group, sometimes called proteutherians, which includes a great variety of Late Cretaceous and Early Cenozoic mammals of uncertain relationships. Living tupaiids have frequently been classed as Primates, for they have remarkably advanced brains and versatile limbs. In such features as dentition, however, they remain quite primitive.

The macroscelids, or elephant shrews, are here treated as a separate order. They have frequently been grouped with tupaiids as a suborder of the Insectivora, or as a distinct Order Menotyphla. Colugos, the so-called flying lemurs, here maintained as a distinct order, Dermoptera, likewise have been considered by some authorities as insectivores.

Figure 5: Reconstruction of *Melanodon*, a shrew-sized insectivorous pantothere from the Late Jurassic of North America.
Drawing by R Keane

Tillodonts and taeniodonts. The relationships of tillodonts and taeniodonts are obscure. Although apparently quite independent, both groups were evidently derived from primitive placental stocks, and both evolved rootless, rodent-like incisors. Neither group was ancestral to later, more successful mammalian types.

Bats. Bats are an ancient group; except for extensive skeletal and sensory modifications associated with flight they share many primitive characteristics with their insectivore ancestors. Bats first appear in the fossil record in the Eocene as highly adapted fliers. Were well-preserved postcranial (body and limb) remains of the earliest Cenozoic insectivores better known, some might well be found to represent intermediate stages in the evolution of flight; to date no such intermediate stages have been found. Many have thought that the Dermoptera might represent a grade through which the lineage of the bats must have passed in evolving truly volant habits; surely dermopterans and bats are not closely related, save in their retention of primitive characters of early placentals. In recent years research has brought to light important differences between the two suborders of bats, the Megachiroptera and the Microchiroptera, and some workers have suggested that the two groups be treated as separate orders, maintaining that the similarities between them are due to parallelism and convergence in adapting to the stringent demands of flight.

Primates. The Primates form a relatively coherent group, although the distinction between them and their insectivore ancestors is a difficult one and some groups, such as the tree shrews, can be placed in either order with nearly equal justification. Disagreement on classification within the order centres on the validity of the suborder Prosimii as a natural unit that includes such divergent kinds as tarsiers, lemurs, lorises, and galagos, and on the relationship between the Old World and New World monkeys. The two monkey groups may have evolved independently from prosimian ancestors; considerable convergence and parallelism no doubt are involved in the similarities between the two as both have radiated widely in response to available arboreal habitats.

Edentates and pangolins. The edentates have undergone their greatest radiation in South America. They are a highly aberrant group, of unknown ancestry, and apparently were isolated early in South America, as were the archaic South American ungulates. Edentates have commonly been subdivided into Loricata (armadillos and extinct glyptodonts), Pilosa (tree sloths and extinct ground sloths) and Vermilingua (anteaters). Each of these subgroups has had a long and independent history, but they share the unique character of xenarthrous vertebrae. The palaeanodonts of the Eocene and Oligocene of North America have been considered as nonxenarthrous edentates (a view presented in the section on *Edentata*); they are here allocated tentatively to the order Pholidota. Little is known of the relationships of pholidotes (pangolins), once considered relatives of the Edentata; the groups are now generally conceded to be convergent.

Aardvarks. Aardvarks (Tubulidentata) also were thought at one time to be related to true edentates, but are now considered an independent lineage. Although they are known from Miocene deposits, no direct evidence exists of relationships with other groups. In some respects the skeleton resembles that of certain early condylarths, and it seems probable that tubulidentates descended from an early ungulate stock.

Lagomorphs. The Lagomorpha long were included (as a suborder Duplicidentata) in the Rodentia on the basis of dental similarities. Although ordinal rank for the Lagomorpha has been firmly established, some recent classifications still include rodents and lagomorphs together in a cohort Glires, again based on dental similarities, which almost certainly represent convergence. Various other mammalian lineages of diverse affinities (multituberculates, taeniodonts, tillodonts, and certain primates, for example) have "experimented" with gnawing incisors. The earliest known fossil lagomorphs clearly represent the group and yield no clues as to origin. On the basis of serology and some dental characters, a relationship to ungulates through the condylarths has been suggested. More than likely, however, those characters held in common are primitive and lagomorphs arose directly from a primitive insectivore stock.

Rodents. In terms of numbers of individuals and numbers and diversity of species, the rodents are the most successful of living mammals and have evidently been so throughout much of the middle and later Cenozoic. The earliest known rodents (paramyids), of Paleocene age, were already highly specialized mammals. Fossil evidence indicating relationships with more primitive groups is lacking; rodents may have been derived directly from a basal eutherian stock.

The higher classification of rodents has been in a state of flux in recent years. Three suborders (Sciuromorpha, Myomorpha, and Hystricomorpha) were recognized, based on the relationship of the zygomasseteric musculature to the infraorbital foramen. The sciuromorphs, or Protrogomorpha, included the earliest known rodents and also modern squirrels, beavers, and sewellels or "mountain beavers." In these taxa the masseter muscle originates from the anterior portion of the zygomatic arch or from the side of the skull in front of the orbit. The infraorbital canal is small, carrying nerves and blood vessels as in primitive mammals. In the Myomorpha, the rats and mice and their allies, the deep portion of the masseter muscle passes through the enlarged infraorbital canal. The so-called hystricomorphs, including Old World porcupines and a great variety of South American rodents, have a greatly enlarged and round infraorbital foramen, rather than a slitlike one like that of myomorphs.

Recent authors have doubted the validity of this arrangement and the utility of the infraorbital canal and zygomasseteric structure as a diagnostic feature. Many would admit the general validity of the Sciuromorpha and Myomorpha although some groups traditionally included would be reallocated. The "Hystricomorpha," on the other hand, is almost unanimously considered to be polyphyletic, and is now commonly subdivided into Caviomorpha for the complex South American "hystricomorph" radiation, and Hystricomorpha for Old World porcupines and their allies. The tendency has generally been to de-emphasize the use of subordinal classification and instead to bring together related families into a number of superfamilies. Perfection of the higher classification of rodents is difficult because fossil evidence is meager for some groups, particularly those of small or modest size, and because the successful radiation of the Rodentia has obviously led to perplexing convergence in numerous lines.

Creodonts. Creodonts were derived from the basic insectivore radiation as early carnivorous mammals, largely in response to the ecological opportunity presented by the evolution of herbivorous types.

Carnivores. True carnivores evidently are not descendants of the creodonts, but direct derivatives of Paleocene insectivores. The diversification of fissiped (terrestrial) carnivores from the basal stock (family Miacidae) occurred in the upper Eocene and lower Miocene, early dividing into arctoid or canoid (canids, ursids, procyonids, mustelids) and aeluroid or feloid (felids, hyaenids, viverrids) lines. The Pinnipedia (seals, sea lions, walruses) are here considered a suborder of the Carnivora. Appearing in the fossil record in the Miocene, the modern pinniped families already were distinct. The previous history of the group

is obscure, but pinnipeds apparently were derived from arctoid fissipeds, although some have thought them to have been derived from creodonts. Some authorities have treated pinnipeds as a distinct order, in which case they represent the most recently evolved mammalian order.

Whales. The whales and their allies have traditionally been treated as a single order, Cetacea, a reasonable arrangement on the basis of certain criteria. It is obvious, however, that cetaceans diverged early into archaeocetes, odontocetes, and mysticetes, if, indeed, the groups had a common ancestry. The earliest known fossils are perfectly good whales and clearly are assignable to one of the three groups; thus there is no concrete evidence linking the three nor is there evidence as to their ancestry. The morphological characters that whales share can be interpreted as due to parallelism resulting from stringent selection in similar habitats, or to the retention of primitive placental characteristics. Until evidence is available to establish the monophyly of cetaceans it seems preferable to treat them as representing three separate orders.

Ungulates. The term "ungulate" denotes a broad, loose association of orders including most large herbivorous mammals. The name of the group implies that its members are hoofed, but some of the ungulates (chalicotheres, for example) had clawed digits and others (such as sirenians) show considerable reduction of digits and limbs. The ungulates may be of common ancestry or may be a product of convergence from several sources among primitive placental stocks. Certain supposed early ungulates (condylarths) and early carnivorous mammals (creodonts) have many characters in common; their supposed descendants frequently have been united in a common cohort, Ferungulata.

The principal characteristics shared by ungulates are those of the dentition and limbs, related to modification of the primitive placental into an efficient herbivore.

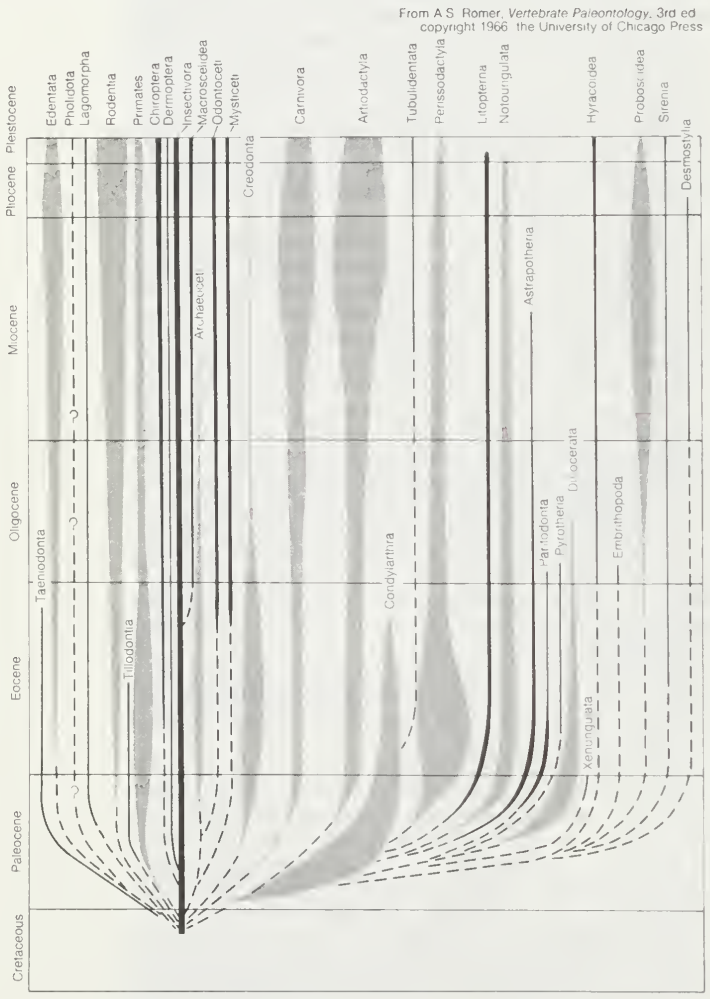

Figure 6: Dendrogram of the placental mammals.

There has been a tendency toward elongation of individual molar cusps to form crescentric ridges (selenodonty) or to form ridges between adjacent cusps (lophodonty). A concomitant trend has been an increase in the height of molars from low-crowned (brachyodont) to high-crowned (hypsodont), which has allowed the efficient utilization of abrasive forage such as grass. The extent of the grinding surface has been increased by increasing the length of the molars or by "molarization" of premolars.

The radiation of large herbivores was accompanied closely by a radiation of large carnivores. The adaptive response of ungulates to predation has been varied: modified dentition (tusks), skeletal elements (horns, antlers), and behaviour have been turned to defensive purposes. Extremely large size or swift, cursorial locomotion were at a premium. Defensive gregariousness is common in extant species.

The general trend in mammalian locomotion has been plantigrade to digitigrade to unguligrade, frequently with reduction of digits. One mode of digit reduction has been mesaxonic, the axis of the foot passing through digit III (as in horses); other groups have paraxonic limbs, with the axis lying between digits III and IV. Elongation of metapodials has occurred commonly, forming a third functional segment of the limb, allowing fast cursorial gaits.

Exceptions to these trends in limb modifications occur in lineages with early trends toward extremely large size. In such groups, columnar, graviportal limbs have developed with proximal segments (femur, humerus) emphasized and metapodials de-emphasized; all digits usually are retained.

The ungulate radiation has been complex. Various subdivisions have been proposed. The condylarths may or may not be basal to the entire radiation, but they evidently gave rise to the perissodactyls.

Perissodactyls. This is a compact order, consisting of five subdivisions: horses, chalicotheres, titanotheres, rhinoceroses, and tapiroids. The history of the perissodactyls is perhaps better known than that of any other mammalian group. *Hyracotherium* ("*Eohippus*"), usually considered the base of the horse lineage, was probably near the source of the entire order.

Artiodactyls. The Artiodactyla first appear in the early Eocene. Dental characters point to an origin for the group among hypsodontid condylarths but the earliest known artiodactyls already had the unique and specialized "double-pulley" astragalus. Knowledge of transitional stages between condylarthran and artiodactyl tarsi would be of considerable interest and importance.

Archaic ungulates. A number of kinds of archaic ungulates, which generally evolved in the Western Hemisphere, have been lumped in the past in a single order, Amblypoda. Each of these groups—pantodonts, uintatheres (Dinocerata), pyrotheres, xenungulates—is here accorded ordinal rank. The relationships of these groups—if any—are obscure and their origin is unknown.

Litopterns. The Litopterna of South America were early derivatives of the condylarths, and some workers would include both in a single order. One family (Prototheriidae) closely paralleled the contemporaneous radiation of perissodactyls on the northern continents, but the macrauchenids converged toward the camels.

Notoungulates. The order Notoungulata was an early and varied assemblage, apparently restricted to South America in the Eocene, perhaps by competition with early members of more advanced ungulate groups. The greatest development of the order was in the Oligocene, after which there was a gradual decline, hastened by the entry into South America of placental carnivores and modern artiodactyls. The origin and affinities of the notoungulates are unknown, but the order may well have descended from the condylarths.

Astrapotheres. Astrapotheres were once considered to have been notoungulates. It is now generally conceded that their peculiarities recommend recognition as a separate order. This group may have had its origin among primitive notoungulates, or it may have arisen independently.

Hyracoids. The products of the early Cenozoic radiation of ungulates in Africa are commonly grouped as "subungulates." The Hyracoidea is the most generalized

of these orders but the true relationships of the hyracoids to other ungulates are unknown. In common with other subungulate orders, hyracoids were more diverse in the Middle Cenozoic than they are today.

Embrithopods. The extinct Order Embrithopoda contains a single known genus, *Arsinoitherium.* Relationship with hyracoids has been suggested but concrete evidence is lacking. Aside from logical association with other subungulate groups, little can be said of the position or affinities of the Embrithopoda.

Elephants and allies. The best known of the subungulates are the Proboscidea. The later record of the order is relatively good and indicates a remarkably successful and widespread radiation in the latter part of the Cenozoic—a radiation characterized by the recurrence of several trends in separate lines. Among these trends were an emphasis on the development of the upper tusk with loss of the lower tusk in most groups, increase in the size of the skull and shortening of the neck, increase in the length of the proboscis, increase in overall size, with perfection of graviportal limbs and girdles, lengthening of the lower jaw (secondarily shortened in some groups), and reduction and specialization of cheek teeth.

Sirenians. The origin of the Sirenia is obscure. The earliest known sirenians were completely aquatic although the pelvic girdle was not so much reduced as in later forms. Dental and cranial peculiarities suggest that proboscideans and sirenians may have arisen from a common swamp-dwelling or amphibious ancestor. Concrete evidence is generally lacking regarding this and other relationships among subungulates due to a paucity of fossiliferous continental sediments of early Cenozoic age in Africa.

Desmostylians. Because of dental peculiarities and their association with shallow-water marine sediments, fossil remains of the order Desmostylia were long thought to represent aberrant sirenians; recent discoveries of massive limb bones of these mammals indicate, however, that they had quite different adaptations. The nature of the cheek teeth and their mode of replacement suggests relationships with the largely African subungulates, although desmostylians are known only from fossil deposits along the shores of the North Pacific. (J.K.J./D.M.A.)

MAJOR MAMMAL ORDERS

The following sections consist of a review of living mammals, beginning with the most primitive—monotremes and marsupials—and continuing with the major orders of placental mammals. Groups are identified at the order level of biological classification and arranged in accordance with the *Annotated classification* above.

Extinct groups and species (designated in the annotated classification by a dagger [†]) are treated throughout this article under the subheadings *Evolution and paleontology;* for additional information about extinct mammals, see GEOCHRONOLOGY: *Fossil record,* which also treats the subject of mammalian evolution. (Ed.)

Monotremata (platypus, echidnas [spiny anteaters])

The Monotremata (monotremes) are a distinctive order of primitive mammals, the only surviving members of the subclass Prototheria.

Monotremes lay eggs and are reptilelike in many other ways but possess such essentially mammalian characters as mammary glands, hair, a large brain, and a complete diaphragm.

GENERAL FEATURES

Only two monotreme types, the platypus (*Ornithorhynchus anatinus,* family Ornithorhynchidae) and the echidnas, or spiny anteaters (*Tachyglossus aculeatus* and *Zaglossus bruijni,* family Tachyglossidae), are known. The earliest monotreme fossils known come from the Australian Pleistocene (2,000,000 or more years ago), and they are essentially the same as the living forms, which range in body length from about 30 to 80 centimetres (12 to 32 inches) and weigh from about one to 10 kilograms (two to 22 pounds).

The platypus, found in eastern Australia from north Queensland to Tasmania, is one of the most remarkable of all mammals. It has a ducklike "bill," webbed feet, and a flattened beaver-like tail. When the first stuffed specimens reached England around the end of the 18th century, they were thought to be fakes, made by sticking together bits of different animals.

The echidnas also rank high among the world's most interesting mammals and are readily kept in captivity for physiological studies. Superficially, they are quite unlike the platypus. They are recognized by their sharp-pointed spines and tubelike noses. *Tachyglossus* is found throughout Australia, including Tasmania, and part of New Guinea. *Zaglossus* has an extensive distribution in New Guinea.

Neither the platypus nor the echidnas are readily seen by the casual visitor, but they may be fairly common in some areas. Platypuses are not kept in zoos outside Australia.

The monotremes do not appear to be carriers of diseases harmful to man. Both monotreme types are now wholly protected by law in Australia.

NATURAL HISTORY

Ecology. The platypus is amphibious, with a habitat ranging from alpine waters at an altitude of 1,500 metres (about 4,900 feet) in southeastern Australia to the sluggish subtropical Queensland coastal streams. It digs winding burrows with side branches in the banks of the streams and lakes that it inhabits. These burrows are usually five to 10 metres (15 to 30 feet) long but may be as long as 30 metres (100 feet). The entrance is normally above the water level, however during floods it may be submerged.

Enemies of the platypus

The platypus has few natural enemies. It was formerly hunted extensively for its valuable velvet-like fur but for many years has been completely protected by law, and as a result it has increased in numbers. It appears to be relatively free of competition from other species in the water, where it feeds mainly on insect larvae, small crayfish, tadpoles, and other aquatic animals. Some authorities have suggested that the introduced rabbit (*Oryctolagus cuniculus*), which burrows in the banks of streams where the platypus once dwelt in quiet seclusion, is responsible

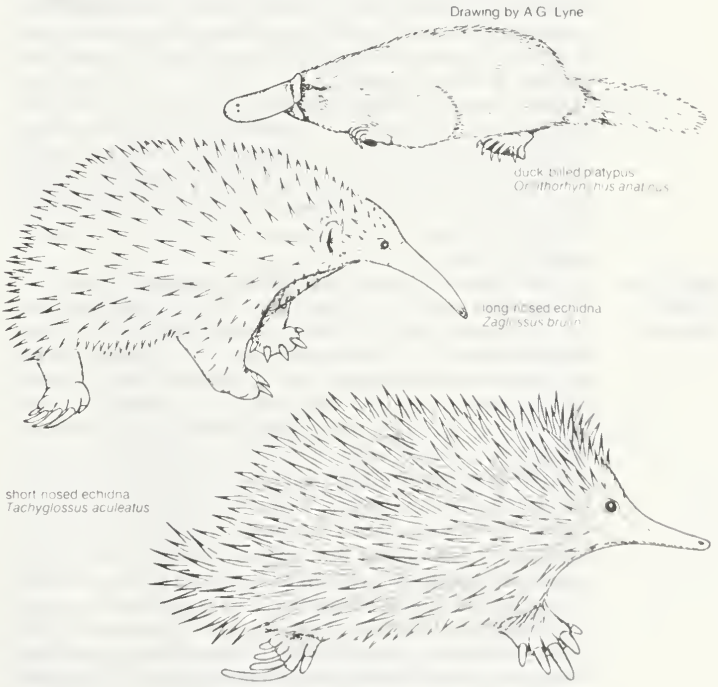

Figure 7: The three extant monotreme species.

for the disappearance of the platypus from many settled regions.

The echidnas are terrestrial animals, living in forests, scrubland, and deserts. Although usually encountered only by accident, *Tachyglossus* is one of the most widely distributed mammals in Australia. In New Guinea the habitats of *Zaglossus* include the humid forests that are almost continually blanketed by cloud cover. The animal has a known altitudinal range in these forests from about 1,100 to about 2,900 metres (3,600 to 9,500 feet).

Tachyglossus lives largely on ants and termites. The one element common in all the habitats occupied by this echidna is the presence of ants; termites are present in only some of the localities occupied.

Unfortunately, little is known of many aspects of the ecology of the monotremes, such as population density and social behaviour.

Life cycle and reproduction. The platypus breeds once annually, from July to August in the northern part of its range and to October in the southern part. Mating is believed to occur in the water, and it has been suggested that the spurs on the hind legs of the male may be used to hold the female. No spur grip was noted in an observation of copulation recorded by Australian zoologist D.H. Fleay in the course of an extensive study. An unusual courtship precedes mating, in which, among other manoeuvres, the male grabs the female's tail and the pair swim in circles.

In the breeding season, the female platypus digs a special burrow that twists and turns and may be very long. She then builds a nest of grass, leaves, and other plant material in a chamber at the end of the breeding burrow. This special burrow is blocked with earth in one or more places by the female during the period when she is laying and incubating the eggs. Only the left ovary is functional, and the eggs are always found in the left uterus. One to three, usually two, leathery-shelled eggs are laid. When there are two or three eggs they adhere together, but the sticky fluid that covers the eggs when they are laid soon dries and loses its stickiness. The eggs vary from 16 to 18 millimetres (about 0.60 to 0.70 inches) in length and from 14 to 15 millimetres in breadth.

The platypus has been bred in captivity on one occasion only, by Fleay in 1943. His observations suggest that the period from mating to egg laying is probably 12 to 14 days and the incubation period an additional 10 to 12 days. The young are not more than about 18 millimetres long at hatching and do not leave the breeding burrow until they are about 17 weeks old. At this age they are fully haired and about 34 centimetres (13 inches) long. Because the female platypus has no teats, the milk is apparently sucked from the skin as it exudes from the ducts of the mammary glands. The life-span of the platypus is said to be 10 to 15 or more years; at least one captive animal has lived more than 10 years.

More research has been done on the echidna *Tachyglossus* than on the platypus, mainly because it is less difficult to maintain in captivity. In southeastern Australia, echidnas breed once a year from late June to late September. The period between copulation and egg laying is at least 16 days and may be as long as 28 days. Both ovaries are functional.

Egg laying in the echidna

In the breeding season the female echidna develops an abdominal pouch. Egg laying has not been observed, but there is circumstantial evidence that the egg is laid directly into the pouch by the female's curving her body during this process. One egg (rarely two or three) is laid at a time; it is creamy yellow and the shell has a rubbery texture. The eggs of echidnas are slightly smaller than those of the platypus, being from 14 to 17 millimetres (0.55–0.67 inch) long and from 13 to 15 millimetres wide. Within the pouch the egg is not stuck to the hairs but is quite loose and from time to time is located in different positions, apparently retained by the apposition of the lips of the pouch. The incubation period of the egg in the pouch is 10 to 10.5 days, and the newly hatched echidna is about 15 millimetres (0.6 inch) long and weighs about 0.38 gram (about 0.01 ounce). After hatching, the young lives in the pouch and imbibes milk by sucking two special areas of the skin—the mammary areolae—where the ducts from the mammary glands open to the exterior on either side of the midline of the pouch. As in the platypus, no teats are present.

(Left) Echidna (*Tachyglossus aculeatus*) held head downward to show egg in pouch. (Right) Echidna hatching.
M.E. Griffiths

Authorities disagree on whether the young echidna takes milk by sucking or by licking. After detailed observations, an Australian zoologist, Mervyn Griffiths, stated that advanced pouch young take milk by sucking and not by licking it off the hairs in the mammary region, but he considered it possible that newly hatched and early stages of pouch young get their milk by licking it up as it is ejected onto the surface of the skin.

Information on how long the young stay in the pouch and what happens to them when they are cast out is meagre. One of the echidnas studied by Griffiths increased in body weight from 240 grams (about 0.5 pound) to 850 grams (about 1.9 pounds) in 43 days, a mean daily increase in weight of about 14 grams per day. The young was cast out of the pouch when it reached a body weight of 400 grams (about 0.9 pound). Thereafter, the mother's pouch regressed quickly, but she continued to suckle the young for some time. At the time when the young was dropped from the pouch, its eyes were open and the sharp spines projected from the skin. In wild echidnas it has been reported that the mother deposits the young in a burrow when its spines emerge and it is too large to be carried in the pouch.

Tachyglossus has been bred in captivity on only three occasions, once in Berlin and twice in Basel in Switzerland. In captivity *Tachyglossus* has lived up to 50 years, and *Zaglossus* up to about 30 years.

Behaviour and locomotion. Both the platypus and echidnas exhibit extreme specializations for feeding and locomotion.

The platypus emerges from its burrow for feeding usually in the early morning or late afternoon, but is sometimes in the water at other times of the day. When it is burrowing or walking on land the web of the front feet, which extends beyond the claws, is folded under the palms. The muzzle and the claws of the front feet are used in burrowing. The platypus swims gracefully and expertly, using the front feet. The hind feet, in conjunction with the flattened tail, are used mainly for stablization. The tail also assists the platypus in diving. The animal often swims along the surface with only the upper part of the muzzle and a small part of the head and body above the water. When submerged, the eyes and ears are closed by a fold of skin. The sensitive muzzle is an important organ for guiding the platypus while it swims blind, often close to the bottom. It may stir up the mud or move stones to locate its food. It surfaces often to breathe and to chew the prey, which it stores in cheek pouches while it is submerged. It can rest near the bottom for a few minutes by wedging itself under stones or logs. In captivity, the platypus has an enormous appetite, devouring each day the equivalent of half or more of its own body weight.

Swimming by the platypus

Echidnas are generally solitary. They appear to be more uncommon than they are because of the inaccessible nature of the places they choose to hide in and because of their remarkable ability to dig vertically into the ground and cover themselves with dirt when disturbed.

Observations on *Tachyglossus* in various parts of Australia indicate that its activity is closely related to the ambient temperature. In north Queensland, they are active primarily at night; but in the more temperate parts of eastern Australia, they are active both day and night. In desert regions they retire into crevices in rock outcrops during the day, where the humidity is higher and they are protected from intense sunlight.

Although echidnas are well adapted for digging, they do not excavate burrows, and they dig primarily to obtain food and escape enemies. They also retreat into hollow logs or under rocks or roots and wedge themselves into crevices and even into slight depressions in such a way that it is practically impossible to dislodge them. They can withdraw their appendages and erect their spines, as does a hedgehog. Echidnas walk with the legs fully extended so that the undersurface of the body is relatively high off the ground and with the hind toes directed outward and backward. They can run and climb well. *Tachyglossus* is extremely powerful and can tear apart rotten logs in search of termites or dig down to ant nests in rocky terrain.

FORM AND FUNCTION

General characteristics. One of the most striking features of the monotremes is that they lay eggs from which the young are subsequently hatched. These eggs are like those of reptiles in that they have large yolks and rubbery shells. Other interesting reptilian features are seen in the structure of the urogenital organs and in the skeleton. In both sexes of the monotremes, as in all reptiles, the intestine, bladder, and reproductive organs all open into a common chamber, the cloaca, with only one external opening. The penis of monotremes is used solely for delivering sperm and not also for urination as in most other mammals. In the skeleton, the shoulder gridle not only retains well-developed coracoid bones, which are reduced to vestiges in other mammals, but also an interclavicle. The pelvic girdle carries epipubic bones, which, as in some reptiles and marsupials, act as supporting structures for the ventral (abdominal) body wall.

Similarities to reptiles

The skull of monotremes has a smooth, rounded cranial portion, terminating in a long rostrum, or snout. Both monotreme types are toothless as adults, and the echidnas are toothless throughout life. The platypus has teeth when young, but they are shed before the animal becomes adult and are replaced by horny pads. The testes are abdominal and there are no teats and no vibrissae (whiskers). The limbs are modified for digging or swimming. The posture of the platypus resembles that of reptiles, especially lizards. In the echidnas, however, the limbs support the body well off the ground, even when the animals are stationary or walking slowly.

An interesting feature of the digestive system of monotremes is that the whole inner surface of the stomach is lined with a cornified (horny) epithelium. There are no glands of any kind. Particularly interesting is the lack of those that produce hydrochloric acid and peptic enzymes, which together initiate the digestion of protein in other mammals. Some other insectivorous mammals also have cornified epithelium covering most of the stomach lining, but there is a small glandular area. It has been suggested that the breakdown of food in the stomach of *Tachyglossus* is assisted by the grinding action of ingested dirt.

Platypus. The platypus has a flattened body covered with dense, short, fine hairs and coarse guard hairs, usually dark brown on the back and much paler on the belly. There is practically no neck. The tail is broad and flat like that of a beaver. It is covered with coarse hair, which is usually worn off on the under surface. The adult male is 50 to 60 centimetres (20 to 24 inches) in total length and the adult female is 40 to 50 centimetres (16 to 20 inches). An average-sized male weighs nearly two kilograms (4.4 pounds). One of the most conspicuous features of the platypus is its elongated and flattened muzzle, which bears a superficial resemblance to a duck's bill. This muzzle is covered with a soft, rubbery, naked, and sensitive skin, which is a blue-gray colour on its upper surface and pale pinkish or mottled below. Dorsal (toward the back) and ventral flaps, or shields, of naked skin extend backward from the muzzle over the adjacent hair. The nostrils are located on the upper surface of the muzzle near its anterior end. The eyes are small and there are no external ears. Both the eyes and ears open into a facial furrow that is closed when the platypus is below the surface of the water. There are cheek pouches in which food is stored until it can be chewed. The limbs are short and the feet webbed. The webbing on the hind feet reaches to the base of the claws, and on the front feet beyond the claws, making extra large paddles for swimming.

Venom apparatus of the platypus

The male platypus has a sharp, movable, horny poison spur on the inner side of each hind limb near the heel. Each spur is about 15 millimetres (0.6 inch) long and connected by a duct to a venom-secreting gland, called the crural, or poison, gland, situated on the dorsal aspect of the upper part of the hind limb. The function of the venom apparatus is unknown. An Australian zoologist, J.H. Calaby, stated that "If, as is generally believed, the crural gland is actively secreting only during and near the breeding season it seems very likely that the chief use of the venom apparatus would be combat between males for territory or females." The poison is not fatal to man but causes intense pain.

Echidnas. Superficially, the echidnas are quite unlike the platypus. They have a rounded body covered on the back and sides with stout, sharp-pointed spines and some hairs. The spines of *Tachyglossus* may measure up to six centimetres (2.5 inches) in length, those of *Zaglossus* up to about three centimetres. The undersurface is covered with coarse hair and is usually without spines. The colour of the spines and hair ranges from light brown to almost black, depending on species and individual variation. Adult males are larger than adult females. There is a long, naked, and sensitive muzzle, a very short tail, and no neck. In some echidnas a definite external ear is present, but in others it is inconspicuous. The nostrils open near the tip of the muzzle. The mouth is small, only sufficient for the protrusion of the long, sticky tongue. The limbs are short and powerful and have strong claws for digging. In *Tachyglossus* one of the claws of the hind foot is particularly elongated and is used for scratching the skin between the spines.

The echidnas resemble the platypus in that there is a venom apparatus on each hind leg, but the spur and crural gland are smaller. In *Tachyglossus,* the spur (about five to 10 millimetres [0.2–0.4 inch] long), which is situated on the inside of the ankle, is present in all males and some females. No observations on the use of the venom apparatus by the echidnas have been published.

Temperature regulation and hibernation. Monotremes are better able to control their body temperature than are reptiles. Except during hibernation, or torpidity of some species, the eutherian, or placental, mammals maintain a high and virtually constant body temperature usually between 36° and 40° C (97° and 104° F). The body temperature of most reptiles varies with that of the surroundings. The body temperature of the monotremes, however, does not quite reach that of the eutherian mammals, being about 31° to 32° C (88° to 90° F). The monotremes are usually described as physiologically primitive in regard to temperature regulation. It has been shown, however, that *Tachyglossus* is an excellent temperature regulator in some situations but less capable in others. It is probably no poorer in this respect than many eutherian mammals (*e.g.,* anteaters, armadillos, and sloths). In cold surroundings the echidna maintains a well-regulated body temperature. Studies of temperature regulation and torpor in *Tachyglossus* have shown that this echidna appears to be a true mammalian hibernator, with the ability to arouse from torpor without the aid of heat from external sources. This ability is lost after repeated periods of torpor in the laboratory at 5° C (41° F). The echidna resembles other hibernators in that torpor is not continuous but is interrupted by frequent arousals. Continuous periods of torpor

lasting 9.5 days, with intervening periods of wakefulness ranging from 30 hours to 11 days, have been recorded for the echidna.

The platypus has periods of hibernation or semihibernation, at least in southeastern Australia. In captive animals, Fleay found that the hibernation periods were short and irregular during the cooler months, the longest single period being 6.5 days.

Laboratory studies have shown that the platypus is slightly superior to *Tachyglossus* in temperature regulation. The platypus has sweat glands on the muzzle and over the body surface, whereas *Tachyglossus* has them only in the pouch area. The heat tolerance of *Zaglossus*, which has many well-developed sweat glands distributed over the body, has not been studied. In its natural environment it is unlikely that the platypus will be exposed to high heat loads. The highly insulating coat of the platypus would protect it against heat loss in water and allow it to exploit cold environments.

EVOLUTION, PALEONTOLOGY, AND CLASSIFICATION

The monotremes are without living relatives outside Australia and New Guinea, and, apart from the presence of fossil monotremes in the Australian deposits of the relatively modern Pleistocene Epoch (the last 2,500,000 years or so), little is known of their ancestry. The fossils so far discovered differ from the existing forms only at the species level. It is interesting to note, however, that large echidnas of the genus *Zaglossus*, which now live only in New Guinea, were common and widespread in Australia during the Pleistocene.

Although the existent monotremes are highly specialized in many of their features, their possession of such typically mammalian characters as mammary glands, hair, and a large brain carries the suggestion that such characters are primitive features of early mammals.

Origin of the order

Most authorities regard the order Monotremata as the sole group of the subclass Prototheria and believe that it originated from a line of mammal-like reptiles different from that which gave rise to the other mammals. It has been suggested, because of the similarities between marsupials and monotremes, that they should be grouped together in a subclass of the Mammalia, the Marsupionta, but the idea has not gained wide acceptance. It does not take into account the many similarities between marsupials and eutherian mammals. It has also been postulated that a group of early prototherian mammals, of which the monotremes are specialized derivatives, gave rise to the marsupials and the eutherian mammals, but this view is not accepted by most biologists.

The ducklike muzzle, or "bill," alone distinguishes the platypus from all other mammals. Although platypuses have been divided into several subspecies, based mainly on differences in size, all authorities agree that the family Ornithorhynchidae has only a single genus and species, *Ornithorhynchus anatinus*.

Two genera of echidnas are recognized in the family Tachyglossidae; in *Tachyglossus* (short-nosed echidnas) the elongated muzzle is straight and not greatly prolonged, and in *Zaglossus* (long-nosed echidnas) the elongated muzzle is greatly prolonged and curved downward.

Although Griffiths recognized *Tachyglossus aculeatus* as the only species of the genus, he distinguished six subspecies, some of which he considered of doubtful validity. Some authorities consider that the relatively hairy Tasmanian echidna is a distinct species (*T. setosus*). Some mammalogists who have studied *Zaglossus* in detail have concluded that only one variable species, *Z. bruijni*, should be recognized. It can be seen that much more work on the biology of the monotremes needs to be done to clarify the place these extraordinary animals occupy in nature.

(A.G.Ly.)

Marsupialia (kangaroos, bandicoots, phalangers, opossums, koala, wombats)

The Marsupialia is an order (or superorder, depending on the authority) of mammals characterized by premature birth and continued development of the newborn while attached to the nipples on the lower belly of the mother. The pouch, or marsupium, from which the group takes its name, is a flap of skin covering the nipples. Although prominent in many species, it is not a universal feature among marsupials; in some species, for example, the nipples are in a well-defined area but are fully exposed or are bounded by mere remnants of a pouch. The young remain firmly attached to the milk-giving teats for a period corresponding roughly to the latter part of development of the fetus in the womb of a eutherian, or placental, mammal.

The largest and most varied assortment of marsupials—more than 100 species—is found in Australia alone: kangaroos, wallabies, wombats, the koala, and a bewildering assemblage of smaller rodent-like forms. About 70 more species are distributed more widely, in Australia (including Tasmania), New Guinea, and a cluster of nearby islands. The wide array of Australian marsupials is reflected in the extensive popular vocabulary of names, many of which are derived from descriptive Aboriginal words. Only two families of marsupials—totalling more than 70 species—are found in the Americas, vestiges of a larger group that originated there as long ago as the Cretaceous Period (from 136,000,000 to 65,000,000 years ago). The family Didelphidae comprises about 65 species of South and Central American opossums, one of which ranges as far north as southern Canada. The family Caenolestidae consists of seven species of ratlike marsupials confined to South America.

GENERAL FEATURES

Scientific and economic importance. Marsupials are of interest to zoologists for several reasons: their current geographical distribution, their remarkable evolutionary expansion in Australasia, their similarity in many respects to placental mammals, and, most obviously, their reproductive adaptations and often bizarre structure.

The question of origin and spread

Fossil evidence indicates clearly that the marsupials originated in the New World, and although the oldest fossils referable to marsupials are found in North America, it is believed that South America is equally likely as the origin of these animals. The current concentration of diverse types of marsupials in Australia and its nearby islands is thought to have occurred as a result of passage over presumed land connections with South America during a mild early geological period before the rise of the placental mammals. Later, toward the beginning of the Tertiary Period (starting 65,000,000 years ago), Australia was isolated from all other continental masses, and the marsupials were free to evolve unrestricted by competition from other groups of mammals. Elsewhere, however, the marsupials did badly; they faced strong competition from and were supplanted by the more advanced placental mammals.

Australian marsupials provided products—meat and hides particularly—for the Aboriginal people, whose primitive hunting methods posed no threat to the continued success of the animals as a group. With the appearance of modern methods of hunting and trapping, however, several species of the kangaroo family (Macropodidae) were soon rendered extinct, and many others were brought close to that fate. For a time during the first half of the 20th century, many of the larger marsupials were slaughtered in great numbers for their pelts, which were an item of export in the fur trade; for their hides, which were made into shoes; and for their flesh, which was processed into dog and cat food. The gray kangaroo (*Macropus giganteus*), for example, is a casualty of such wholesale killing. Fortunately, in Australia most marsupials have since that time been accorded protection under law, and efforts are proceeding to conserve many species that were brought to the brink of extermination. The Tasmanian wolf, tiger, or thylacine (*Thylacinus cynocephalus*), thought to have become extinct in the 1930s, may still survive. In 1961 an expedition claimed to have found thylacine tracks in a rain forest on the west coast of Tasmania. The Tasmanian devil (*Sarcophilus harrisii*), once dangerously close to extinction, is now thriving in Tasmania. In the Americas marsupials are also hunted locally for food and other products, but, since numerous and equally desirable placental mammals abound, hunting pressure and the resulting threat of species death are not so strongly felt.

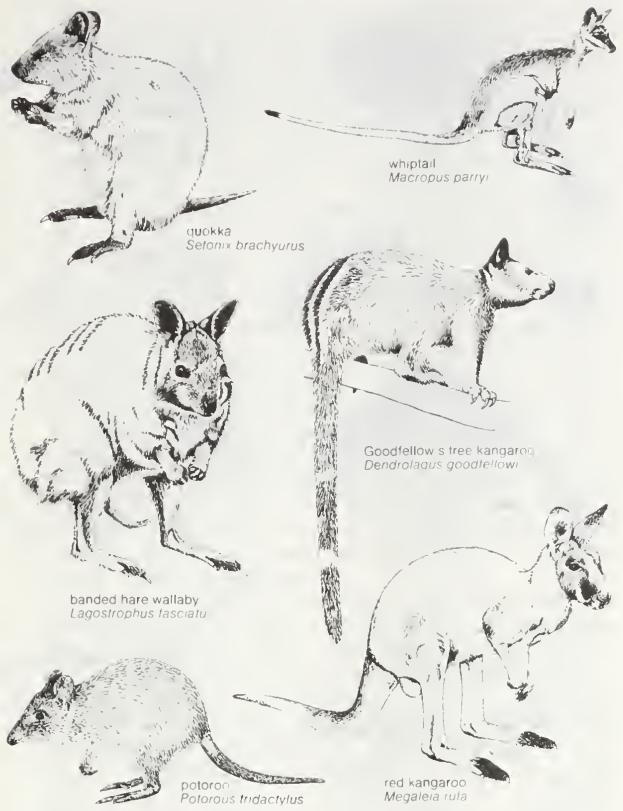

Figure 8: Representative species of the family Macropodidae.
Drawing by A G Lyne

Not only man but also his introduced animals have played a part in the extinction of certain marsupials. Foxes, dogs, and cats continue to prey upon many species of marsupials, as also do the dingoes, canines introduced by the Aboriginals long ago and since gone wild. Brush and forest fires as well as climatic change and the encroachment of civilization are also factors tending to reduce the numbers of marsupial species.

Size range and diversity. No extant marsupial even approaches the tremendous size of certain extinct forms, which apparently rivalled the mastodons in bulk. Among the largest living marsupial is *Macropus giganteus,* some individuals of which reach about two metres (six feet) in height, three metres (10 feet) from muzzle to tail tip, and weigh up to 90 kilograms (about 200 pounds); red kangaroos (*Megaleia rufa*) grow to about the same size. The smallest is the planigale (*Planigale ingrami*), a species of marsupial mice that is barely 12 centimetres (4.7 inches) in total length. The vast majority of marsupials lie in the range from the size of a squirrel to that of a medium-sized dog (Figures 8–10).

Parallels with placental mammals

Structural and behavioral parallels with placental mammals are in some cases quite striking. Such resemblances are examples of convergent evolution, a tendency for organisms to adapt in similar ways to similar habitats. Thus, there are marsupials that look remarkably like moles, shrews, squirrels, and mice. Others, less in structure than in habits, are the ecological counterparts of cats, small bears, and rabbits. Even the larger grazing marsupials, which resemble no placental mammal at all, can be thought of as filling the same ecological role as deer and antelope found elsewhere.

Distribution and abundance. There are about 175 species of marsupials native to the Australasian area, primarily in Australia (including Tasmania), New Guinea, Timor, and Celebes. Through man's agency, however, marsupials have been introduced to nearby islands of Australia and especially to New Zealand. The more than 70 native American species occur in South and Central America, with the range extended into North America by the common, or Virginian, opossum (*Didelphis marsupialis*). A number of other species extend into the southern portion of North America.

In terms of numbers of species the didelphids, or New World opossums, rank highest with 65. In sheer abundance, there are more vegetarian than carnivorous marsupials and perhaps more pouched mice than any other kind of marsupial.

The brush-tailed possums (*Trichosurus vulpecula*) are examples of marsupials that have readily adapted to changing conditions brought about by man. As recently as 1932, more than 1,000,000 pelts of this species were sold under such names as Adelaide chinchilla. Protected for part of the year, the brush tails have now become plentiful over the vast interior of Australia and even pestiferous in urban centres. Their adaptability to different locales is attributed to their tolerance for a variety of food, including household refuse.

Koalas (*Phascolarctos cinereus*), reduced to a few thousand in the 1930s as a result of disease and logging and trapping for fur, have recovered their numbers sufficiently to be reintroduced into forested regions.

Although the red kangaroos (*Megaleia rufa*) are being killed in large numbers for commercial products and by farmers and ranchers whose grazing lands they sometimes visit during periods of drought, they are numerous in many parts of inland Australia. The total range of this

Figure 9: Representative species of the families Phalangeridae, Petauridae, Vombatidae, Phascolarctidae, Peramelidae, and Tarsipedidae.

species is about 2,000,000 square miles. Changes in vegetation resulting from domestic stock have improved the habitat for it in many parts of its range, and the species has increased in abundance.

NATURAL HISTORY

Life cycle. The life cycle of marsupials exhibits the peculiarities of a mammalian group advanced over the egg-laying monotremes but primitive to the placental mammals. The uterine cycle of the female marsupial has no secretory phase, and the uterine wall is not specialized for the implantation of the embryos. The period of intrauterine development in marsupials ranges from about eight days in the native cat *Dasyurus viverrinus* to 40 days in the red-necked wallaby (*Wallabia rufogrisea*). The young, born in a vulnerable embryonic condition, make their own way to the shelter, warmth, and nourishment of the pouch; in pouchless marsupials the young simply cling to the teats. Those fortunate enough to survive this arduous journey may succeed in attaching themselves to the mother's nipples, which then swell and become firmly fastened—almost physically fused—to the mouth tissues of the young. In this condition the young continue their development for weeks or months, after which they are weaned and begin to look after themselves. Frequently the partially developed young outnumber the available teats, and the excess individuals perish. In *Didelphis marsupialis,* litters of as many as 25 young have been reported, but the pouch usually contains only 13 teats.

The primitive reproductive cycle of *Didelphis marsupialis*

Didelphis marsupialis exemplifies one of the more primitive cycles and serves to illustrate the sequence of events in greater detail. It may have two litters yearly throughout most of its range (possibly only one in the northern reaches). The female experiences estrus (heat) and becomes receptive to the male about every 28 days during the breeding season. Heat lasts one or two days, during which an average of 22 ova are shed. Usually only 10 young are born in a litter.

During the first five or six days embryos form very slowly, but thereafter the rate of development speeds up. The gestation period is short—about 13 days. Just before birth, the mother thoroughly cleans the pouch and her belly fur, licking a smooth path from the birth canal to the pouch. When expelled from the birth canal, the newborn are no larger than honeybees. Blind and grublike, except for their well-developed, clawed forelimbs, they emerge and immediately begin grasping and swimming-like movements along the mother's dampened fur. The strong ones reach the pouch in less than a minute, an extraordinary feat for so small and incomplete a creature. Only about 60 percent of the newborn reach the pouch; these attach themselves immediately to the teats, at which they remain for four or five weeks (Figure 11). They then begin to leave the pouch for short intervals, scampering back to it whenever danger threatens. The young stay with the mother for 90 to 100 days—toward the last not in the pouch but clinging to her fur. Shortly afterward they are weaned and begin their independent lives.

Behaviour. The marsupials are notably less intelligent than placental mammals, a fact that is attributable in part to a simpler brain (see below *Form and function*). It is not surprising, therefore, to find a repertory of behavior that differs somewhat from that of the more advanced placentals. One peculiarity that may stem from this underdevelopment is restricted vocal ability. Although marsupials are not entirely silent, few of them emit loud sounds of excitement or distress; apparently, none utter grunts of contentment or even cries of hunger when young. What vocalizing they do is more limited and less variable than that of placentals.

There seems to be little detectable social organization among marsupials beyond the short-lived pair bonds during mating. The reproductive cycle in many marsupials is seasonally controlled, and estrus occurs in a predictable rhythm. In the quokka (*Setonix brachyurus*) and many other kangaroos and wallabies, however, the females may bear young at any time of the year. Only one young, called a joey, can be carried by the mother at a time. After suckling for about six months in the pouch, the joey begins to venture out but remains very close to the mother, plunging headfirst into the pouch when alarmed. The males have no interest in the young and will protect neither them nor the females against danger.

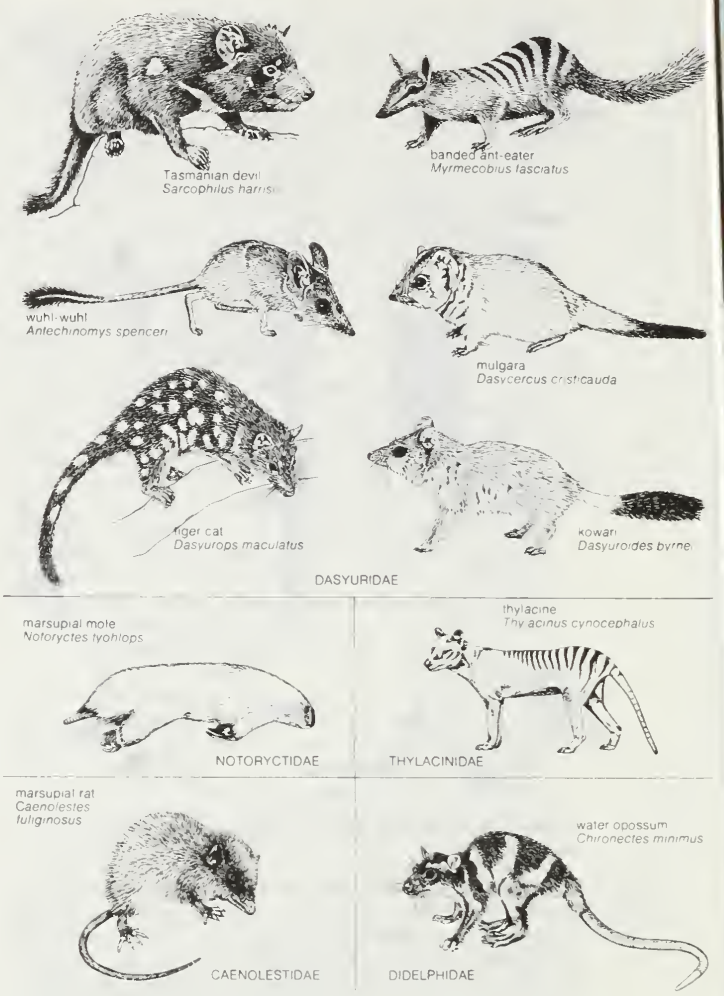

Figure 10: Representative species of the families Dasyuridae, Notoryctidae, Thylacinidae, Caenolestidae, and Didelphidae.
Drawing by A.G. Lyne

Many of the grazing marsupials, such as the kangaroos and wallabies, move in feeding groups called mobs, but these associations do not merit distinction as true herds since the individual members appear to move at liberty, without attention to any leaders or elders. One member can send the mob into a wild rout—individuals bounding off in all directions—by thumping its tail on the ground in a signal of alarm.

The larger marsupials, especially, embody nervous alertness and dull-witted consternation at the same time. A typical response of a red kangaroo when startled is to bound off in full flight—up to 65 kilometres per hour (about 30 miles per hour)—for a relatively short distance, stop short to reconnoitre the disturbance, and, in what appears to be sheer panic, double back toward its adversary and jump over it, sometimes clearing more than three metres (10 feet) in height and a distance of more than eight metres (25 feet) in a single leap.

Defensive behaviour of kangaroos

Although well equipped for escape, a boomer, or large male kangaroo, can stand fast against many of its foes. With agile arms it can spar vigorously, behaviour learned in playful bouts as a joey. But, much more effectively, it can use the forepaws to grip its enemy, while it rocks back on its tail and then swiftly drops its huge clawed hindfeet, an action that has been known to disembowel dogs and men. Despite such fearsome ability, the kangaroos are usually gentle, as are most of the vegetarian marsupials. Whatever violence they commit is usually in response to a distinct threat to themselves.

Such marsupials as the possums (families Burramyidae,

Petauridae, and Phalangeridae), wombats (Vombatidae), and koala (Phascolarctidae) usually sleep by day and move about toward dusk in search of food. Except for the agile possums—notably the gliders (*e.g., Acrobates, Schoinobates*)—most of these animals are slow-moving and, consequently, easy prey for carnivorous animals. The bush-tailed possum, however, is not easy prey for carnivorous animals.

The most mild-mannered marsupial is perhaps the numbat, or banded anteater (*Myrmecobius fasciatus*), a small, slow forest prowler who searches out termites, its favourite food. When disturbed, the numbat hisses; if caught it neither struggles nor bites but simply vents a few grunts in protest. Equally inoffensive and similarly vulnerable to predation is the teddy-bear-like koala, which rummages about at night among eucalyptus branches munching endlessly on the only food it eats—eucalyptus leaves. Its name, an Aboriginal dialect word meaning "no drink," refers to the koala's curious and apparently lifelong abstinence from water. Koalas provide a eucalyptus "soup" for their young at the time of weaning; it is lapped up directly from the parent's anus. The densely furred cuscuses (*Phalanger*) move among the trees with the same deliberation of the koalas, eating leaves as they go.

Bandicoots—whose apt name means "pig rat"—are especially fond of earthworms and insects and are only occasionally herbivorous. Although generally shy and retiring, bandicoots can at times display a surprising belligerence: with their sharp-clawed feet they can literally scratch their victims to death. Certain marsupial mice (*e.g., Sminthopsis* species) are so hyperactive—like shrews—that to supply their high energy needs they must devour their own weight in food, chiefly insects, each day.

A curious and effective defensive behaviour has been developed to a high degree in *Didelphis marsupialis* of North America: when harassed it hisses and departs, but when attacked and not able to flee, it feigns death (plays possum) so well that the aggressor may lose interest and leave.

The carnivorous marsupials are equipped with other behavioural traits. They are the fierce hunters of flesh. Although as a rule not as fast as comparable placental carnivores, they are persistent in the hunt and swift to kill. The Tasmanian devil is a stout fighter, likened in its bloodlust to the American wolverine. Yellow-footed marsupial mice (*Antechinus flavipes*) cling so tenaciously to their prey that they can be caught like fish on bait. The thylacine, which has been known to rise up on its hindlegs kangaroo fashion when pressed, makes up in perseverance what it lacks in speed and cunning. In sharp, foxlike snaps, thylacines have been known to dispatch an antagonist as formidable as a hunting dog.

Life-styles

Ecology. The niches, or ecological roles, that marsupials fill are closely associated with structure. The burrowing species, such as the marsupial mole and the wombats, have powerful foreclaws with which they can tunnel into the ground for food and for shelter. Terrestrial forms, such as the kangaroos and wallabies, possess well-developed hindlimbs that serve both as formidable weapons and catapults by which they can bound over the plains. The greater glider (*Schoinobates volans*) and other Australian "flying" possums have a membrane along either flank, attached to the forelegs and hindlegs, that enables these arboreal animals to glide down from a high perch. A few marsupials spend most of their lives in trees; koalas, for example, are so thoroughly arboreal that they seem comfortable only when they are among the branches of trees. One marsupial is semi-aquatic, the water opossum—yapok or yapó (*Chironectes minimus*)—of Central and South America. Its thick, oily fur, partially webbed feet, and constrictable pouch opening suit it admirably for swimming and diving in search of food.

The diet of marsupials is as varied as the niches. Many live chiefly on insects and other small animals. Such are the marsupial mice and many of the smaller native cats (family Dasyuridae). The tiger cat and the Tasmanian devil feed largely on birds and small mammals. The numbat uses its remarkable wormlike tongue to lap up termites and ants. Many Australian possums, bandicoots, and American opossums have a mixed diet of plant matter and insects. Certain other marsupials are strictly vegetarian. The wombats feed on grasses, roots, and fungi, which they dig up with their clawed forepaws. The small honey possum (*Tarsipes spenserae*) is specialized to feed on the nectar of flowers.

The entire family of macropodids—the "big-footed" ones—are primarily grass eaters. They include the kangaroos and walleroo, the wallabies and pademelons, and the rat kangaroos and musk kangaroo. The walleroo, or euro (*Macropus robustus*), in particular, has a diet almost as restrictive as that of the koala: it can subsist in large part on spiky spinifex grass. Macropodids digest their vegetable food in the same manner as do sheep, cattle, and other ruminants, by relying on intestinal bacteria and protozoans to break down plant matter.

In their turn, marsupials are food for other animals. Foremost among the predators of didelphids and small dasyurids are owls and other birds of prey, snakes, and many carnivorous mammals, including dogs and cats. Some of the larger species of American opossums are eaten locally by man. The enemies of the larger marsupials, the macropodids, include the dingo, fox, eagle, pythons, goannas, and especially man.

Charles Philip Fox

FORM AND FUNCTION

Marsupials share with other mammals the presence of hair and mammary glands. With minor differences the various systems of the body, such as the muscular and skeletal systems, are those of the placentals generally. The skull and the brain, however, differ considerably from those of placentals. Differences also exist in the dentition and in the arrangement of digits of the feet.

Bodily adaptations. In gross structure, many marsupials have hindlimbs that are larger and more powerful than the forelimbs; such an arrangement is most obvious in the large terrestrial grazing marsupials but is of wide occurrence in some degree throughout the Marsupialia. Arboreal and burrowing marsupials have forelimbs almost as well developed as the hindlimbs, understandable adaptations to their modes of living. Claws, often of considerable size, are invariably present in all marsupials and assist in climbing or digging. The tail, of tremendous size in kangaroos and wallabies, serves as an organ of stability and balance; in smaller and arboreal species it may also be prehensile (adapted for grasping), allowing the animal to hang by it.

Brain peculiarities

Compared with placentals, marsupials differ markedly in both the structure and bulk of the brain. Most notably they lack a corpus callosum, that part of the placental brain that connects the two cerebral halves. In addition, the marsupial brain is smaller relative to skull size: a marsupial cat has about half as much brain tissue as a placental cat of similar skull size. Such insufficiency may account in part for the relative backwardness of marsupials when contrasted with placental mammals.

A feature peculiar to marsupials is the presence of a pair of bones associated with the pelvic girdle. Called the epipubic, or marsupial, bones, they were earlier thought to be a supportive element for the pouch.

The teeth in marsupials are numerous—usually 40 to 50, but as few as 22 in the honey possum and as many as 52 in the numbat. The relationship of milk teeth to adult teeth is not clear; some authorities claim that a single set of teeth lasts throughout life. Typically, there are seven cheek teeth on each side of the jaw, top and bottom, which are divided into three premolars and four molars; this contrasts with the typical placental condition in which there are four premolars and three molars. Also unlike the placental condition, the number of front, or incisor, teeth differs in upper and lower jaws.

In earlier studies of marsupials much was made of the number and type of incisors (Figure 12). Marsupials with more than three incisors in the upper jaw were said to be polyprotodont and of a presumed more primitive type since the teeth were more or less unspecialized. Marsupials with three or fewer upper incisors and a corresponding set of modifications of the primitive condition were said to be diprotodont. Subsequent investigations disclosed a gamut of intermediate dentitions, thereby discrediting the distinction.

Another equally unsatisfactory distinction was based on the curious but minor condition in which the second and third toes of the hindfeet are covered in a common sheath of skin. Species showing that condition were syndactylous, and the remainder were didactylous. Classifications were founded on such matters, and the groups were named appropriately Polyprotodontia and Diprotodontia in one scheme, and Syndactyla and Didactyla in another (see below *Classification*).

Reproductive adaptations. The most extraordinary anatomical features of the marsupials are the specializations associated with the reproductive system. The most striking of these is the protective pouch around the nipples of the female in many species. The pouch is well developed in kangaroos, wallabies, and wombats; in the tuan (*Phascogale tapoatafa*) and some dasyurids it is poorly developed, represented by lateral abdominal folds. In several South American didelphids, in the rat opossums (family Caenolestidae), and in the numbat, the pouch is lacking entirely. Even among species that have pouches, the degree of development depends upon the breeding condition of the animal, being most obvious when the female is lactating. The pouch in most forms opens forward, especially in upright and arboreal species; in the water opossum and many quadrupedal species the pouch is directed backward. There may be as few as two nipples (as in the koala and wombats) or as many as 27 (as in *Monodelphis*, the short-tailed opossum). The number of teats does not indicate the number of young that are nursed, however; in some cases more young are born than can be suckled at one time, but in most cases fewer young than the number of nipples are brought to full term.

Differences in pouches

The female reproductive tract is double for most of its length, becoming joined at the posterior ends of the two lateral vaginae. A birth canal, or median vagina, forms at the time of birth; copulation is accomplished by the insertion of the male's penis into the urogenital sinus of the female. The end of the penis is forked in some species. In addition to the peculiar penis, the male also has a scrotum in which the testes hang in front of the penis rather than behind; the testes are abdominal in the pouched male (*Notoryctes*). Most marsupials specialize in brief gestation, as indicated earlier. The developing embryo obtains its food chiefly from its own yolk sac, an embryonic organ provided by the mother. In the majority of marsupials, embryonic gaseous exchange is also effected by means of the highly vascular yolk sac. Typically, there is no intimate mother–fetus connection by means of a true (chorioallantoic) placenta, as in placental mammals. The bandicoots are unique among living marsupials in having a rudimentary placenta, but it lacks the extensive ramifying projections (villi) that provide the close connection of mother and fetus tissue in the placentals.

EVOLUTION AND PALEONTOLOGY

Geologically, no marsupials have been discovered in Asia, and they are definitely not known from Africa. On the whole they are considered as primitive mammals, but for some 100,000,000 years they have shown a remarkable parallel and convergent evolution with placental mammals in habits, physiological processes, and structures.

Among the oldest marsupials are those represented by undisputed fossils from the Late Cretaceous strata of North America. These specimens are represented mostly by tiny isolated teeth, but parts of jaws have also been found. Until recently, all of the fragments were classified in the American opossum family, Didelphidae, but it has been observed that these early marsupials were already specialized in different directions. *Alphadon*, a genus of primarily

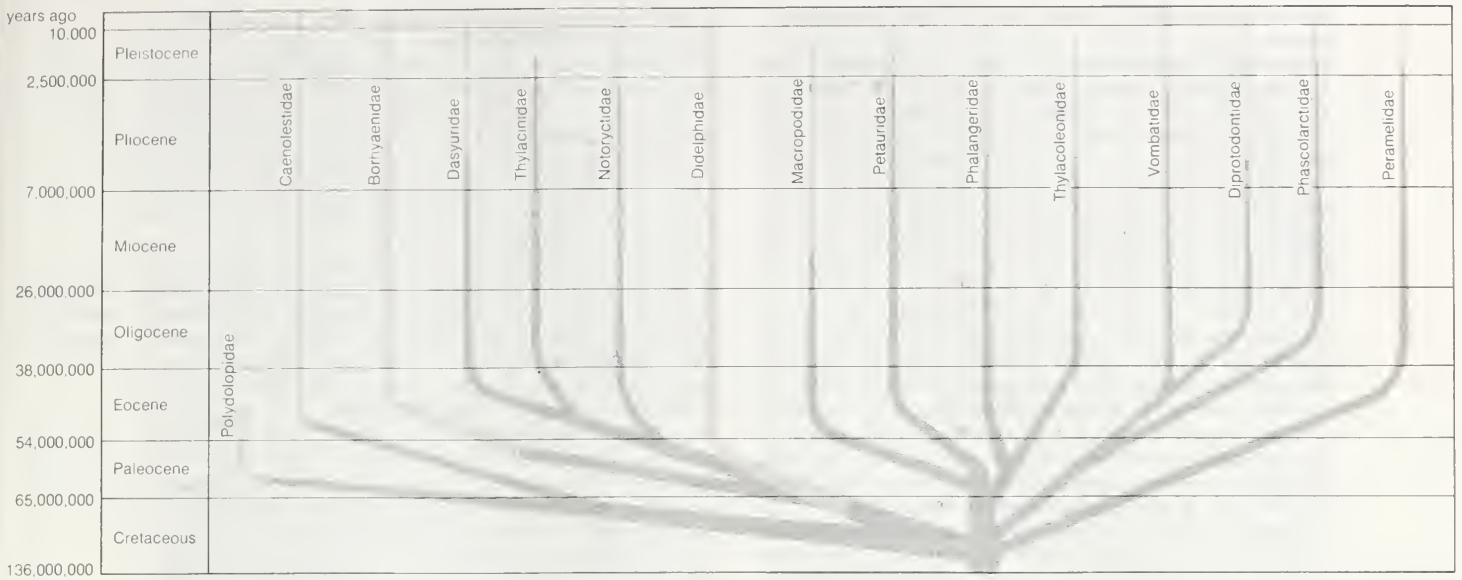

Figure 13: Dendrogram of the marsupials.

tiny animals, is most likely a didelphid. On the other hand the group of small to medium-sized creatures, represented by the genus *Pediomys,* seem rather clearly not didelphids and are now placed in their own family, the Pediomyidae. The widely known genus *Eodelphis* is almost certainly not didelphid. Among its more conspicuous differences from the Didelphidae are the single- (not double-) rooted, much reduced first lower premolar and the presence of three, not four, lower incisors, of which the middle incisor is greatly enlarged. It is likely that this marsupial is not ancestral to any of the known later genera. Another specimen, known as *Thlaeodon,* is the largest known Cretaceous mammal. Its bulbous premolars and large canines are indicative of an adaptation to a mixed (omnivorous) diet. It apparently is referable to another family. *Alphadon,* earlier thought to be nearer than any of the other Cretaceous genera to an ideal ancestral position for the marsupials as a whole, has been superseded by later finds. Fossil fragments of even earlier date (the Middle Cretaceous of Texas, about 100,000,000 years ago) have been tentatively referred to as *Holoclemensia* and assigned as a new genus in the family Didelphidae.

Evidence suggests that marsupials became widespread in the Tertiary Period, beginning 65,000,000 years ago, but they never succeeded as well on other continents as they did in South America and Australasia.

Primitive marsupial characteristics

American marsupials. *Didelphoids.* Primitive marsupial characteristics in the superfamily Didelphoidea have long been recognized by mammalogists. Some of the features in the dentition, skull, and body skeleton may be reasonably expected to be remarkably like those in the Mesozoic ancestors of all later marsupials. Characters in the molars indicate that didelphoids and the South American borhyaenoids of the Paleocene Epoch (beginning 65,000,000 years ago) and Eocene Epoch (beginning 54,000,000 years ago) are closely related, but the lack of enough fossils makes it impossible to trace the lineage of all marsupial superfamilies back to the known North American Cretaceous fossils (possibly the more direct ancestors of some of the other superfamilies existed at that time). Better knowledge of the skeletons and dentitions of fossil marsupials from the Cretaceous Period and even the Early Cenozoic Era (beginning 65,000,000 years ago) may eventually alter considerably the present interpretation of their superfamily relationships.

Borhyaenoids. The oldest known South American marsupials are of the later Paleocene Epoch (about 55,000,000 years old). At that time three superfamilies, Didelphoidea, Borhyaenoidea, and Caenolestoidea, were already in existence. Patterns of the known cheek teeth of the Paleocene and early Eocene borhyaenoids and didelphoids indicate that these marsupials may have descended from a common ancestor no earlier than the Late Cretaceous.

The fossil record of the family Borhyaenidae starts in the late Paleocene and continues into the Pliocene (ending 2,500,000 years ago). No genera are known to have occurred outside South America. Borhyaenids were the flesh-eating mammals of the southern continent during nearly all the Tertiary Period. (True carnivores presumably did not reach that region until late in the Pliocene and Pleistocene.) The family name is derived from the genus *Borhyaena,* hyena-like specimens found in the early Miocene strata (about 26,000,000 years ago) of Argentina. These carnivorous marsupials had massive skulls with thick crushing teeth. Some genera—*e.g., Proborhyaena*—were shorter faced and more robust.

All borhyaenids were not hyenoid, however. There were the wolflike *Prothalycinus* and *Lycopsis* and the fox- to marten-sized *Cladosictis* and *Amphiproviverra.* One of the most specialized of all was the Pliocene sabre-toothed borhyaenid *Thylacosmilus;* it was about the size of a puma and even more specialized as a stabbing mammal than most sabre-toothed cats. In all, more than 20 borhyaenid genera have been described, revealing a long evolutionary history in South America from a Cretaceous didelphid-like mammal.

Necrolestoids. One fossil with a molelike adaptation, called *Necrolestes,* is known from the Miocene of Patagonia. It is the only known genus that can be referred to the family Necrolestidae (superfamily Necrolestoidea) and is probably basically related to the Borhyaenoidea or Didelphoidea.

The early rat opossums

Caenolestoids. The South American rat opossums (superfamily Caenolestoidea) are also undoubtedly descendants of a Cretaceous group, but the oldest known caenolestoids are already too specialized to reveal affinities with any of the known Mesozoic fossils. Any resemblances they have to Australian groups apparently result from convergent evolutionary trends in certain structures.

The family Caenolestidae has been recorded from early Eocene deposits, but the genera were more numerous later in the Oligocene and Miocene periods. These little marsupials were long known from fragmentary fossils, but in 1895 this supposedly extinct family was discovered as represented in the living Andean mammalian fauna of Ecuador and Bolivia by an animal resembling a small rat in size and appearance and named *Caenolestes.* The diprotodont incisor teeth are suggestive of those in some of the Australian phalangeroids, but the hindfeet show no trace of the phalangeroid syndactylism of the second and third toes. Other genera with living species are *Orolestes* in Peru and *Rhyncholestes* in Chile.

The Polydolopidae is an Early Cenozoic family of small specialized marsupials related to the Caenolestidae. Their fossil remains are abundant in the South American strata of that time. They had transversely compressed and laterally ridged premolars, with serrated crests, and rodent-like incisors. The polydolopids, probably in a large measure,

occupied the ecological niches that were later occupied by rodents.

Australasian marsupials. Although pre-Pleistocene fossils of Australian marsupials are relatively rare, representatives of the families Dasyuridae, Peramelidae, Phalangeridae, Thylacoleonidae, Macropodidae, and Diprotodontidae appear as fossils in strata as early as the late Oligocene Epoch (26,000,000 years ago). During the Miocene and Pliocene epochs that followed, fossils of the family Vombatidae were laid down. These findings suggest that the Australian families of marsupials originated in the Early Cenozoic.

Dasyuroids. The oldest dasyuroid lived during the Middle Tertiary of South Australia; about the size of the present-day *Dasyurus quoll*, it was probably near the stem from which the thylacine evolved. *Glaucodon ballaratensis*, one of the most important fossil dasyurids, is possibly of Pliocene age; it bore a resemblance to both *Dasyurus* and a Pleistocene member of *Sarcophilus*. The thylacine (*Thylacinus cynocephalus*), which constitutes the family Thylacinidae, is the largest and most widely known of the dasyuroid marsupials. Although its distribution is usually recorded as being restricted to Tasmania, it was represented on the mainland of Australia less than 10,000 years ago and also lived on New Guinea. The last certainly known thylacine was captured in Tasmania in 1930; however, sightings have been recorded of thylacines and their tracks as late as 1961 along a wild stretch of the west coast of Tasmania.

The doubtfully extinct thylacine

The family relationships of the thylacine are still not fully understood. (Its classification with the extinct Borhyaenidae of South America has almost conclusively been disproved.) Its characters, however, display a remarkable convergent evolution with the American borhyaenids. It seems reasonable to assume that the thylacine and the dasyures arose from a common ancestry. Many authorities place *Thylacinus* in the family Dasyuridae, but until its ancestry is adequately known it seems best to treat it as forming a separate family.

Without a fossil record it is not possible to conclude how closely *Notoryctes*, constituting the family Notoryctidae, is related to the basal stocks of the dasyuroids and to that of the bandicoots, but the absence of syndactyly in the hindfeet suggests they are closer to the dasyuroids. *Myrmecobius*, also lacking a fossil record, is grouped with the family Dasyuridae because of similarities.

Perameloids. Members of the superfamily Perameloidea display one of the most primitive characters seen in any Australian marsupials: the retention of an incisor formula of $\frac{5}{3}$ (polyprotodont) in most of the genera. They have syndactylism in the hindfoot: the proximal and median phalanges (bones) of the second and third digits are enclosed in the same sheath of skin.

Among the perameloids, both *Macrotis* and *Perameles* are represented in the late Pleistocene faunas of Australia. An extinct genus, *Ischnodon*, has been found in the Pliocene strata of South Australia. The most peculiar of all peramelids is the probably extinct (it has not been seen since about 1926) pig-footed bandicoot (*Chaeropus ecaudatus*). The common name is derived from the construction of the front foot, in which the second and third digits are of equal length and closely united. The nails, of equal size and length, give the appearance of cloven hooves.

Phalangeroids. Only a very hypothetical phylogeny, indicating possible ancestral relationships of the superfamily Phalangeroidea to the other superfamilies, can be outlined until an adequate fossil record from the Late Mesozoic and Early Cenozoic has been compiled. The Phalangeroidea were probably derived from an ancestral stock that also gave rise to the Perameloidea. Evidently, in this early stock (in contrast to the Dasyuroidea) natural selection was toward syndactylism. Subsequently, one syndactyl stock led to the ancestors of the rat kangaroos, kangaroos, diprotodontids, wombats, koalas, marsupial lions, and phalangers; the other stock gave rise to the bandicoots.

Of the phalangers, *Eudromicia* is the most primitive of all the living genera. It comprises in part the dormouse possums. The retention of the fourth molars and the double-rooted first and second upper premolars distinguish *Eudromicia* from the other dormouse possums, *Cercartetus*, which they notably resemble.

The remains of a tiny marsupial called *Burramys* has been found in New South Wales, Australia. The shape of the skull and the pattern of the molars resemble those in *Cercartetus* (including *Eudromicia*), but the premolars are high and serrated. This genus is the basis for the family Burramyidae. Once thought to be extinct, several specimens of *Burramys* have been found since 1966 in northeastern Victoria.

One of the oldest fossil marsupials of Australasia is part of the skeleton of a brushtail-like possum, Wynyardia *bassiana*, found in late Eocene or Oligocene deposits near Wynyard, Tasmania. It constitutes the family Wynyardiidae. Fossils more closely related to later species occur in the Pleistocene of Australia; others much older occur in the Middle Tertiary of South Australia.

The oldest Australasian fossil

Among the most bizarre of all marsupials are the woolly possums, or cuscuses (*Phalanger*), from which the family and superfamily names are derived. *Wyulda*, the scaly-tailed possum, which is terrestrial and lives among rocks in northwestern Australia, is somewhat intermediate between the brush-tailed possums and the cuscuses. There has been much discussion about the relationships of the so-called marsupial lion (*Thylacoleo*). Most authorities agree that it belongs in a separate family, the Thylacoleonidae. Specimens of the cranium and lower jaws are well-known, and parts of the limb bones and body skeleton have been found. *Thylacoleo* was about the size of an African lion. Its teeth were even more specialized for meat shearing than those in the true cats; for example, the large posterior premolars were as long as 5.7 centimetres (2.24 inches). All the remaining teeth were greatly reduced, except the upper and lower median incisors, which apparently were utilized in capturing other animals. These great carnivorous marsupials became extinct in Australia less than 26,000 years ago.

Although the genera referred to as the rat kangaroo family (Potoroidae) are closely related to the kangaroo family (Macropodidae) and are classified by some as a subfamily of that group, they apparently have represented a distinct lineage since Eocene time. They may be distinguished from kangaroos by, among other features, several peculiarities of dentition and skull features. The female urogenital system is more specialized than in the Macropodidae. A Pleistocene genus, *Propleopus*, is known, and a species of *Bettongia* and an undescribed genus occur in the Middle Tertiary of South Australia.

The most widely known marsupials are the kangaroos and their relatives (family Macropodidae). The gigantic forms during the Pleistocene were *Procoptodon*, *Sthenurus*, *Protemnodon*, and two species of *Macropus*. *Prionotemnus* is from the Pliocene, but the oldest kangaroos come from rocks probably as old as Miocene.

The macropodids are adapted for jumping. The principal digit in the hindfoot is the fourth, the fifth being somewhat reduced; the syndactyl second and third are reduced to splinters but still bear tiny claws. *Procoptodon* and *Sthenurus* differ from the other kangaroos in having lost all but the fourth digit.

Vombatoids. The superfamily Vombatoidea includes the diprotodonts, the koala, and the wombats.

The extinct family Diprotodontidae included the largest of all marsupials, *Diprotodon optatum*. It was built something like a huge ground sloth and attained the size of a large rhinoceros. Special dentition included the large, chisel-shaped median incisors and molar teeth, somewhat like those in certain kangaroos or tapirs, composed of two cross crests. *Diprotodon* was probably abundant in Australia in the late Pleistocene and subrecent time. Its remains have been found in levels contemporaneous with man. At least two other genera, *Nototherium* and *Euowenia*, representing much smaller diprotodontids, also occur in Australian Pleistocene faunas. *Palorchestes*, also of the Pleistocene, previously considered as the largest of all kangaroos, is now known to be a diprotodontid.

The massive diprotodonts

This family, like the Macropodidae, had a long Cenozoic history in Australia. *Meniscolophus* is known from the Pliocene, and remains of a rather primitive undescribed

genus and species are thought to be as old as the Oligocene Epoch. It appears that all known diprotodontids were herbivorous. The family may have been an early offshoot of the phalangeroid stock and perhaps was distantly related to kangaroos and wombats.

One of the most famous of all Australian marsupials is the koala, family Phascolarctidae. Only one species is known, although a rather distantly related genus, *Perikoala,* from the Tertiary of South Australia, has been described. The koala, with its short tail and rather stocky body, so resembles the wombat that the two are considered by some authorities to have arisen from a common ancestor, perhaps not very far back in Cenozoic time. Others believe, however, that the koala is much closer to the ringtails and greater gliders. The wombats (family Vombatidae), which resemble koalas in having no tails, are represented by two Pleistocene fossil genera: the giant wombat, *Phascolonus,* which was as large as a black bear, and *Ramsayia.* (Ed.)

CLASSIFICATION

Distinguishing taxonomic features. Two earlier classifications of marsupials were based on the number and arrangement of the front teeth and on the appression or separateness of certain toes. Marsupials having at least four upper incisors were named Polyprotodontia; those having three or (usually) fewer upper incisors and no lower canines, Diprotodontia. Marsupials having entirely separate toes on the hindfeet were called Didactyla; those having the second and third toes of the hindfeet enclosed in a common envelopment of skin, Syndactyla. These terms no longer have taxonomic validity, but their adjectival forms are still used to describe the dentition and the character of the hindfeet.

Additional aspects, such as the pattern of hair tracts, blood chemistry, details of reproductive anatomy and physiology, chromosomal morphology, sperm morphology, and behaviour, are currently being employed to structure a new taxonomic system representing more natural units that reflect what are presumed to be fundamental phylogenetic relationships.

Annotated classification. The time-honoured position of the Marsupialia as an order of mammals, generally unacceptable for a variety of reasons (see below *Critical appraisal*), is gradually giving way to a system first presented in 1964. As further modified, that arrangement raised the Marsupialia to the rank of a superorder and encompassed four orders, 10 superfamilies, and 23 families, as given below. Wholly extinct groups are preceded by a dagger (†).

SUPERORDER MARSUPIALIA (Metatherian, or pouched mammals)

Origin during the Cretaceous, expansion at beginning of the Tertiary, and decline with the rise of placentals thereafter. Currently established in Australia and nearby islands (introduced on New Zealand) and in the Americas. Young born after brief gestation in an embryonic condition; development completed while young are attached to teats, usually in a pouch, or marsupium. Skull elements differ from placentals; braincase small; brain relatively small and simple compared with placentals. Epipubic bones associated with the pelvic girdle. Fewer incisor teeth in lower than in upper jaws. Female reproductive tract doubled in large part (paired vaginae and uteri); testes usually in a scrotal sac and anterior to the forked penis (abdominal testes in *Notoryctes*). Comprises about 80 genera and about 240 species in 4 orders.

Order Marsupicarnivora

Comprises 3 extinct superfamilies and 2 extant superfamilies of primarily carnivorous marsupials.

†*Superfamily Argyrolagoidea*

Comprises a single family, Argyrolagidae, represented by *Argyrolagus* from the upper Pliocene to the lower Pleistocene in South America.

†*Superfamily Borhyaenoidea*

Comprises a single extinct family, Borhyaenidae, flesh-eating marsupials of South America during the late Paleocene and into the Pliocene Epoch (about 5,000,000 years ago). Many species had massive skulls and heavy crushing teeth. Named after hyaena-like specimens from Argentinian fossils. Examples: *Prothalycinus, Borhyaena, Lycopsis,* and the sabre-toothed marsupial *Thylacosmilus.*

Superfamily Dasyuroidea

Primarily terrestrial carnivores that resemble the didelphids in certain anatomical features. Incisors small and unspecialized (polyprotodont). Digits in hindfeet never joined (didactylous). Marsupium not present in all species; when present it is poorly developed and opens backward. Three families ranging from Australia to nearby islands.

Family Dasyuridae. A group widespread over Australasia and represented by marsupial mice and rats (*e.g., Sminthopsis, Antechinus, Antechinomys, Planigale, Murexia,* and *Phascogale*), native cats (*Dasyurus, Dasyurops*), Tasmanian devil (*Sarcophilus*), numbat (*Myrmecobius*). Includes the smallest known extant marsupial, *Planigale ingrami* (about 12 centimetres [4.7 inches] in total length). About 18 genera and 48 species.

Family Notoryctidae (marsupial moles). Mole-sized marsupials, of the deserts of central and western Australia, remarkably convergent with placental moles of other continents. Pouch opens backward, and there are epipubic bones. One genus, *Notoryctes,* and 2 species.

Family Thylacinidae (thylacines). German-shepherd-sized wolflike marsupials. Represented on the mainland of Australia less than 10,000 years ago and in New Guinea, the thylacine was last captured in Tasmania in 1930. A single species, *Thylacinus cynocephalus,* constitutes the family.

Superfamily Didelphoidea

Primarily terrestrial American marsupials. Earliest fossils from Cretaceous strata. One extant family, Didelphidae, and 2 fossil families.

Family Didelphidae (American opossums). Central and South America boasts many species of unusual adaptations, notably *Chironectes* (water opossum), *Philander* (4-eyed opossums), *Metachirus,* and *Lutreolina. Didelphis* ranges as far north as southern Canada. Includes 12 genera and about 65 species.

†*Family Pediomyidae.* One genus, *Pediomys,* from the Upper Cretaceous in North America.

†*Family Stagodontidae.*

†*Superfamily Necrolestoidea*

Comprises 1 family, Necrolestidae. Based upon molelike fossils from the Miocene (starting 26,000,000 years ago) of Patagonia. One genus, *Necrolestes.*

Order Paucituberculata

Comprises a single superfamily of marsupials.

Superfamily Caenolestoidea

South American terrestrial marsupials. Earliest fossils from the early Eocene Epoch (about 50,000,000 years ago). One extant family, Caenolestidae, and 2 extinct families.

Family Caenolestidae. Ratlike in size and appearance. Diprotodont incisors suggest relationships to Australian phalangeroids, but other evidence disputes such affinities. Includes *Caenolestes* (Ecuador and Bolivia), *Orolestes* (Peru) and *Rhyncholestes* (Chile). Comprises 3 genera and 7 species.

†*Family Groeberiidae.* One genus, *Groeberia,* from the late Oligocene.

†*Family Polydolopidae.* Known from several genera including *Polydolops* and *Amphidolops* from upper Paleocene to late Eocene in South America.

Order Peramelina

Comprises 1 extant superfamily with 1 family of primarily carnivorous marsupials. Specimens of modern species are common in Pleistocene cave deposits in various parts of Australia.

Superfamily Perameloidea (bandicoots)

Comprises 1 family, Peramelidae. Terrestrial Australian marsupials that resemble rodents, rat-sized to hare-sized. Most genera have primitive polyprotodont dentition: 5 incisors above and 3 below. Syndactylism in hindfeet. Pouch is directed backward. Eight genera and 22 species, including: *Peroryctes, Microperoryctes,* and *Rhynchomeles,* primitive genera restricted to New Guinea and adjacent islands; *Perameles* and *Isoodon,* of wide distribution; *Macrotis* (bilbies) and *Chaeropus* (pig-footed bandicoot), restricted to Australia. Largest of the family (weight to 7 kg, or 15 lb.) is *Peroryctes broadbenti.*

Order Diprotodonta

Comprises 3 extant superfamilies of primarily herbivorous marsupials.

Superfamily Phalangeroidea

Australasian marsupials ranging from squirrel-sized arboreal species to large terrestrial bounders. Syndactylism of the second and third digits in the hindfeet. Four extant families; 2 extinct families.

Family Burramyidae. Primarily arboreal mouse- to squirrel-sized marsupials. Includes *Acrobates* (feathertail gliders), *Bur-*

ramys, and *Cercartetus* (pigmy possums). Comprises 3 genera and 6 species.

Family Macropodidae. Primarily terrestrial medium- to large-sized Australian marsupials. Adapted for jumping, with long hindlegs and long tail for balance. Forelimbs have sharp claws, and thumbs are not opposable. Main digit in hindfoot is the fourth. Extinct giant forms occurred during the Pleistocene, but oldest forms can be traced to the Miocene. Extant macropodids include *Macropus* (gray kangaroos and wallaroos), *Megaleia* (red kangaroos), *Wallabia* (wallabies), *Thylogale* (pademelons), *Dendrolagus* (tree kangaroos), and *Setonix* (quokkas). There are about 19 genera and 47 species.

Family Petauridae. Terrestrial and arboreal marsupials. First and second digits of the forelimbs are opposable to the other digits. Molars are adapted for chewing leaves. Includes *Pseudocheirus* (ring-tailed possums), *Petaurus* (sugar gliders), *Schoinobates* (greater gliders), *Gymnobelideus* (Leadbeater's possum), and *Dactylopsila* (striped possums). About 5 genera and 25 species.

Family Phalangeridae. Squirrel-sized to cat-sized arboreal species. Includes *Trichosurus* (brush-tailed possum), *Phalanger* (cuscuses), and *Wyulda* (scaly-tailed possum). About 6 genera and 15 species.

†*Family Thylacoleonidae.* So-called Australian marsupial lions, which became extinct less than 26,000 years ago. Teeth remarkably specialized for meat shearing. One genus, *Thylacoleo.*

†*Family Wynyardiidae.* Brushtail-like possums, the oldest fossil marsupials of Australasia, from presumed late Eocene rocks of Tasmania. One species, *Wynyardia bassiana.*

Superfamily Tarsipedoidea (honey possums)

Comprises a single family, Tarsipedidae. Adapted for feeding on nectar of flowers. One species, *Tarsipes spenserae*, of southwestern Western Australia.

Superfamily Vombatoidea

Terrestrial and aboreal Australian marsupials, syndactylism of the second and third digits of the hindfeet. Two extant families; 1 extinct family.

†*Family Diprotodontidae.* Large herbivorous marsupial represented in the Australian fossil record as far back as the Miocene.

Family Phascolarctidae (koalas). Small bearlike Australian marsupials. Adapted to arboreal living and restricted to a diet of the leaves of a few species of eucalyptus. First and second digits of the forelimbs are opposable to the other digits. There is no tail. Pouch opens backward. One species along the eastern Australian coast: *Phascolarctos cinereus.*

Family Vombatidae (wombats). Woodchuck-like marsupials distinct from all others in having a single pair of ever-growing upper and lower incisors and in having rootless, high-crowned cheek teeth. The tail is very short. Includes *Phascolonus*, the giant wombat of the Pleistocene; *Vombatus* (common, or naked-nosed, wombat); *Lasiorhinus* (hairy-nosed wombat). Comprises 2 genera and 4 species.

Critical appraisal. An earlier classification, which is still encountered (see section *The class Mammalia*), attributes ordinal rank to the marsupials. Under that system are listed 6 superfamilies and from 13 to 18 families, according to the authority followed. Various attempts to subdivide the order into suborders to accommodate necessary changes required by accumulated taxonomic findings have not been widely accepted. Along with a resurgence of interest in marsupial relationships has developed a growing body of opinion that the order rests too heavily on the presence of a pouch or its vestige. Such a foundation is as unwarranted as the reduction of all recognized orders of placental mammals into a single order because they all possess a placenta. In fact, as many variations and as great a degree of variations are found within the marsupials as are found in the placental mammals. Current opinion, therefore, favours the recognition of the Marsupialia as a superorder comprising four orders as given above.

(H.M.V.D.)

Insectivora (shrews, moles, hedgehogs, tenrecs, solenodons)

The mammal order Insectivora includes the shrews, moles, hedgehogs, and several lesser known groups. Of about 400 species in the order, nearly 300 are shrews of the family Soricidae. All insectivores are small, as mammals go, the largest being about the size of a small rabbit.

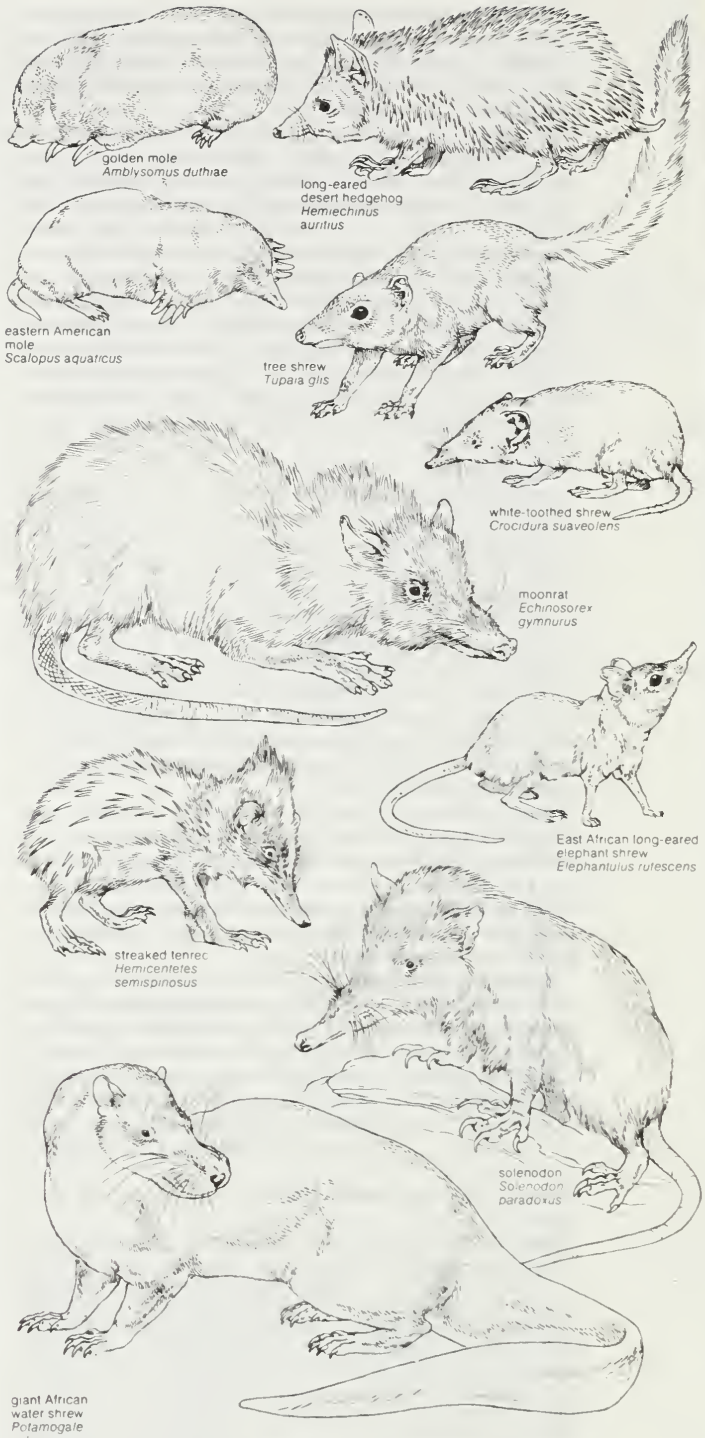

Figure 14: Representative insectivores.

Drawing by R. Keane based on photos courtesy of (golden mole) Herbert Lang through J. Meester, (eastern American mole) *U.S. Fish and Wildlife Service* (white-toothed shrew) Liselotte Dorfmuller (streaked tenrec) Howard E. Uible (solenodon) New York Zoological Society from (long-eared desert hedgehog, tree shrew, East African long-eared elephant shrew) E.P. Walker, *Mammals of the World*, (giant African water shrew) Grzimeks Tierleben *Enzyklopadie des Tierreiches*, Kindler Verlag Zurich

Shrews are probably the smallest of all mammals; some species of *Sorex* and *Crocidura* weigh as little as 2.5 grams (0.09 ounce). The general body plan (Figure 14) varies greatly within the order. Many shrews are superficially mouselike but may be distinguished from mice and other rodents by the absence of chisel-like incisor teeth. Typical moles (Talpidae) and golden moles (Chrysochloridae) are cylindrical, burrowing animals with short, thick limbs and reduced tails and eyes. Hedgehogs (Erinaceidae) and some hedgehog-like tenrecs (Tenrecidae) are stocky animals whose upper surfaces are covered with short spines. Elephant shrews (Macroscelididae) are rather delicate animals, with long hindlegs like those of kangaroo rats or

jerboas. Within the larger families the body plan is quite variable. Most insectivores live at or near ground level, except for the squirrel-like tree shrews and several aquatic moles, shrews, and tenrecs.

Importance to man. Small and secretive, most insectivores are rarely seen by man and are of almost no economic importance. The velvety fur has poor durability, but mole skins have occasionally been used for trimming various garments and for complete coats.

The burrows of moles in lawns may cause the collapse of the turf, and those in fields and gardens provide small rodents with access to plant roots. Indirectly, the more abundant insectivores are ecologically important as consumers of invertebrates and occasionally of small vertebrates and as prey for larger animals. None is an important disease carrier, although elephant shrews harbor malaria, and some soricid shrews may carry plague.

Role of shrews in mythology

A few insectivores are the subjects of aboriginal myths. Some Eskimos believe that the red-toothed shrews (*Sorex*) will attack a man and kill him by burrowing through his body to the heart. The hero shrew (*Scutisorex congicus*), whose backbone of fused and arched vertebrae protects it from crushing, is venerated by central African natives, who believe that consumption of its heart will confer the animal's strength upon the eater.

Distribution. Insectivores are widely distributed but are not found in Antarctica, the Australian region, and South America (except for extreme northern regions). Various marsupials found in Australia are ecologically equivalent to certain insectivores, including a marsupial mole. Why insectivores are absent from South America has not yet been satisfactorily explained.

NATURAL HISTORY

Life cycle. *Reproduction.* Temperate zone insectivores, such as shrews, moles, and hedgehogs, have cyclic reproductive periods. Males develop enlarged testes in late winter or early spring that begin to produce sperm. At the same season females develop enlarged ovarian follicles in preparation for ovulation (release of eggs). Because female hedgehogs may undergo several periods of heat during which copulation does not result in pregnancy, it seems likely that ovulation occurs at a specific time, regardless of other reproductive activities. In shrews and moles, by contrast, every mating results in pregnancy; it has thus been supposed that ovulation in these animals is induced by copulation. An inverse relationship seems to exist between gametogenesis (the production of eggs or sperm) and the development of certain cells in the ovaries and testes. Female moles also exhibit a vaginal cycle, in which the vagina opens to the exterior only during the season of heat, pregnancy, and lactation. The majority of tropical insectivores appear to breed throughout the year; presumably, sperm production is continuous, and ovulation can occur at any appropriate time. Some evidence indicates that, in tropical areas with wet and dry seasons, the majority of births take place with the approach of the rainy season and the accompanying increase in the abundance of invertebrates. In West Malaysia, for example, 41 percent of the recorded pregnancies of one species of white-toothed, or musk, shrew (*Suncus*) occur from October through December, and the peak of the monsoons occurs in January; 19 percent of the pregnancies occur from April through June, before the height of the dry season in July. South African golden moles breed during rainy seasons. Some tenrecs become dormant during the Madagascan dry season, so it is likely that their reproductive period is also related to approaching rains.

Courtship and mating have seldom been observed among insectivores. Males and females of most species remain together for a brief period during which mating takes place. Among tenrecs the male may bite the female's neck; copulation then takes place, with the male mounting the female from behind in all known cases. Shrews may remain locked together for up to five minutes after the male dismounts, while the female drags the male after her. The ejaculate of the male short-tailed shrew (*Blarina brevicauda*) includes a waxy plug that blocks the vaginal orifice, preventing the loss of semen.

Gestation periods

The length of the gestation period varies from two or three weeks in shrews to 50 to 60 days in elephant shrews and tree shrews. In part, the length depends upon the condition of the young at birth; shrews and moles, for example, with a gestation of three or four weeks, have naked, blind, and helpless young. Hedgehogs, with a slightly longer period, have young that, although essentially helpless, do have partially developed spines. Tenrecs may have a 50-day gestation; the young have spines and rather quickly develop neuromuscular integration sufficient to enable them at about four days of age to walk and to exhibit at five days the stereotyped tenrec "bucking" defensive behaviour pattern (see below). Newly born elephant shrews have fur, open eyes and ears, and the ability to follow the parent. That a long gestation does not necessarily produce more developed young in insectivores, however, is shown by tree shrews, which bear helpless young after a relatively long gestation period. After giving birth, females of some species, such as tree shrews and some red-toothed shrews, may immediately mate again.

The number of young produced depends in part on species, latitude, and condition of young at birth. Elephant shrews, tree shrews, otter shrews (Potamogalidae), solenodons (Solenodontidae), and golden moles have one to three young. In the hedgehog family the spiny species have one to seven young; the nonspiny tropical Asian gymnures commonly have two. Moles average two to five young, depending on the species. Shrews have more young in temperate areas than in the tropics. Average numbers recorded range from two to three in Africa; two on the island of Guam; three, four, and five in various parts of India; and seven to eight in Great Britain. Various tenrecs may hold the record for number of young among placental mammals, *Centetes* having as many as 25; the presence of more than 30 embryos has been recorded.

Maturation and longevity. Embryonic development has been studied in only a few insectivores. In most shrews, moles, hedgehogs, and tenrecs, the eyes and ears open in about a week, and the babies are weaned in three or four weeks. Tropical white-toothed shrews reach sexual maturity in about five weeks, as do elephant shrews; tenrecs attain this condition in two months, a time that may also apply to other tropical insectivores. Temperate zone shrews, moles, and hedgehogs attain reproductive maturity in the second year of life. The characteristic chain-forming behaviour of young white-toothed shrews (in which the young form a chain behind the mother, each animal gripping with its teeth the rump fur of the one ahead) may begin after the ears open but before the eyelids part, suggesting that this behaviour is organized by sound stimuli.

The average life-span of most wild insectivores, like that of most small mammals, is probably quite short. It has been estimated at six weeks for shrews. Some individuals of populations of temperate zone shrews and moles, however, must live at least one year in order to participate in reproduction. These species seemingly are programmed for a year of healthy life, but few live beyond this; they succumb from wornout teeth. Captive shrews have survived two and one half years, elephant shrews three years, and hedgehogs 10 years.

Response to adverse conditions. As a normal part of their annual cycle, various insectivores have developed strategies for surviving intervals during which food is in short supply. In temperate regions this occurs in winter; in tropical areas dry seasons often are times of privation. Hedgehogs cope with the problem of food shortage by seeking a shelter, rolling themselves into a ball, and becoming dormant. Although the temperature of the extremities drops to that of the surrounding air, that of the heart remains at the level of an active animal; in this way energy is used slowly. In the dormant hedgehog, white blood cells concentrate in unusual numbers around the stomach and intestine, the sugar level in the blood drops by one half, and the level of magnesium in the blood rises to twice the normal value. In a normally dormant hedgehog, the Islets of Langerhans, which are tissues in the pancreas that secrete the hormone insulin, are active. Certain tenrecs are the only other insectivores definitely

Dormancy in hedgehogs

known to become dormant, a state they may enter during the dry season or in cool weather. The body temperature drops to that of the environment, and the respiratory rate may slacken to five or six breaths per minute. One kind of golden mole, *Chrysospalax*, has been reported to become dormant.

Another common stratagem used by many animals to survive lean times, the storage of food, is known for only a few insectivores. Some kinds of shrews store such invertebrates as snails. The European mole (*Talpa europaea*) may paralyze earthworms before burying them in groups in its mound. Energy may be stored as fat by some hedgehogs, tenrecs (*Microgale*), and star-nosed moles (*Condylura*). The last two genera use the tail as a storage organ.

A curious and unexplained aspect of the annual cycle of some temperate zone shrews involves the volume of the brain and the height of the braincase; both decrease to a minimum in midwinter, then increase again.

Behaviour. *Feeding behaviour.* All insectivores feed wholly or partly on animal matter and spend a substantial amount of time foraging. Shrews consume large quantities of invertebrates and occasionally small vertebrates. Moles eat soil invertebrates, including worms. Larger species eat larger prey; hedgehogs, for example, may consume frogs, mice, birds, lizards, and snakes and in captivity will eat bread and milk. The diet of golden moles is not well-known, although some species are known to prefer legless lizards (*Anguis*); others consume earthworms and insect pupae and larvae. Tree shrews are omnivorous, eating many insects as well as fruit; in captivity they thrive on commercial monkey food. Elephant shrews avidly eat locusts and, in captivity, thrive on bird meat. The aquatic tenrec *Limnogale* eats the tubers of the pondweed *Aponogeton*, and also takes fish. The water shrews consume aquatic animals, sometimes even small fish, and the otter shrew eats crabs, fish, and amphibians.

Many insectivores probe through leaf litter or soft soil. Solenodons proceed in this way until the long snout contacts prey; then the forepaws sweep forward and inward, gathering the object into the mouth. So stereotyped is this behaviour that even in captivity the animal captures inert food items in this way. Young solenodons follow the foraging parent and may learn the scent of acceptable food by smelling the mouth of the female. Young tenrecs may also learn to discriminate food by following their mother. Tenrecs, which often forage in groups, become excited at the scent of earthworms and begin to root enthusiastically. The sound of rooting and chewing stimulates other tenrecs in their searching activity. Shrews search through leaf litter or underground passageways of other mammals, locating prey by smell and contact. Moles do much of their hunting in their burrows, which may act as natural traps into which invertebrates fall. Golden moles emerge after rains and forage in the surface soil. Some shrews hold food items in their paws while eating and may carry food to preferred sites to eat it. Tenrecs may use the forefeet to hold down worms while they are torn in pieces.

A number of insectivores are reported to drink water, although elephant shrews probably do not do so. Tree shrews use water for drinking and bathing. Many insectivores may obtain sufficient water from their food or from dew.

Orientation and activity periods. Except for tree shrews and elephant shrews, both of which are primarily diurnal (*i.e.*, active by day), insectivores rely relatively little on vision for orientation. In most species, olfactory, tactile, and auditory cues are most important. Shrews, some tenrecs, and possibly the solenodons use a crude form of echolocation, a process by which objects are located by sound waves reflected back to the animal. Tenrecs produce clicks with the tongue at frequencies from five to seven kilohertz. Spiny tenrecs produce high frequency noises by vibrating together rows of overlapping spines on the middle of the back; the sounds produced in this way probably are used in social communication rather than orientation. Shrews and solenodons produce, probably with the larynx, clicks of 10 to 31 kilohertz (in solenodons) and 25 to 60 kilohertz (in shrews). Many insectivores, when exploring strange surroundings, maintain contact with a solid surface such as a wall or a log, which is probably tested with the facial sensory hairs (vibrissae). After a territory has become familiar, many insectivores are able to traverse it by memory and may become severely disoriented if the landscape changes.

Sound production

Most insectivores are active at night, although shrews may be active throughout the 24-hour period. Most elephant shrews and tree shrews are diurnal, but at least one genus in each family is nocturnal. True moles and apparently also the little-studied golden moles are active by day or night.

Locomotion. In walking, most insectivores proceed by moving the right forefoot and left hindfoot, then left forefoot and right hindfoot forward together (crossed extension limb synchrony). Solenodons run with a quadrupedal rhichochetal (springing) gait, in which both forefeet and then both hindfeet strike the ground together. Other large insectivores also probably run in this way. Elephant shrews may hop bipedally, but their locomotion has not yet been studied. Tree shrews are skillful climbers but spend much of their time on the ground; some tenrecs are also partly arboreal. A few insectivores, such as otter shrews, several species of shrews and moles, and one tenrec, are partially aquatic and swim with alternate strokes of the hindfeet. The American water shrew (*Sorex palustris*) has been observed to scamper over the surface of still water, apparently being supported by the surface tension and the fringe of stiff hairs on its feet. The water tenrec (*Limnogale*) has webbed feet, as do the aquatic moles *Desmana* and *Galemys*. Some aquatic insectivores may use a laterally compressed tail in swimming, such as is found in the water shrew *Nectogale elegans*, the water moles *Desmana moschata* and *Galemys pyrenaicus*, and the otter shrew *Potamogale velox*.

Movements in water

Grooming. All insectivores spend some time in self-grooming. The universality of this behaviour suggests that it is necessary for keeping the hair in proper condition for its role in thermoregulation. Solenodons use only the hindfeet in grooming, perhaps because the forefeet are enlarged for digging, and the elongated snout hinders the use of the mouth in grooming. Shrews use the hindfeet and also the tongue. (Why the forefeet are not used by shrews is not clear.) Hedgehogs likewise do not use the front feet for cleaning. The tenrec *Echinops* uses both hindfeet and front feet. Tree shrews of the genus *Tupaia* use all four feet, but the forepaws and mouth are the dominant cleaning organs. These animals also comb the fur with the lower incisors.

Burrowing and nesting. Probably the most complex insectivore shelters are built by moles. A mole may have an underground nest chamber surrounded by concentric rings of tunnels interconnected by radiating ones. Shallow surface tunnels extend from this deeper complex and are evidenced by raised ridges, which mark their course. The mole may also throw up a large mound of earth on the surface that marks the location of its deep tunnel system. Burrows are dug by using the spadelike forefeet in a manner resembling the breaststroke of swimmers. The golden moles may use the same method, but little is known concerning their excavations. Some shrews dig tunnels, but many species use the runs of other animals. Shrews build surface nests, lined with shredded plant material, in which they rest or bear their young. Solenodons construct nest chambers during the breeding season, as do hedgehogs and tenrecs. The last two also build nests for keeping warm when the temperature drops. Elephant shrews often seek shelter among rocks and probably seldom excavate their own burrows; they may, however, occupy those abandoned by rodents. Tree shrews build nests of leaves and other vegetation, often among roots or fallen timber or in a tree cavity above the ground. When frightened, many insectivores immediately flee to a nearby burrow entrance.

Defensive behaviour. Spiny insectivores, such as hedgehogs and tenrecs, defend themselves by rolling into a ball with the spineless undersurface curled inward. Hedgehogs have a specialized muscle that is capable of pulling the spiny dorsal skin about the animal so that only a small unprotected area remains. Spiny tenrecs, when disturbed, exhibit a stereotyped defense behaviour in which the

spines on the head and neck are erected, and the animal "bucks" by throwing its forequarters upward. The action would drive spines into an attacker. Solenodons and tenrecs gape and hiss at intruders, a pattern also seen in the unrelated American opossum, a marsupial. Shrews, when confronted with strangers, open the mouth and emit bursts of high-pitched cries.

Shrews and solenodons have been shown to produce saliva with poisonous properties; it probably functions in quieting large prey animals. Shrew bites may be painful to humans.

Social behaviour. The majority of insectivores are rather antisocial, except at breeding time and in the context of the female–young relationship. Adult shrews and moles tolerate other adults of their species briefly during the period of mating, following which the female and young form a group until the young are full grown; the young rarely appear alone during this interval. Young white-toothed shrews (*Crocidura*) exhibit chain formation, in which each animal grasps the rump fur of another, one grasping the mother, after whom they then trail. Baby shrews are rather indiscriminate and may attempt chain formation with such inappropriate subjects as white mice.

Juvenile behaviour

Solenodons have a prolonged period of juvenile dependency during which the young follow the female, perhaps learning to locate favoured foraging areas and to discriminate in food selection. Adult solenodons approach each other with open mouths, perhaps emitting high-frequency clicks. Contact involves one animal closing its mouth over the snout of the other, then pressing the snout against its own flanks and back. Several solenodons may occupy a burrow. Various tenrecs forage in large groups which probably consist of one or more females and young. Elephant and tree shrews live solitarily or in groups of two or three, consisting of a female and her young. Hedgehogs may also form temporary groups of female and young.

Hedgehogs and spiny tenrecs perform an unexplained "self-anointing" behaviour, which is triggered by the presence of such substances as urine or certain chemicals. The animal licks the material until a frothy spittle is produced; in some species this is then spread over the body by the tongue in typical hedgehogs (*Erinaceus*) or by the mouth and forefeet in tenrecs.

Ecology. *Predation upon insectivores.* Shrews are preyed upon by a variety of birds, mammals, and snakes, but seemingly the strong odour produced by the flank gland of shrews makes them unpalatable to some predators. Skulls of shrews are commonly found in owl pellets (regurgitated indigestible remains of prey). Little is known about the predators of elephant and tree shrews. True moles and golden moles may be safe from many predators because of their subterranean habits; spiny hedgehogs and tenrecs may, for the same reason, be relatively safe. In Madagascar some tenrecs are preyed upon by man. Solenodons seemingly suffered little predation on Cuba and Hispaniola until man introduced dogs, cats, and mongooses there. These carnivores have drastically reduced solenodon populations, probably because the solenodons had evolved no defenses against such predation.

Territoriality. Each adult shrew occupies its own territory of about 0.1 to 0.4 hectare (0.25 to one acre). About 40 percent of its behaviour involves avoiding other shrews. When shrews from adjacent territories encounter one another, they engage in mutual avoidance if possible. Avoidance is made easier by an oily odoriferous substance exuded by the flank glands, which helps to warn off other shews of the same species. A similar kind of territoriality probably is practiced by moles. Population structure of most other insectivores has not yet been studied. Tree shrews apparently defend nest territories, and males may mark these areas by smearing onto branches the yellow exudate from throat and chest glands.

Habitats. Insectivores utilize diverse habitats. Shrews occupy the ground surface in forests and grasslands but are less common in deserts, although *Notiosorex* and *Diplomesodon* occupy New and Old World deserts, respectively. Moles are largely confined to North Temperate Zone forests and meadows, especially in areas of deciduous forests and adjacent prairies. Hedgehogs live in forests, grasslands, and deserts of the Old World. Spineless hedgehogs (Echinosoricinae) live in tropical rain forests of Asia. Golden moles occupy many habitats in southern Africa. Otter shrews live in riparian situations (*i.e.*, on the banks of natural water courses), in the Congo Basin and environs. Elephant shrews prefer African savanna areas, but some are forest dwellers. The tenrecs live in most habitats on Madagascar; some are partly arboreal. Tree shrews are largely terrestrial in tropical Asian forests, but most can climb well and are partly arboreal. Solenodons are strictly terrestrial foragers in the forests of Cuba and Hispaniola.

FORM AND FUNCTION

The order Insectivora is the most difficult of living mammalian orders to define because the groups included retain traits of primitive placental mammals and are not very specialized. Although each family has specializations, they are not such as to suggest that each group should be raised to ordinal level. Furthermore, many of the families are as old as many mammalian orders, and the evidences of common relationship are often obscured.

Skull. The skull of insectivores is typically low in that the braincase does not rise abruptly from the level of the rostrum (the bony support for the snout), which tends to be long and tapered. Seen from above, the skull is triangular in outline. The cerebral cortex of the brain is not well developed, and the olfactory bulbs are large, in conjunction with the well-developed sense of smell. In addition, the elongated rostrum supports muscles that activate a still longer, highly mobile snout with well-developed tactile capabilities that are useful in probing for food. The middle ear cavity is partly or wholly enclosed by the tympanic bone. In such forms as shrews and hedgehogs, the tympanic bone (surrounding the middle ear) is ringlike and attached to the base of the skull (basicranium) only at one point, probably the primitive situation. Other forms, such as moles and golden moles, have an expanded tympanic bone fused to the basicranium to form an auditory bulla (an enclosed chamber). The bulla of tree shrews and elephant shrews includes an entotympanic bone, a trait also seen in primates. Many insectivores have small external ear pinnae (the projecting "shells" of the ear); this is nearly or quite lacking in burrowing forms such as moles but may be rather prominent in such forms as desert hedgehogs. In shrews and tenrecs, at least, sensitivity to high-frequency sounds is well developed.

Presence of tympanic bone

Orbital fossae (eye sockets) and eyes are variably developed in insectivores, most species having relatively small eyes. In moles and golden moles, in which the eyelids are fused shut, probably only differences in light intensity can be detected. Large eyes and well-developed vision are present only in tree and elephant shrews. In the former the orbital fossa is completely encircled with bone.

Dentition. Insectivores have from 26 to 44 teeth, the latter being the maximum for placental mammals. Incisors range from three to six pairs. The second lower incisors of solenodons are long and grooved and transmit venom from the submaxillary salivary glands, the ducts of which end at the bases of these teeth. The upper and lower first incisors of shrews are provided with one or more accessory cusps. These specialized teeth close so as to provide the animal with a delicate tool for picking up small invertebrates. The incisors of tenrecs may also be provided with accessory cusps, but tenrecs lack the other dental specializations of shrews. The lower incisors of tree shrews form a comblike structure and are used for grooming the fur. The canine teeth, though present in insectivores, are usually small, rarely extending much above the level of the other teeth; they are not strong and elongated as those in carnivores (an exception is the Palearctic mole *Talpa*). The canine teeth of hedgehogs and moles have double roots, an unusual condition among mammals. Premolars range from the simple one-cusped structures seen in shrews and some moles to multicusped molariform teeth. The molariform premolar is usually the fourth or, more rarely, the third.

Molars

Insectivoran molars are of a primitive placental type. The crown supports several usually conical cusps arranged in a triangular pattern (called protocone, paracone, and

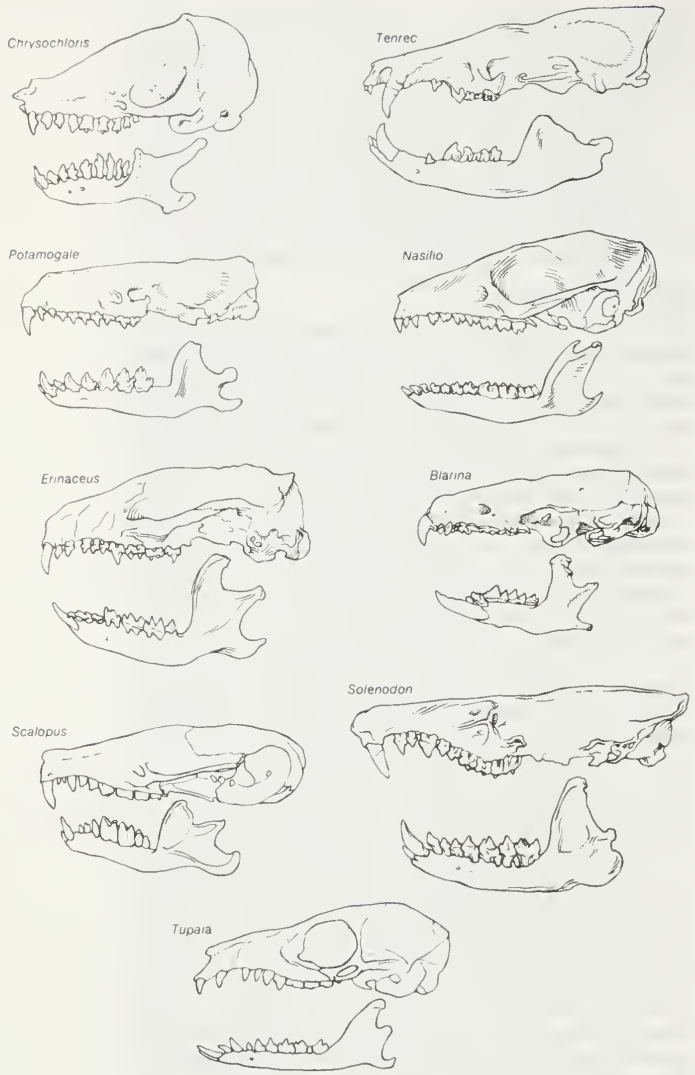

Figure 15: Skulls (cranium and lower mandible) of representative insectivores.

Drawing by R. Keane based on (*Chrysochloris, Tenrec, Potamogale, Nasilio*) P.-P. Grasse *Traite de Zoologie*, vol. 17 (©1955), Masson & Cie, Paris, (*Blarina, Scalopus*) E.R. Hall and K.P. Nelson *The Mammals of North America*, copyright © 1959 The Ronald Press Company, New York, (*Tupaia*) *Proceedings of the U.S. National Museum*, vol. 45.

metacone on the upper teeth; protoconid, paraconid, and metaconid on the lower). The upper triangle is often squared off by the addition of a posteromedial hypocone (*i.e.*, on the rear inner corner). To the lower triangles is added a posterior shelf (talonid) frequently made up of cusps called hypoconid and entoconid. These molars close so as to allow some degree of both slicing and crushing action; the term tuberculosectorial is applied to them. Omnivorous forms tend to emphasize the squaring up of the teeth and the crushing, rather than the slicing, function by lowering the cusps so that the closing surface is made up of low hillocks. This type, the bunodont molar, is best developed in hedgehogs. When the triangular part of each crown is emphasized and elevated, the result generally indicates a carnivorous diet; such teeth are seen in tenrecs, otter shrews, golden moles, and solenodons. In these four groups the paracone and metacone (outer cusps, forming the base of the upper triangle) are close together and medially removed from the outer edge of the tooth. Such a molar type is called zalambdodont. Moles and shrews have converted the paracone and metacone into V-shaped ridges, such that the two produce a W-shaped pattern on the upper molar (termed dilambdodont). The result is that there are four, rather than two, cutting edges on the upper molar. This specialization, seen also in insectivorous bats, is seemingly especially useful in chopping up small invertebrates. The molars of tree shrews and elephant shrews are also dilambdodont; in the former the appearance is sufficiently similar to that of true shrews to suggest some dependence on insects. The teeth of elephant shrews show a curious parallel to those of artiodactyls in being somewhat high crowned, with considerable molarification of the premolars. The extent to which elephant shrews are vegetarians, as their dentition suggests they may be, has not been measured. Shrews may replace their milk teeth while still in the uterus.

Limbs. The appendicular skeleton of insectivores retains many traits seen in primitive placental mammals. All except the otter shrews retain a clavicle connecting scapula (dorsal part of pectoral girdle) to sternum (breastbone). Since absence or reduction of the clavicle usually characterizes mammals that are specialized for rapid leaping locomotion, such as artiodactyls (antelopes, pigs, and cattle) and perissodactyls (horses, rhinoceroses, and tapirs), its absence in otter shrews, which are reported to be clumsy on land, is perplexing. The humerus (upper bone of the forelimb) of insectivores retains an entepicondylar foramen (an opening in the articular surface), absent in many more specialized mammals. The radius and ulna (bones of the forearm) are separate and well developed. The manus (forefoot) is rarely specialized, usually possessing five digits and a relatively full complement of wristbones (carpals). In some forms (shrews and hedgehogs) one wristbone, the centrale, is missing or fused with an adjacent bone, as it is in most primates. Moles have broad forefeet, in which supernumerary bones are closely knit to form a rigid plane, as in the blade of a shovel. Golden moles have the hand digits reduced to four, two of which are greatly enlarged and bear huge, picklike claws. The pelvic girdle shows no peculiarities. In a few families (shrews, moles, golden moles, and otter shrews) the pubic bones do not form a symphysis (union); in others a short or long symphysis is present. The femur (thighbone) is marked by a laterally placed third trochanter (a ridge) for muscular attachment, presumably a primitive trait but one seen in a variety of other mammals. The tibia and fibula (lower bones of the hindlimb) are usually fused distally (near the ankle), but in solenodons this fusion takes place only with old age and in some tenrecs and all tree shrews not at all. Fusion reduces the lateral mobility of the foot but promotes more efficient forward and backward motion. In hedgehogs and elephant shrews the toes may be reduced to four. All insectivores except elephant shrews have plantigrade foot posture; *i.e.*, the entire sole is placed down in walking. In some species, however, the heel is frequently lifted from the ground.

Fusion of tibia and fibula

Tail. The tail structure varies according to the behaviour of the animal. Burrowing insectivores have little or no tail, in common with most other burrowing animals. Climbing and running species have well-developed tails, haired or nearly naked. The slow-moving hedgehogs generally have short tails. In aquatic forms, such as aquatic shrews, moles, and potamogales, lateral compression of the tail seemingly suits it for steering functions.

Fur texture and coloration. Specializations of the hair are seen in hedgehogs and some tenrecs, which possess

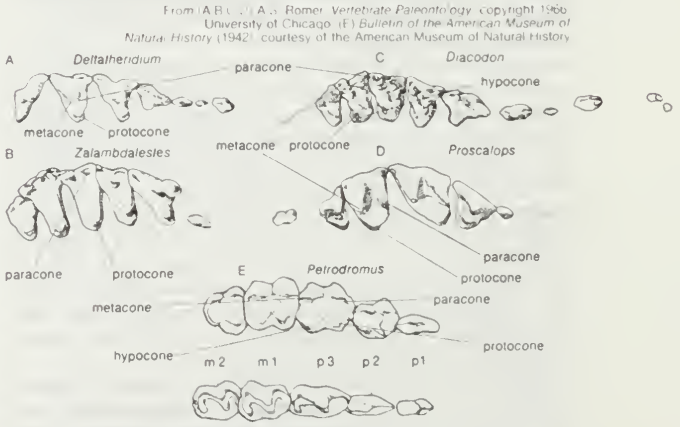

Figure 16: Major molar types in insectivores.
(A) An early zalambdodont placental. (B) A Cretaceous leptictid. (C) An early hedgehog with omnivorous bunodont tooth type. (D) A dilambdodont mole. (E) A putatively vegetarian elephant shrew (see text)

spiny hair. Burrowing species have reversible fur, which can lie down either anteriorly or posteriorly as the animal moves forward or backward in the tunnel. The fur of golden moles has a distinctive metallic sheen or iridescence. Few insectivores are strikingly coloured; most are brown, gray, or black with little countershading. Exceptions occur in diurnal species, which may be more brightly coloured and have some indication of patterns.

Digestive and reproductive specializations. Tree shrews and elephant shrews possess a cecum (a blind pouch) at the junction of small and large intestines. An intestinal cecum is not present in carnivorous insectivores, since it serves for storage and continued digestion of plant food. Elephant shrews, whose teeth suggest a diet consisting largely of plants, have a large cecum; tree shrews, which probably eat relatively less plant food, have a comparatively small cecum.

A true scrotum containing the testes is present only in tree shrews; in some other forms, such as moles and tenrecs, the testes lie close to the surface in the perineal region (the area ventral to the anus) but do not leave the abdominal cavity. A penis bone (baculum) is found in tenrecs and moles. Elephant shrews have a trifurcate penis, a trait that led some early students to ally them with the marsupials, some of which have a bifurcate structure. The form of the uterus is Y-shaped, or bicornuate, as in many other mammals.

Metabolism. Although insectivoran physiology has been studied in connection with special abilities, such as dormancy in hedgehogs, it is not well-known for the order.

Metabolism in shrews

Of great interest are the smaller shrews, which, because of their minute size and relatively large ratio of body surface to volume, have an exceptionally high rate of metabolism, necessitated by the high rate of energy loss in the form of heat. As a result shrew life consists largely of a frenetic search for food. A captive female *Sorex* ate 3.3 times her own weight every 24 hours.

EVOLUTION AND CLASSIFICATION

Evolution. In late Cretaceous and early Cenozoic times (beginning about 100,000,000 years ago) a number of primitive placental mammals existed that did not display the specialized characteristics of modern orders; they possessed tritubercular (three-cusped) cheek teeth, with the paracone and metacone well separated and located laterally on the occlusal (closing) surface. These animals, the Leptictidae, some of which persisted until Oligocene times (about 38,000,000 years ago), were close structurally to Eocene hedgehogs and may well be ancestral not only to many modern insectivores, especially hedgehogs, shrews, and moles, but also to a variety of other modern mammals, such as ungulates and primates. These insectivores, in which the paracone and metacone are well separated and are near the lateral edge of the molar, are thought by some paleontologists to have descended from Late Cretaceous leptictids and to form a separate lineage from the zalambdodonts. The fossil record is fairly clear in showing common ancestry of shrews and moles, and probable derivation from late Eocene or early Oligocene hedgehog-like ancestors (perhaps 40,000,000 years ago). Some paleontologists believe that the presence of zalambdodont molars in tenrecs, otter shrews, and golden moles is indicative of independent descent from the zalambdodont deltatheridiids, a family of doubtful ordinal affinities, of Late Cretaceous time. It has recently been suggested that solenodons also descended from a hedgehog-like ancestor, which reached the Greater Antilles in early Tertiary time. Tree shrews are known from Paleocene time (about 65,000,000 years ago) and probably come closest among living mammals to representing the appearance of the early Cenozoic primitive placentals. Fossil elephant shrews from the African Miocene (about 26,000,000 years ago) offer few clues to the origin of the Macroscelididae, which were in all likelihood derived from the unspecialized Early Cenozoic placental group. Tenrecoids and golden moles have an exclusively African and Malagasy fossil history, also stemming from the Miocene.

Classification. *Distinguishing taxonomic features.* Insectivores are characterized by the lack of distinctive features seen in other mammalian orders rather than by the possession of unifying morphological traits. All possess a low braincase, a rather long conical rostrum (snout) and unspecialized legs, feet, and locomotion. They can be distinguished from similarly built rodents by the lack of the gnawing incisors (followed by a diastema, or space) that characterize the rodents and from similarly built marsupials by the lack of an abdominal pouch.

Annotated classification. Taxonomists disagree on the relative degrees of relationship among insectivoran families (except that shrews, moles, and hedgehogs are conceded to form a cohesive phyletic unit); the classification omits subordinal and superfamilial groupings.

ORDER INSECTIVORA

Primitive placental mammals characterized by a low braincase, conical snout, and lacking locomotor or dental specializations of other mammalian orders; 77 genera, 406 species.

Family Erinaceidae (hedgehogs and gymnures)

Eocene to Recent; Eurasia and Africa. Spiny pelage (covering) present (subfamily Erinaceinae, hedgehogs) or lacking (Echinosoricinae, gymnures); zygomatic arch (below eye orbit) present in skull; molars quadrate, bunodont (see above *Dentition*); auditory bulla a tympanic ring, not fused to cranium. Terrestrial, omnivorous, often hibernating or estivating. Hedgehogs are Eurasian and African; gymnures native to the Asian tropics, often shrewlike. Ten genera, 14 species.

Family Talpidae (moles)

Eocene to Recent; Holarctic. Manus very broad and specialized for digging; molars with W-shaped crests; zygomatic arch present; auditory bulla fused to cranium; eyes minute; ears without pinnae; humerus bone extremely broad and short. Burrowing (fossorial), sometimes aquatic. Fur of some commercial value. Fifteen genera, about 22 species.

Family Soricidae (shrews)

Eocene to Recent; Africa, Eurasia, North America, northern edge of South America. First upper and lower incisors procumbent, multicusped; zygomatic arch lacking; bulla a tympanic ring, unfused to skull; molars with W-shaped crests; small size. Terrestrial, aquatic, or subfossorial foragers in ground litter or water for small invertebrates. Twenty-four genera, approximately 291 species.

Family Solenodontidae (solenodon, almiqui)

Pleistocene to Recent; Cuba and Haiti. Molars zalambdodont; zygomatic arch incomplete; incisors canine-like, lower ones grooved; long scaled tail; long mobile snout. Terrestrial, perhaps nearing extinction. Two genera, 2 species.

Family Tenrecidae (tenrecs)

Miocene to Recent; Madagascar. Molars zalambdodont; zygomatic arch incomplete; bulla composed of a tympanic ring and basicranial elements; form variable from nearly tailless, spiny, rabbit-sized *Tenrec* to long-tailed, soft-furred, shrewlike *Microgale. Oryzorictes* is molelike, while *Limnogale* is muskrat-like and a vegetarian. Nine genera, 20 species.

Family Potamogalidae (otter shrews)

Recent; West Africa. Webbed feet, otter-like form; zalambdodont molars. Riparian, aquatic, feeding on aquatic vertebrates and invertebrates. Two genera, 3 species, often included as a subfamily of Tenrecidae.

Family Chrysochloridae (golden moles)

Miocene to Recent; Africa. Two digits on front feet with enormously enlarged claws; proximal segments of arm recessed into sides of thorax; heart and lungs elongated; zalambdodont molars; complete zygomatic arch composed of maxillary rather than jugal bone. Eyes covered with skin; tail rudimentary; pelage with metallic sheen or iridescence. Fossorial. Five genera, 11 species.

Family Macroscelididae (elephant shrews)

Miocene to Recent, Africa. Cecum well-developed; feet greatly elongated; molars quadrate and high-crowned; eyes large; auditory bullae complete, including entotympanic bone; zygomatic arch complete; resembling long-snouted kangaroo rats or jerboas. Diurnal, terrestrial, saltatory, animalivorous and phytophagous. Five genera, about 28 species.

Family Tupaiidae (tree shrews)

Paleocene to Recent, tropical southeast Asian mainland, Sumatra, Borneo, Philippines. Small cecum; orbital fossa ringed with bone; zygomatic arch complete; molars quadrate with W-shaped crests; eyes large; audital bulla includes entotympanic bone; generally like a long-nosed squirrel in appearance and behaviour. Terrestrial and arboreal; diurnal or nocturnal. Five genera, 15 species.

In addition to the above, 14 families of primitive extinct mammals are sometimes assigned to the Insectivora. These families, with their geologic time spans, are listed below.

Family Dimylidae. Oligocene–Palcocene.
Family Picrodontidae. Paleocenc.
Family Zalambdalestidae. Cretaceous.
Family Leptictidae. Cretaccous–Oligocenc.
Family Adapisoricidae. Paleocenc–Miocene.
Family Pantolestidae. Paleocene–Oligocene.
Family Apternodontidae. Eocene–Oligoccne.
Family Apatemyidae. Paleoccne–Oligocene.
Family Mixodectidae. Paleocene.
Family Anagalidae. Eocenc–Oligocene.
Family Paroxyclaenidae. Eocene–Oligocene.
Family Ptolemaiidae. Oligocene.
Family Pentacodontidae. Paleocene–Eocenc.
Family Plesiosoricidae. Eocene–Pliocene.

Critical appraisal. It is possible, though current opinion does not support it, that insectivores with zalambdodont teeth (tenrecs, solenodons, golden moles) form a monophyletic unit descended from either pre-tritubercular Mesozoic (Jurassic, about 190,000,000 years ago) pantotheres or the zalambdodont deltatheridiids of late Cretaceous and Paleocene times. More likely, zalambdodont teeth were derived from the tritubercular type seen in leptictids. Zalambdodont and dilambdodont teeth represent different ways of increasing the length of shearing edge of a tritubercular tooth. Tupaiids and macroscelidids share a number of traits that have led some authorities to separate them as a group called Menotyphla, while grouping the other insectivores as the Lipotyphla. Some authorities have considered the colugos (Cynocephalidae) to belong in the Insectivora, but most now place them in a separate order, Dermoptera. Tupaiids share some traits with primitive primates and have been included in that order by some prominent authorities (see, for instance, the section *Primates*). Elephant shrews have many of these same traits, however, and would have to be included in the Primates as well. Some mammalogists treat the elephant shrews as a distinct order, Macroscelidea (see section *Mammalia*). A growing body of evidence suggests that soricids, talpids, erinaceids, solenodons, tenrecs, otter shrews, and possibly chrysochlorids form a naturally related group to which the ordinal or subordinal term Lipotyphla should apply. This group, as well as elephant shrews, tree shrews, primates, bats, and others, apparently have been separate from one another since earliest Tertiary times, and consistency may in the end dictate assignment of a separate ordinal name to each. (J.Fi.)

The Lipotyphla

Chiroptera (bats)

Bats, which comprise the mammalian order Chiroptera, are the only mammals to have evolved true flight. This ability, coupled with the benefits deriving from their system of acoustic orientation (so-called bat sonar), has made the group a successful one in numbers of species and individuals. About 900 species are currently recognized, belonging to some 174 genera. Many species are enormously abundant. Observers have concluded, for example, that some 100,000,000 female Mexican free-tailed bats (*Tadarida brasiliensis mexicana*) form summer nursery colonies in Texas, where they produce about 100,000,000 young in five large caves. Adult males of this species, although equal to the females in numbers, may not range as far north as Texas. (Individuals of the species also range widely throughout tropical America.) Thus, bats of one species alone number at the very least in the hundreds of millions of individuals.

GENERAL FEATURES

Most bats are insectivorous. Little is known of the spectrum of insect species consumed, but the quantities are formidable. The Mexican free-tailed bats of Texas have been estimated to consume about 20,000 tons of insects per year. Bats would thus seem to be important in the balance of insect populations and possibly in the control of insect pests. Some bats feed on fruit and aid in dispersing seeds; others feed on pollen and nectar and are the principal or exclusive pollinators of a number of tropical and subtropical plants. The true vampires of tropical America feed on the blood of large birds and mammals, occasionally becoming significant pests of livestock and sometimes serving as carriers of rabies.

Certain aspects of the physiology of some bats, particularly those involving adaptations for long hibernation, daily lethargy, complex temperature regulation, acoustical orientation, and long-distance migrations, are of interest to experimental scientists.

In tropical countries, in particular, large colonies of bats often inhabit houses and public buildings, attracting attention by their noisiness, guano (droppings), and collective odour. In the West, bats have been the subject of unfavourable myths; in parts of the Orient, however, these animals serve as symbols of good luck, long life, and happiness.

Noxious bats

Diversity of structure. All bats have a generally similar appearance in flight, dominated by the expanse of the wings, but they vary considerably in size. The order is usually divided into two well-defined suborders: the Megachiroptera (Old World) and the Microchiroptera (worldwide). Among members of the Megachiroptera, a flying fox, *Pteropus vampyrus,* may have a wingspread of about 1.5 metres (about five feet) and a weight of about one kilogram (2.2 pounds). The largest insectivorous bat is probably *Cheiromeles torquata;* it weighs about 250 grams (about nine ounces). The largest of the carnivorous bats (and the largest bat in the New World) is *Vampyrum spectrum,* with a wingspread of over 60 centimetres (24 inches). The tiny Philippine bamboo bat, *Tylonycteris pachypus meyeri,* has a wingspread of barely 15 centimetres (six inches) and weighs about 1.5 grams (about 0.05 ounce).

Bats vary in colour and in fur texture. Facial appearance, dominated by the muzzle and ears, varies strikingly with family and often with genus. In several families, a

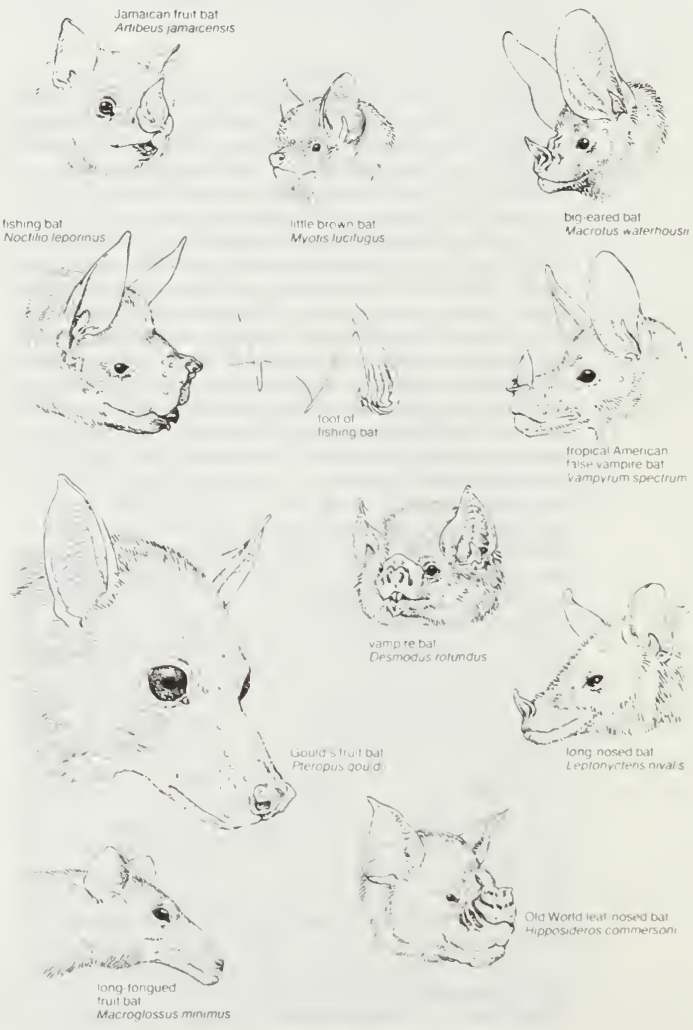

Figure 17: Heads of various bats.

complex fleshy adornment called the nose leaf surrounds the nostrils. Wing proportions are modified according to modes of flight. The tail and the interfemoral (between the legs) membrane also differ, perhaps with feeding, flight, and roosting habits. Finally, at the roost, bats vary in the postures they assume, particularly in whether they hang suspended or rest on the wall and in the manner in which the wings are folded and used.

Distribution. Bats are particularly abundant in the tropics. In West Africa, for example, 31 genera embracing 97 species have been catalogued; in the United States 15 genera, totalling 40 species, are known. Of the 17 living families, three (the Vespertilionidae, Molossidae, and Rhinolophidae) are well represented in the temperate zones. A few phyllostomatid species range into mild temperate regions. Several vespertilionids range well into Canada.

The Vespertilionidae are found worldwide, excepting only the Arctic and sub-Arctic, Antarctic, and isolated islands. The genus *Myotis* has a range almost equal to that of the order. The Molossidae and Emballonuridae also encircle the earth but are restricted to the tropics and subtropics. The Rhinolophidae extend throughout the Old World, the Hipposideridae and Pteropodidae throughout the Old World tropics, and the Phyllostomatidae throughout the New World tropics and slightly beyond. The other families have more restricted ranges.

IMPORTANCE TO MAN

Bats are important to man primarily because they affect other living things through predation, pollination, and seed dispersal. Although losses of commercially valuable fruit are normally small, bananas and figs must, in some cases, be protected by early harvest or by nets. Vampire bats are considered serious pests of livestock in some parts of tropical America, because the small wounds they cause provide egg-laying sites for botflies and because the vampires may transmit rabies and trypanosomiasis to cattle. Other bats also carry rabies or related viruses.

Bat guano as fertilizer

The guano deposits of insectivorous bats are used for agricultural fertilizer in many countries and, in the past, were used as a source of nitrogen and phosphorus for munitions. Large guano deposits, in addition, cover and thus preserve many archaeologically interesting artifacts and fossils in caves.

In some parts of Southeast Asia and on some Pacific islands, flying foxes (*Pteropus*) are hunted for food. Small bats are also widely but irregularly eaten.

In species and numbers, bats constitute an important and, on the whole, nonintrusive part of wildlife. Several zoos have established interesting exhibits of bats; indeed, some flying foxes and fruit bats have been exhibited in European zoos since the mid-19th century. Bats are interesting pets and have been kept widely for research purposes but require somewhat specialized care.

NATURAL HISTORY

Life cycle. Details of the life cycle are known for only a few species from North America or Europe. In these, there is an annual cycle of sexual activity, with birth taking place between May and July. In males, the testes, normally located in the abdominal region, descend seasonally into the scrotum, and active spermatogenesis occurs. In females, sexual receptivity may be associated with egg maturation and release. Tropical bats may exhibit a single annual sexual cycle or may be diestrous (*i.e.,* with two periods of fertility) or polyestrous (with many).

The sexual cycles of entire populations are closely synchronized, so that almost all mating activity occurs within a few weeks. The periods of development (gestation), birth, lactation, and fledging are also usually synchronized. Gestation varies in duration: five or six months in *Pteropus,* more than five months in *Desmodus,* three months in some small *Hipposideros,* and six or seven to 14 weeks in several small vespertilionid genera. The length of gestation may be influenced by ambient (surrounding) and body temperature.

In several North American and Palaearctic (northern Eurasian) vespertilionids and rhinolophids that hibernate, copulation occurs in the fall, and the sperm are stored in the female genital tract until spring. Ovulation, fertilization, and implantation occur after emergence from hibernation, when the female again has available an abundant food supply and warm roost. The favourable environmental conditions greatly enhance the young bat's chances of survival.

Most bats bear one young, but the big brown bat (*Eptesicus fuscus*) may bear twins, and the red bat (*Lasiurus borealis*) bears litters of one to four.

At birth the young, who may weigh from one-sixth to one-third as much as the mother, usually have well-developed hindlegs with which they hold on to their mother or to the roost. The wings are very immature. The young, nude or lightly furred, are often briefly blind and deaf. Female bats normally have one pectoral (at the chest) or axillary (at the armpit) mammary gland on each side. Several families that carry their young while foraging also have a pair of false pubic nipples, which the infant may hold in its mouth when its mother flies. The infants are nourished by milk for a period of about five or six weeks in many small Microchiroptera and for five months in *Pteropus giganteus.* By two months of age, most of the Microchiroptera have achieved adult size, having begun to fly and forage three or four weeks earlier.

Nursery roosts

In many species, females late in pregnancy migrate to special nursery roosts, in which large numbers of pregnant females may aggregate, usually to the exclusion of nonpregnant females, males, and bats of other species. In some cases, the nursery roosts seem to be chosen for their high temperature, which may derive from the sun, the bats themselves, or from decomposing guano. When foraging, some bats (*Erophylla*) leave their infants hanging quietly, one by one, on the cave wall or ceiling. In other cases (*Tadarida brasiliensis, Natalus*), the closely spaced infants may move about and mingle on the wall. Among others, especially molossids in buildings, the infants may form play groups and rough-and-tumble on the floor. Some bats carry their young with them. Generally, each mother, on returning to her roost, seeks out her own child by position, smell, and acoustical exchange. In the huge nursery colonies of *Tadarida brasiliensis mexicana* and *Miniopterus schreibersii,* however, the mothers appear to feed the first one or two infants they encounter on returning. This is called the milk-herd system.

Mother dog-faced fruit bat (*Cynopterus sphinx*), with clinging young, in flight.

Some bats achieve sexual maturity in the first year; others in the second year. Infant mortality appears to be high. Developmental and genetic errors and disease take their toll, but accidents seem to cause more serious losses—the young may fall from the ceiling or have serious collisions in early flight attempts. A fair number of bats probably fail to make the transition from dependent infants to self-sufficient foragers.

Life-span

Adult bats have low mortality. Predation is rarely serious, especially for cave-dwelling species. Disease, parasitic infestation, starvation, and accidents apparently take small

tolls. There are records of several big brown (*Eptesicus fuscus*), little brown (*Myotis lucifugus*), and greater horseshoe bats (*Rhinolophus ferrum-equinum*) that have lived more than 20 years. Probably many bats in temperate climates live more than 10 years. Longevity has not been established for tropical species.

Several factors probably contribute to the unusual longevity of bats. Generally isolated roosts and nocturnal flight substantially protect them from predation, from some elements of weather, and from exposure to the sun. The largely colonial way of life may ensure that entire populations experience contagious infection and subsequent immunity; indeed, such a pattern may, in the past, have hastened adaptation to disease. The persistent use of various seasonal roosts probably ensures isolation and security, food and water supply, and access to mates. Many bats, moreover, drop their body temperature at rest. Not only is there a probability that this conserves some cellular "machinery," since metabolism is reduced, but fewer hours need be spent in actively seeking food and water.

Behaviour. *Activity patterns.* Nocturnal activity is a major feature of the behavioural pattern of bats: nearly all species roost during the day and forage at night. Carnivorous bats, vampires, and perhaps fishing bats may have an advantage at night over inactive or sleeping prey. In addition, nocturnal flight protects bats from visual predators, exposure to the sun, high ambient temperature, and low relative humidity. The large area of naked wing skin might mean that bats would absorb rather than radiate heat, if they were active during the day. They would also lose body water required for temperature regulation and would then be forced to forage near water or to carry extra water in flight.

The nocturnal-activity pattern in bats is probably kept in synchrony with changing day lengths by their exposure to light at dusk or dawn. Bats often awaken and fly from the cave exit well before nightfall. Should they be too early, their internal clock may be reset. A few species of bats, *Lavia frons* and *Saccopteryx bilineata*, may forage actively during the day, but little is yet known of their special adaptations.

Locomotion. Flight is the primary mode of locomotion in all bats, although the flight styles vary. Some groups (the Molossidae, for example), adapted for flight in open spaces and often at high altitudes, have long, narrow wings, swift flight, and a large radius of turning. Other bats (the Nycteridae, Megadermatidae, and the Glossophaginae), adapted for hovering as they pick prey off vegetation or feed on flowers, have short, broad wings, slow flight, and a small radius of turning. Some bats take flight easily from the ground: members of the genus *Macrotus* do so simply by flapping, vampires (*Desmodus*) leap into the air and then spread their wings and fly. The molossids, however, roost well above the ground since, on takeoff, they fall before becoming airborne.

Speed in flight

Though flight speeds in nature are hard to measure, four vespertilionid species, carefully observed, have been timed on the average at 18.7 to 33.3 kilometres (11.7 to 20.8 miles) per hour. In flight, the posture of each of the four fingers incorporated into the wing is under precise and individual control. Finger and arm postures, which determine the shape, extension, and angle of the wings, govern such actions as turning, diving, landing, and hovering. Except when interrupted by insect catches or obstacles, bat flight paths are straight. Insects may be pursued and captured at a rate of up to two per second; during each catch, the flight path is interrupted and thus appears erratic.

In many cases (especially in the families Nycteridae, Megadermatidae, Rhinolophidae, and Hipposideridae), there is little locomotion other than flight. These bats may move across the cave ceiling from which they hang, by shifting their toehold, one foot at a time. A few genera (especially among the Pteropodidae) may crawl along branches, in a slothlike posture, using their thumb claws as well as their feet. The Emballonuridae and Rhinopomatidae hang on vertical surfaces suspended by their hind claws, but with their thumbs and wrists propped against the surface. In this orientation, they can scramble rapidly up or down and forward or backward, as well as sideways.

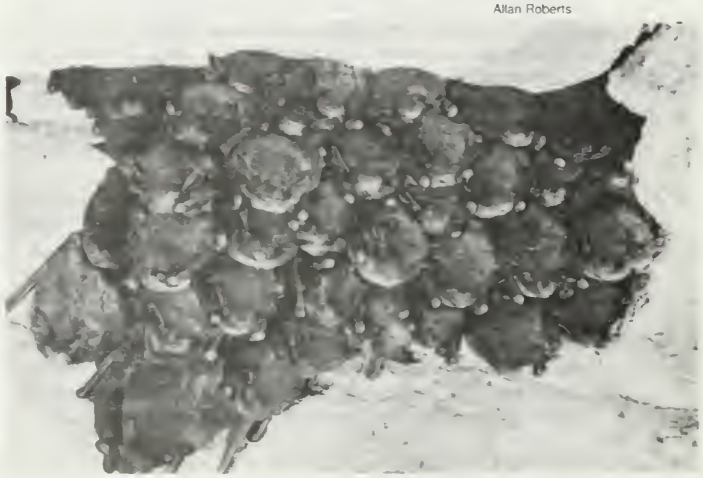
Bats of many genera (Vespertilionidae, Molossidae, Noctilionidae, Desmodontidae) walk or crawl on either horizontal or vertical surfaces using hindfeet, wrists, and thumbs. Many move freely either backward or forward, a convenience for entering and leaving crevices. The vampires may also leap from roost to roost. The Thyropteridae and Myzopodidae, as well as the vespertilionid *Tylonycteris*, have specialized wrist and sole pads for moving along and roosting on the smooth surface of leaves or bamboo stalks.

Bats are not known to swim in nature except, perhaps, by accident. When they do fall into the water, however, they generally swim competently.

Roosting. Bats choose a variety of diurnal roosts. Each species favours a particular kind of roost, though this varies with sex, season, and reproductive activity. Many bats favour isolated or secure roosts—caves, crevices in cliff faces, the interstices of boulder heaps, tree hollows, animal burrows, culverts, abandoned buildings, portions of buildings inaccessible to man (*i.e.*, roof, attic, hollow wall), and the hollow core of bamboo stalks. Some species roost externally—on tree trunks or in the branches of trees, under palm leaves, in unopened tubular leaves, or on the surface of rocks or buildings. For some, the darkness, stability of temperature and humidity, and isolation from predators provided by caves and crevices seem essential. Others prefer the heat and dryness of sun-exposed roosts. Many species choose special nursery or hibernation roosts. Buildings are so widely exploited by bats (especially Vespertilionidae, Molossidae, and Emballonuridae) for regular diurnal or nursery roosts that the numbers of many species have probably become more abundant since the advent of architecture. Many bats also occupy nocturnal roosts, often rocky overhangs or cave entrances, for napping, for chewing food, or for shelter from bad weather.

Bats are usually colonial; indeed, some form very large

Allan Roberts



Indiana bats (*Myotis sodalis*) hibernating on a cave roof.

cave colonies. Generally, large colonies are formed by bats that roost in dense clusters, pressing against one another, although many roost spaced out, not touching. In trees, *Pteropus* may form outdoor camps numbering hundreds of thousands of individuals. Many species form smaller groups of several dozen to several hundred. Less commonly, bats are solitary; sometimes, the adult female roosts only with its most recent child. Occasionally one sex is colonial, and the other is apparently solitary. Some species regularly form mixed colonies (*e.g.*, *Mormoops* and *Chilonycteris* with *Leptonycteris*, *Monophyllus*, *Carollia*). The advantages of colonial or solitary life and the factors that govern colony size in bats with colonial predilection have not yet been established.

The roost requirements of many bats, rather precise in terms of light, temperature, and humidity, limit their distribution in space. Some of the Megachiroptera strikingly defoliate the trees on which they roost.

Elaborate communities of other animals are often satellites of cave-bat colonies. Among these are cave crickets, roaches, blood-sucking bugs, a variety of parasites (*e.g.*,

fleas, lice, ticks, mites, and certain flies), and dermestid beetles and other insects that feed on cave-floor debris—guano, bat and insect corpses, and discarded pieces of food or seeds. Molds and other fungi are also conspicuous members of the cave-floor community. Bats and their excretions alter the cave environment by producing heat, carbon dioxide, and ammonia.

Migration. Many bats of temperate climates migrate annually to and from summer roosts and winter hibernation sites, with an individual often occupying the same roosts in seasonal sequence each year. Members of the same species may converge on a single hibernation cave or nursery roost from many directions, indicating that the choice of migration direction to and from these caves cannot be genetically determined. Migration time probably is genetically determined (*i.e.,* instinctive) and influenced also by weather conditions and the availability of food. Nothing is known of how migration goals are recognized or how their location is learned by succeeding generations. Female young, of course, are born at a nursery roost and may memorize its location, but how they know where to go at other times of year is not clear.

Separation of male and female migrants

Female Mexican free-tailed bats migrate from Central Mexico to Texas and adjacent states each spring, returning south in the fall. Mating probably occurs in transient roosts during the spring flight. The migration is believed to remove pregnant (and lactating) females to a region of high food supply where they need not compete with males of their own species. Presumably they return to Mexico for its suitable winter climate and food supply and to meet their mates.

The North American red and hoary bats (*Lasiurus borealis* and *L. cinereus*) and the silver-haired bat (*Lasionycteris noctivagans*) migrate in the fall from the northern U.S. and Canada to the southern states, returning in spring. Little is yet known of energy storage, navigation, or other specializations for migrations.

Orientation. Bats of the suborder Microchiroptera orient acoustically by echolocation ("sonar"). They emit short, high-frequency pulses of sound (usually well above the range of human hearing) and listen to the echoes returning from objects in the vicinity. By interpreting returning echoes, bats may identify the direction, distance, velocity, and some aspects of the size or nature or both of objects that draw their attention. Echolocation is used to locate and track flying and terrestrial prey, to avoid obstacles, and possibly to regulate altitude; orientation pulses may also serve as communication signals between bats of the same species. Bats of the megachiropteran genus, *Rousettus,* have independently evolved a parallel echolocation system for obstacle avoidance alone. Echolocation pulses are produced by vibrating membranes in the larynx and emitted via the nose or the mouth, depending upon species. Nose leaves in some species may serve to channel the sound.

The principle of echolocation

The echolocation signals spread in three dimensions on emission, the bulk of the energy in the hemisphere in front of the bat or in a cone-shaped region from the nostrils or mouth. When the sound impinges on an intervening surface (an insect or a leaf, for example) some of the energy in the signal is reflected or scattered, some absorbed, and some transmitted and reradiated on the far side; the proportion of sound energy in each category is a function of wavelength and of the dimensions, characteristics, and orientation of the object. The reflected sound spreads in three dimensions, and some portion of it may impinge on the bat's ears at perceptible energy levels.

Bats' external ears are generally large, probably enhancing their value for detecting direction of incoming signals, and their middle and inner ears are specialized for high-frequency sensitivity. In addition, the bony otic (auditory) complex is often isolated acoustically from the skull, probably enhancing signal comparison by both ears. The threshold and range of hearing have been studied in several genera of bats, and, in each case, the region of maximum sensitivity coincides with the prominent frequencies of the outgoing echolocation signals.

The characteristics of echolocation pulses vary with family and even with species. Echolocation pulses of a substantial number of bat species have been analyzed in terms of frequency, frequency pattern, duration, repetition rate, intensity, and directionality. The prominent frequency or frequencies range from 12 kiloHertz (one kiloHertz is equivalent to 1,000 cycles per second) to about 150 kiloHertz or more. Factors influencing frequency may include bat size, prey size, the energetics of sound production, inefficiency of propagation of high frequencies, and ambient noise levels.

Orientation pulses may be of several types. The individual pulse may include a frequency drop from beginning to end (frequency modulation, FM) or the frequency may be held constant (CF) during part of the pulse, followed by a brief FM sweep; either FM or CF pulses may have high harmonic content. The pulse duration varies with the species and the situation. In cruising flight, the pulses of the Asian false vampire (*Megaderma lyra*) are 1.5 milliseconds (0.0015 second), those of Dobson's mustache bat (*Chilonycteris psilotis*) 4 milliseconds, and those of the greater horseshoe bat 55–65 milliseconds. In goal-oriented flight, such as the pursuit of an insect or the evaluation of an obstacle or a landing perch, the pulse duration is systematically altered (usually shortened) with target distance, sometimes ending with pulses as short as 0.25 millisecond.

During insect pursuit, obstacle avoidance, and landing manoeuvres, there are three phases of pulse output design: search, approach, and terminal. The search phase, during which many bats emit about 10 pulses per second, precedes specific attention to a target. In the approach phase, which starts when the bat detects an object to which it subsequently devotes its attention, the bat raises the pulse rate to about 25 to 50 per second, shortens the pulses with decreasing distance, and often alters the frequency pattern. The terminal phase, which often lasts about 100 milliseconds, is characterized by extremely short pulses, repeated as rapidly as 200 or more per second, and ceases as the bat intercepts the target or passes it (the stimulus being, perhaps, the cessation of echoes); another search phase follows. During the brief terminal phase (a fraction of a second), the bat is engaged in final interception (or avoidance) manoeuvres and appears to pay little attention to other objects.

The use of echolocation to gain sensory information requires integration of the vocal and auditory centres of the brain, in addition to sensitive ears. Not only must the nervous system of the bat analyze in a few thousandths of a second the reflected, and thus altered, form of its own pulse, but it must separate this echo from those of other individuals and from others of its own pulses. All of this must be done while the animal (and often the target) is moving in space. In the laboratory, bats have been found to be able to identify, pursue, and capture as many as two fruitflies (*Drosophila,* about three millimetres [0.12 inch] long) per second, and to locate and avoid wires as fine as 0.1 or even 0.08 millimetre (0.004 or 0.003 inch) in diameter.

Capabilities of bat sonar

Research has provided some information on the mechanisms of bat sonar. There is evidence that the multiple frequencies of FM or harmonic patterns serve in determining target direction. The relative intensities of the various frequencies will be different at the two ears, allowing the animal to determine target direction when three or more frequencies are received. Target velocity may be measured by constant-frequency bats through the use of the Doppler shift, a change in perceived frequency due to the relative motion of the bat and its target. Changes in pulse–echo timing may provide information on target distance and velocity. The ratio of useful signal to background noise is increased by several mechanisms, including specializations of the middle ear and its ossicles (tiny bones), isolation of the cochlea (the area where sound energy is converted into nerve impulses), and adaptations of the central nervous system.

Food habits. Most bats feed on flying insects. In some cases, prey species have been identified from stomach contents or from discarded pieces under night roosts, but such studies have not yet provided an adequate measure of the spectrum of bat diets.

Insects are identified and tracked in flight by echolocation. Large insects may be intercepted with the wing membranes and pulled into the mouth. Some moths, however, (Noctuidae, Arctiidae) are able to avoid capture by bats.

Some genera of bats (*Macrotus, Antrozous, Plecotus, Nycteris*) feed on arthropods, such as large insects, spiders, and scorpions, which they find on the ground, on walls, or on vegetation. These bats may either land on and kill their prey before taking off with it or pick it up with their teeth while hovering.

Fishing by bats

Three genera (*Noctilio, Pizonyx,* and *Myotis*) include at least one species that catches small fish and possibly crustaceans. All fish-eating species also feed on flying insects or have close relatives who do so. Each is specialized in having exceptionally large hindfeet armed with long, strong claws with which the fish are gaffed.

The Megachiroptera and many of the phyllostomatid genera feed on a variety of fruits, often green or brown in colour; usually such fruits are either borne directly on wood or hang well away from the bulk of the tree and have a sour or musky odour.

The pteropodid subfamily Eonycterinae (and some other fruit bats) and the phyllostomatid Glossophaginae feed, at least in part, on nectar and pollen. Many tropical flowers, adapted for pollination by these bats, open at night, are white or inconspicuous, have a sour, rancid, or mammalian odour, and are borne on wood, on pendulous branches, or held beyond or above the bulk of the plant. The phyllostomatid Phyllonycterinae may also feed on flowers.

Several phyllostomatid and megadermatid genera are carnivorous, feeding on small rodents, shrews, bats, sleeping birds, tree frogs, and lizards. The true vampires, which feed on the blood of large mammals or birds, land near a quiet prospective victim, walk or jump to a vulnerable spot on it where the skin is relatively exposed—the edge of the ear or nostril, around the anus, or between the toes, for example—make a scooping, superficial bite from which the blood oozes freely, and lap the blood with very specialized tongue movements. Each vampire requires about 15 millilitres (about one cubic inch) of blood per night.

The interaction of bats with their food, be it insects, fruit, or flowers, probably has a substantial impact on some biological communities. Many plants are dependent on bats for pollination; other plants benefit from seed dispersal by bats. Moths of two families are known to take evasive or protective action on hearing bat pulses nearby, an adaptation that implies heavy predation.

Maintenance behaviour. Bats are meticulous in their grooming, spending a fair part of the day and night combing and grooming their fur and cleansing their wing membranes. Generally they comb with the claws of one foot, while hanging by the other; they remove the combings and moisten their claws with their lips and tongue. On the wing membranes, in particular, they use the mouth meticulously, perhaps oiling the skin with the secretions of dermal (skin) glands while cleansing it.

Social interactions. Bats often segregate by sex. As noted, in many species, pregnant females occupy special nursery roosts until their young are independent. In some species, the sexes occupy the same general roost but gather in separate clusters. In others, the sexes intermingle or arrange themselves into a pattern within a group—the females centrally, for example, and the males peripherally. Sexual segregation during foraging has been reported for several species. Among bats that migrate over long distances, such as Mexican free-tailed, red, and hoary bats, the sexes may meet only briefly each year.

FORM AND FUNCTION

Anatomical specializations. Bats are mammals with front limbs modified for flight. The fingers, other than the thumb, are greatly elongated and are joined by a membrane that also extends from the posterior border of the forearm and upper arm to the side of the body and leg as far as the ankle or foot. Only the thumb, and occasionally the index finger, end with a claw. The wing membrane consists of two layers of skin, generally darkly pigmented and naked, between which course blood vessels and nerves.

Structure of the wing

When not fully extended, the wing skin is gathered into wrinkled folds by elastic connective tissue and muscle fibres. Some of the fingers, especially the third, fold over when the bat is not in flight; the wing may then be quite tightly folded or may partly enfold the bat's undersurface. The thumb, always free of the wing membrane, is used for walking or climbing in some species; in others, it is used for handling food. Bats that walk often have pads or suction disks on their thumbs or wrists or both, and many female bats use the thumbs for suspending themselves, hammock fashion, when giving birth.

Wing shape, governed by the relative lengths of the forearm and the fingers, varies greatly, in adaptation to flight characteristics.

Most bats have a membrane, consisting of skin like

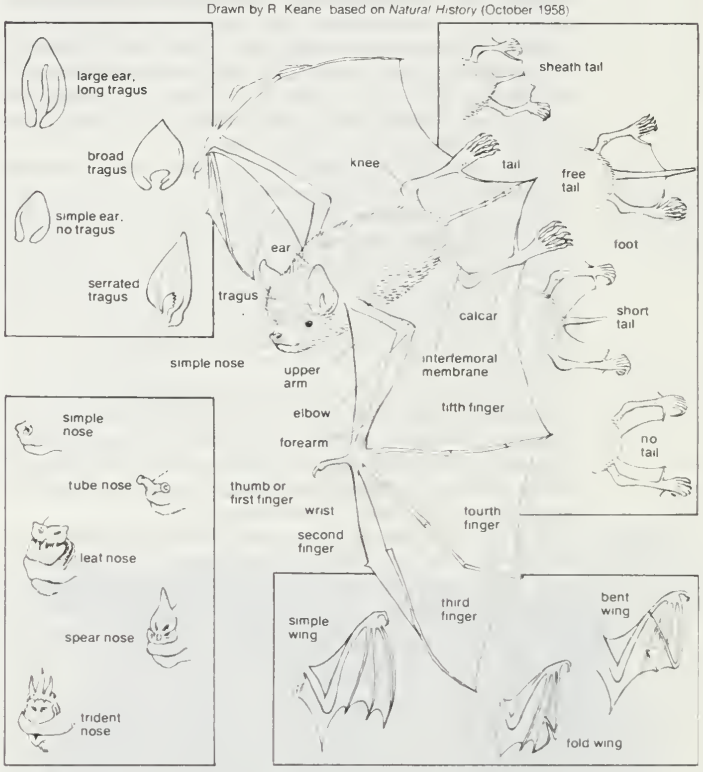


Figure 18: Typical microchiropteran bat (*Myotis*). Insets show variations of structures found in other bats.

the wings, that extends between their legs (interfemoral membrane). In the midline, the interfemoral membrane is usually supported, at least in part, by the tail, and the distal edges are often shaped in flight by greatly elongated heel bones. The interfemoral membrane, especially well developed in insectivorous, carnivorous, and fish-eating bats, is less well developed or even absent in the vampires and in fruit- and flower-feeding bats. Many bats in flight, on catching large prey, bring the membrane forward and by flexing the neck and back tuck the prey against and into the membrane while taking a new tooth hold. By this manoeuvre, the bat takes hold of the victim head first and is able to kill or disable it promptly.

At rest, a bat's head is its most striking feature. The pinna (projecting portion) of the external ear usually is extremely large and often funnel shaped. In several genera that feed on terrestrial arthropods, the ears are particularly oversized, probably for ultraprecise directional assessment. The tragus (a projection on the anterior side of the auditory canal) or antitragus (on the posterior side) may also be conspicuous. The ears are often highly mobile, sometimes flicking back and forth in phase with the production of sonar signals. In some species the ears are immobile, but, in all cases, they probably function jointly for directional analysis.

Shape of the face

Bats often have a muzzle of somewhat rodent-like or foxlike proportions but, in many, the face has a pushed in, pug-dog appearance. In the nectar feeders, the snout is elongated to house the long, extensible tongue. Many bats

have a facial ornament, the nose leaf, consisting of skin and connective tissue surrounding the nostrils and extending as a free flap or flaps above the nostrils and in front of the face. The complexity and shape of the nose leaf varies with family; its presence correlates with nasal emission of orientation signals. Thus, it is supposed that the nose leaf influences sound output, perhaps by narrowing the beam, but evidence is sparse.

A bat's neck is likely to be short and relatively immobile, the chest and shoulders large and well muscled, the hips and legs slender.

Most bats are well furred (except for the wing membranes), generally in shades of brown, tan, gray, or black on top and in lighter shades ventrally. Red, yellow, or orange variants occur in many species. Among species that roost in the open, speckled or mottled fur, bright or light-coloured spots or stripes, or bright red, yellow, or orange shading on the pendant head, neck, and shoulders are common. Mottled fur may blend with lichen-covered bark or rock. Bright spots may simulate the speckled sunlight of the forest canopy as seen from below. Stripes probably break up contours. The colouring seen while the animal is hanging may be a kind of countershading for concealment or it may enhance the bat's simulation of a ripening fruit or a dead leaf. Many bats who roost externally hang from a branch by one foot, which then looks like a plant stem.

Many bats have large dermal (skin) glands (the location of which depends on family), which secrete odorous substances that may serve as species or sex recognition signals. Some glands may also supply oils for conditioning the skin or waterproofing the pelage.

Lowering of body temperature

Thermoregulation. Although some bats maintain fairly even body temperatures, a large number undergo periodic raising or lowering of their temperature. Many of the vespertilionids and rhinolophids and a few molossids drop their body temperature to ambient temperature shortly after coming to rest (a condition called heterothermy). They raise their temperature again on being aroused or when readying themselves for nocturnal foraging. When fully active, bats have a body temperature of about 37° C (98.6° F). During pregnancy, lactation, and juvenile growth, bats probably thermoregulate differently, more closely approximating stability. The drop in body temperature, if the ambient temperature is relatively low, results in the bat's assuming a lethargic state. Energy is conserved by "turning down the thermostat," but the bat is rendered relatively unresponsive to threats by predators or weather. Heterothermic bats, therefore, generally roost in secluded, isolated sites, often in crevices, and have specializations for arousal. One or more sensory systems and the brain remain sensitive at low temperatures and initiate the necessary heat production for arousal. Heat is generated by the metabolism of brown fat and by shivering.

Many bats that exhibit daily torpor hibernate during the winter and must, therefore, store energy as body fat in the fall, increasing their weight by 50 to 100 percent. They must also migrate from the summer roost to a suitable hibernation site (often a cave); *i.e.,* one that will remain cool and humid but will not drop below freezing throughout the winter. Large populations often aggregate in such caves. Hibernation also involves the suspension of temperature regulation for long periods; adaptations of circulation, respiration, and renal function; and suspension of at least some aspects of diurnal activity. Bats of hibernating species generally court and mate in the fall when the males are at their nutritional peak.

Bats of several tropical families are homeothermic. A spectrum of degrees of homeothermy and heterothermy probably will be discovered in the order.

Digestion and water conservation. Digestion in bats is unusually rapid. They chew and fragment their food exceptionally thoroughly and thus expose a large surface area of it to digestive action. They may begin to defecate 30 to 60 minutes after beginning to feed, thus reducing the load that must be carried in flight.

Some bats live in sun-baked roosts without access to water during the day. They may choose these roosts for their heat, thus conserving body heat, but it is not yet known how they hold their body temperature down without using water. In the laboratory, bats die if body temperature rises above about 40–41° C (104°–106° F).

Use of the eyes

Senses. Bats have been considered in folklore to be blind. In fact, the eyes in the Microchiroptera are small and have not been well studied as yet. Among the Megachiroptera, the eyes are large, but vision has been studied in detail only in *Pteropus.* These bats are able to make visual discriminations at lower light levels than can man. The Megachiroptera fly at night, of course, and some genera fly below or in the jungle canopy where light levels are very low. Except for *Rousettus,* none are known to orient acoustically.

Studies of several genera of Microchiroptera have revealed that vision is of use in long distance navigation and that obstacles and motion can be detected visually. Bats also presumably use vision to distinguish day from night and to synchronize their internal clock with the local day-night cycle.

The senses of taste, smell, and touch in bats do not seem to be strikingly different from those of related mammals. Smell is probably used as an aid in locating fruit and flowers and possibly, in the case of vampires, large vertebrates. It may also be used for locating an occupied roost, colleagues of the same species, and individuals of the correct sex. Many bats depend upon touch, aided by well-developed facial and toe whiskers and possibly by the projecting tail, to place themselves in comforting body contact with rock surfaces or with colleagues in the roost.

EVOLUTION AND PALEONTOLOGY

The fossil record of bats prior to the Pleistocene (about 2,500,000 years ago) is limited and reveals little about bat evolution. Most fossils can be attributed to living families. Skulls and teeth compatible with early bats are known from the Paleocene (about 60,000,000 years ago), but these fossils may equally well have been from insectivores, from which bats are clearly separable only on the basis of adaptations for flight. By the middle Eocene (45,000,000 years ago) bats with full flight had evolved.

Two main evolutionary lines of bats

The Chiroptera are readily divided into two suborders—Megachiroptera and Microchiroptera. The Megachiroptera orient visually and exhibit a number of primitive skeletal features. The Microchiroptera orient acoustically. It is not certain that they have a common origin. The suborders either evolved separately from flightless Insectivora or diverged very early in chiropteran history.

The two principal geographic centres of bat evolution appear to be the Australo-Malaysian region, with about 290 species, and the New World tropics, with about 230 species. Comparable ecological niches in the Old and New World are largely occupied by different genera of bats, usually of different families.

CLASSIFICATION

Distinguishing taxonomic features. The order Chiroptera is defined by true flight. The elongated finger bones support the wing membrane. Bats are also characterized by their generally small size, marked pectoral specialization for flight, and relatively weak pelvic and leg development. The ulna is reduced, claws are absent on fingers except for the thumb (and occasionally the second finger), and the knee is directed posteriorly and laterally. The maximum complement of milk teeth is 22 and of permanent teeth, 38; the minimum of permanent teeth is 20. The dental formula indicates the number of pairs of upper and lower incisors, canines, premolars, and molars, respectively, and total number of teeth.

Annotated classification.

ORDER CHIROPTERA

Eighteen living families, 174 genera, and about 900 living species.

Suborder Megachiroptera

One family.

Family Pteropodidae (flying foxes and Old World fruit bats)

Generally large, fruit- or flower-feeding; lack acoustic orientation (except *Rousettus*); ears small, eyes large, vision well-developed; generally roost in trees, often colonial; often show countershading, cryptic markings, or bright fur colours or patterns. Index finger generally clawed, tail short or lacking, inter-

femoral membrane reduced. Muzzle simple in appearance (except *Hypsignathus*). Generally cannot walk but can move along branches in hanging posture. Forearm length varies from 37 mm (1.46 inches; *Macroglossus*) to 220 mm (8.66 inches; *Pteropus vampyrus*). Teeth modified for fruit- and flower-feeding. Dental formula $\frac{(1–2) \cdot 1 \cdot 3 \cdot (1–2)}{(0–2) \cdot 1 \cdot 3 \cdot (2–3)} = 24–34$. Old World tropics and subtropics, including many Pacific islands; 39 Recent genera, about 154 species.

Suborder Microchiroptera

Seventeen families.

Family Rhinopomatidae (mouse-tailed bats)

Small, insectivorous. Tail very long and largely free beyond a narrow interfemoral membrane, forearm very long, ears large, small nose leaf, primitive shoulder girdle. Dental formula $\frac{1 \cdot 1 \cdot 1 \cdot 3}{2 \cdot 1 \cdot 2 \cdot 3} = 28$. Store fat (probably on a seasonal basis). Roost on vertical surfaces, probably not in total darkness or isolation. Tropical distribution from northern Africa through southern Asia as far as Sumatra; 1 genus, 3 species. Generally considered to be the most primitive of all living Microchiroptera.

Family Emballonuridae (sheath-tailed or sac-winged bats)

Small to medium size. Ears large but simply shaped, eyes small, muzzle sharp but plain; tail short, perforating dorsal surface of well-developed interfemoral membrane. Several genera have a glandular pouch in the wing extension, anterior to the arm. Relatively unspecialized shoulder girdle and arm articulation. Dental formula $\frac{2 \cdot 1 \cdot 2 \cdot 3}{3 \cdot 1 \cdot 2 \cdot 3} = 34$, $\frac{1 \cdot 1 \cdot 2 \cdot 3}{3 \cdot 1 \cdot 2 \cdot 3} = 32$, or $\frac{1 \cdot 1 \cdot 2 \cdot 3}{2 \cdot 1 \cdot 2 \cdot 3} = 30$. Insectivorous. Roost on vertical surfaces, such as tree trunks, cliff faces, cave entrances, and walls; some favour buildings, especially belfries. Some densely colonial but not touching one another; others form small groups or are solitary. Hang suspended from toes with wrists propped against wall. Worldwide tropical distribution (excluding West Indies and some Pacific islands); 12 genera, about 50 species; each genus restricted to either Old or New World.

Family Nycteridae (slit-faced or hollow-faced bats)

Small to medium size. The humerus and pectoral girdle not greatly specialized, skull with peculiar nasal fossa (depression), cleft nose leaf, and a deep midline facial cleft behind and above the nostrils. Ears large, wings broad, tail long with bifid (split) end, calcars (heel bones) greatly elongated, tail and calcars supporting well-developed interfemoral membrane. Dental formula $\frac{2 \cdot 1 \cdot 1 \cdot 3}{3 \cdot 1 \cdot 2 \cdot 3} = 32$. Insectivorous, mostly preying on terrestrial forms or those resting on vegetation, rocks, or walls. Cannot walk. Roosts usually dark and humid, some species roosting externally in jungle canopy. Generally form small nontouching colonies, but some are solitary. Distributed through most of tropical Africa, Malaysia, and Indonesia; 1 genus, 13 species.

Family Megadermatidae (false vampires)

Moderately large bats. External ears very large and fused across midline; tragus bifid; nose leaf large with truncated end; eyes relatively large; wings broad, interfemoral membrane well-developed and supported distally by heel bones, no external tail. Females bear false inguinal nipples. Premaxillae lacking; dental formula $\frac{0 \cdot 1 \cdot (1–2) \cdot 3}{2 \cdot 1 \cdot 2 \cdot 3} = 26–28$. Insectivorous, principally on terrestrial arthropods, as in Nycteridae; at least 2 species, *Megaderma lyra* and *Macroderma gigas*, also feed on small vertebrates hunted and taken in the same fashion as arthropod prey. Cannot walk. Form small nontouching colonies usually in dark, secluded caves or abandoned buildings. *Lavia frons* are at least partly diurnal and roost in trees in the savanna and open forest. Central Africa, Southeast Asia, and Australia; 4 genera, 5 species.

Family Hipposideridae (Old World leaf-nosed bats)

Small to large bats. Complex nose leaf with subordinate leaflets and compartments; large ears, widely separated and highly mobile, antitragus well-developed; interfemoral membrane well-developed, tail generally projecting slightly beyond distal edge of membrane. Often bear glandular pouch on forehead; females have false inguinal nipples. Dental formula $\frac{1 \cdot 1 \cdot 2 \cdot 3}{2 \cdot 1 \cdot 2 \cdot 3} = 30$. Colour usually drab brownish but red phases not uncommon. Insectivorous, usually on flying insects. Mostly colonial, nontouching, and roosting in humid caves, tree hollows, culverts, or buildings. A few roost externally in branches of trees, a few are solitary. Do not walk. Old World tropics; 9 genera, about 60 species, the genus *Hipposideros* particularly successful in numbers of species and individuals throughout the Old World tropics.

Family Rhinolophidae (horseshoe bats)

Small to moderately large size. Complex nose leaf; large, highly mobile ears, well-developed antitragus; wings short and rounded; well-developed interfemoral membrane, supported by tail; calcanea (backs of heels) weak. Fur generally brown (red phases occur). Females bear false inguinal nipples. Dental formula $\frac{1 \cdot 1 \cdot 2 \cdot 3}{2 \cdot 1 \cdot 3 \cdot 3} = 32$. Dark, humid roosts selected, especially caves, but tree hollows, buildings, and culverts as well. Generally colonial, nontouching. Cannot walk. Insectivorous, usually on flying insects. Old World, including parts of western Europe, Central Asia, and Japan; 2 genera, about 70 species, the genus *Rhinolophus* one of the most successful in species and numbers.

Family Noctilionidae (bulldog bats)

Medium size. Muzzle heavy but unadorned; lips full; internal cheek pouches; ears large, pointed, and mobile; wings long and narrow. Dental formula $\frac{2 \cdot 1 \cdot 1 \cdot 3}{1 \cdot 1 \cdot 2 \cdot 3} = 28$. Tail well-developed, extending to midpoint of large interfemoral membrane, which is pierced dorsally by tail tip, membrane supported distally by very well-developed calcars and calcanea. Feet large, or very large (*N. leporinus*). Colour dark brown to rufous orange dorsally. Musky odour. Walk well, often roost in crevices, tree hollows, attics, grottoes, and caves; colonial, in touching clusters. *Noctilio labialis* feeds on flying insects, as does *N. leporinus*, which also gaffs fish. Tropical America; 1 genus, 2 species.

Family Mormoopidae

Small. Insectivorous on flying insects. Some walk. All lack nose leaf but have elaborate lip leaves. Colour ranges from brown through orange, red, and yellow. Densely colonial in dark caves, colonies often numbering tens of thousands. Tail and interfemoral membrane well-developed. Dental formula $\frac{2 \cdot 1 \cdot 2 \cdot 3}{2 \cdot 1 \cdot 3 \cdot 3} = 34$. Tropical Central and South America; 3 genera, 9 species.

Family Phyllostomatidae (American leaf-nosed bats)

Small to large size. Nose leaf simply shaped, ears often large and mobile, wings generally short and broad, tail and interfemoral membrane quite varied (from absent to well-developed); dental formula varied, from 26 to 34; fur colour and patterns varied. Insectivorous (the insects eaten may be flying or terrestrial types), carnivorous, fruit- and flower-feeding species. Generally do not walk. Colonial, often densely so; generally roosting in touching clusters in caves, tree hollows, buildings, or culverts or in the open under bridges or eaves, in the crests of palm trees, or on the underside of palm leaves. Flight swift and straight to hovering. Southwestern U.S. through tropical America; 47 genera, about 120 species.

Subfamily Phyllostomatinae. Medium to large. Nose leaf often of striking size, ears large. Insectivorous, fruit-feeding, or carnivorous. Varied dental formulas. Subfamily may be an artificial grouping.

Subfamily Glossophaginae. Small to medium size. Small nose leaf, snout elongated; tongue elongated and extensible. Wings broad; hovering flight. Feed on pollen, nectar, fruit.

Subfamilies Carolliinae, Sturnirinae, Stenoderminae. Medium size. Fruit-feeding; some may be insectivorous. Nose leaves well-developed. Many Stenoderminae have white or light facial stripes, may roost in the open; 2 species alter palm leaves as roosts.

Subfamily Phyllonycterinae. Small bats endemic to the West Indies, probably fruit- and flower-feeding. Legs and feet exceptionally well-developed and body flexible. Beige, maize, or light brown. Nose leaves very small; snout and tongue moderately elongated. Cave-dwelling.

Family Desmodontidae (vampire bats)

Medium-sized bats. Small nose leaf. Teeth highly specialized for cutting skin, cheek teeth reduced; dental formula in *Desmodus* $\frac{1 \cdot 1 \cdot 1 \cdot 1}{2 \cdot 1 \cdot 2 \cdot 1} = 20$. Hindlegs and thumbs very well adapted for walking and jumping. Tail absent; interfemoral membrane reduced. Feed on blood of large mammals or birds. Roost in caves, hollow trees, and culverts; colonial. Most of tropical America, excluding West Indies; 3 genera, 3 species.

Family Natalidae (funnel-eared bats)

Small, slenderly built. Gray, buffy, yellow, or reddish; fur deep. Well-developed tail and interfemoral membrane. Ears large; snout plain; dental formula $\frac{2 \cdot 1 \cdot 3 \cdot 3}{3 \cdot 1 \cdot 3 \cdot 3} = 38$. Natalids walk clumsily but do not enter crevices; they are cave-dwelling, colonial in nontouching groups. Feed on flying insects. Central America, and northern South America, West Indies; 1 genus, 4 species.

Family Furipteridae (smoky bats)

Small, delicately built. Thumb vestigial; snout plain; tail long, ending short of distal edge of well-developed interfemoral membrane; legs long; feet small. Dental formula $\frac{2 \cdot 1 \cdot 2 \cdot 3}{3 \cdot 1 \cdot 3 \cdot 3} = 36$. Biology unknown; probably insectivorous. Northern South America; 2 genera, 2 species.

Family Thyropteridae (disk-wing bats)

Second finger reduced to rudiment, base of thumb and sole provided with sucking disk, simple muzzle, ears large; dental formula $\frac{2 \cdot 1 \cdot 3 \cdot 3}{3 \cdot 1 \cdot 3 \cdot 3} = 38$. Insectivorous, roost alone or in small groups, often in still furled banana leaves. Biology poorly known. Central America and northern South America, excluding West Indies; 1 genus, 2 species.

Family Myzopodidae (Old World sucker-footed bats)

Small, plain muzzle, large ears with peculiar mushroom-shaped lobe, dental formula $\frac{2 \cdot 1 \cdot 3 \cdot 3}{3 \cdot 1 \cdot 3 \cdot 3} = 38$. Thumb and sole with adhesive disks, vestigial thumb claw; tail extends free beyond interfemoral membrane; specialized scapulo-humeral articulations. Probably insectivorous (biology unknown); endemic to Madagascar; 1 species.

Family Vespertilionidae (common bats)

Small to medium sized. Muzzle plain; eyes small; ears moderate to large, tragus well-developed; dental formula varied, $\frac{1 \cdot 1 \cdot 1 \cdot 3}{2 \cdot 1 \cdot 2 \cdot 3} = 28$ to $\frac{2 \cdot 1 \cdot 3 \cdot 3}{3 \cdot 1 \cdot 3 \cdot 3} = 38$. Wings generally long and moderately narrow; tail and interfemoral membrane well-developed. All walk well, often entering crevices. Insectivorous, some on flying, some on terrestrial insects; a few genera (*Pizonyx* and some *Myotis*) eat fishes. Mostly roost in caves, attics, barns, hollow trees, boulder heaps, the twig work of birds' nests, or roof thatching; a few (*Lasiurus*) roost in branches, on tree trunks, or in hollow core of bamboo (*Tylonycteris*). Generally colonial in dense, touching clusters; a few solitary. Many temperate species hibernate and migrate; many drably coloured; several that roost externally are either spotted (*Euderma*) or speckled (*Lasiurus*). Family worldwide to tree line, including many oceanic islands; some genera (*Myotis, Eptesicus,* and *Pipistrellus*) also worldwide; 35 genera, about 290 species.

Family Mystacinidae (New Zealand short-tailed bats)

Small, with simple vespertilionid-like head; highly adapted for walking. Wings fold exceptionally compactly; thumb and toe claws long and sharp; tail perforates interfemoral membrane dorsally. Dental formula $\frac{1 \cdot 1 \cdot 2 \cdot 3}{1 \cdot 1 \cdot 2 \cdot 3} = 28$. Feeds on flying and terrestrial insects. Biology poorly known. New Zealand; 1 species.

Family Molossidae (free-tailed bats)

Robustly built, small to very large. Tail projects well beyond well-developed interfemoral membrane; ears large, rather immobile, often fused to one another, and of very unusual shapes; lips and snout often heavy, eyes tiny. Wings very long and narrow; legs well-developed for walking; toes often bear bristles; dental formula varied from $\frac{1 \cdot 1 \cdot 1 \cdot 3}{1 \cdot 1 \cdot 2 \cdot 3} = 26$ to $\frac{1 \cdot 1 \cdot 2 \cdot 3}{3 \cdot 1 \cdot 2 \cdot 3} = 32$. Often have a conspicuous odour; fur short, usually dark brown or black. Many highly colonial, as many as millions clustering in dense, touching groups; roost pressed against fellows or walls, often in crevices. Occupy caves, tree hollows, and buildings. Walk exceptionally well; many prefer hot, dry roosts. Feed on flying insects; some migrate. Worldwide in tropics and subtropics, with a few species ranging into mild temperate regions; 11 genera, about 90 species (the genus *Tadarida* worldwide).

(A.N.)

Primates (lemurs, lorises, tarsiers, monkeys, apes, and hominids, including man)

The mammalian order Primates, which includes the prosimians, monkeys, apes, and man, has long excited human interest, because it contains man's closest relatives. The obvious similarity of monkeys and apes to man was noted long before any genetic relationship was postulated. Recognizing that monkeys possess intelligence substantially exceeding that of other familiar mammals, man has valued these animals as companions and pets for centuries. In recent decades, in addition to becoming increasingly popular as pets, nonhuman primates have served as substitutes for man in situations, such as experimental medicine and space science, which require near-human biological reactions.

The two main groups of the order Primates are the prosimians (lemurs, lorises, and tarsiers) and the anthropoids (monkeys, apes, and man). As classified at present, the suborder Prosimii consists of six families; the Tupaiidae (tree shrews, though these are considered by some authorities to belong in the order Insectivora, a view elaborated in the section *Insectivora*), Lemuridae (lemurs), Indriidae (indri, sifaka, and avahi), Daubentoniidae (aye-aye), Lorisidae (galagos and lorises), and Tarsiidae (tarsiers). Collectively, the prosimian suborder is frequently referred to as lower primates.

The suborder Anthropoidea, sometimes called "higher" primates, also comprises six families: Callitrichidae (marmosets and tamarins), Cebidae (South American monkeys other than marmosets), Cercopithecidae (African and Asian monkeys), Hylobatidae (lesser apes: siamangs and

Figure 19: Representative prosimians.

gibbons), Pongidae (great apes: orangutan [orangutan], gorilla, and chimpanzee), and Hominidae (men, living and extinct). The two geographically separated stocks, the Old World and the New World monkeys, are often referred to as catarrhines and platyrrhines, respectively, terms which derive from the shape of the nose (see below, *Form and function*).

GENERAL CONSIDERATIONS

Historical background of primate studies. The inclusion of man in the order provides the rationale for the vigour with which this group has been studied by scientists since the time of Galen of Pergamum. Aristotle and Hippocrates, in the 3rd and 4th centuries BC, recognized the similarity of man and apes, but it was Galen who demonstrated the truth of this kinship by dissection. He wrote, "the ape is likest to man in viscera, muscles, arteries, veins, nerves and in the form of bones." It should be noted that Galen was in fact referring to monkeys, not the true apes, which were unknown to western man until the 15th century. None of these early scientists saw any evolutionary significance in the similarity of man and "apes," a correspondence that they regarded as purely coincidental. An inkling of the truth of man's relationship with primates must have penetrated the mind of St. Albertus Magnus, probably the best leading naturalist of the Middle Ages, who produced a classification of animal life in his book *De animalibus*. Albertus' classification, which placed man between "apes" (monkeys) on the one hand and "animals" on the other, provides the first whiff of the "missing-link" concept, which later was to befog the issue of man's place in nature.

The Dark Ages were aptly named as far as knowledge of primates is concerned. The first evidence of a renaissance of interest was in the time of Vesalius, the great Belgian anatomist of the 16th century, who published a comparative anatomy of man and "apes" in order to confound the precepts of Galen. He did not succeed in disproving Galen's assertion that "apes were likest to man" but, unwittingly, he succeeded in stirring up an interest in the biology of primates that has never since flagged. The first true ape studied as a scientific specimen was a chimpanzee dissected by Edward Tyson, an English anatomist, in 1699. Tyson's specimen, which he called the "Orang-Outang, sive Homo Sylvestris," is to this day housed in the British Museum (Natural History), mounted in a standing position that reflects Tyson's belief that he had discovered the pygmy, a race of humans known since the time of the ancient Greeks. Tyson wrote of his "pygmie" that it was "no man, nor yet a common ape but a sort of animal between both." It never occurred to Tyson or his contemporaries, who believed that all animals had been created independently in their current image, that man, apes, and monkeys were connected by common evolutionary descent. In 1758, Linnaeus—the father of animal and plant classification—added the lemurs and bats to the monkeys, apes, and man and called the whole assemblage the Primates. It is to be noted, however, that Linnaeus was sufficiently perceptive to see that man was a primate. His conclusion was regarded as a grave blow to human dignity, and it was followed by new classifications such as that of Blumenbach in 1776, placing man in a separate order. Man was not again considered part of the primate order until a century later when the English anatomist St. George Mivart in the climate of post-Darwinian thought published his classification of primates.

Discovery of the first true ape

The first evolutionist was a French scholar of the late 18th century, the Chevalier de Lamarck, who saw animal life as an uninterrupted continuity in which old species were transformed into new species in a sequence of increasing complexity and perfection. In 1821 Baron Georges Cuvier, a rabid anti-evolutionist, had the historic distinction of describing *Adapis*, the first fossil primate genus ever recognized. Fossils such as *Adapis*, Cuvier believed, were the remains of animals destroyed by past catastrophes (floods, earthquakes, etc.) and living animals were new stocks divinely created to fill the vacuum, a view consistent with the widely held notion that species were immutable. During the early 19th century a number of geologists and biologists questioned the doctrine of immutability, but it was not until 1859, with the publication of Charles Darwin's "On the Origin of Species by Means of Natural Selection," that positive evidence was provided, along with a sound alternative theory. The Darwinian contention that not only had man evolved, but he had evolved from a simian ancestor resulted in acrimonious debate among scientists, theologians, philosophers, and laymen. As influential zoologists and anatomists rose to support Darwin, the truth of man's primate consanguinity began to be accepted, if not actually relished. Today, few scientists deny that man and the lower primates belong in the same order; in fact, much current research is directed toward closing the apparent gap between the highest of the nonhuman primates, the chimpanzee and gorilla, and man.

In times past, the public image of primates was largely dictated by prevailing religious beliefs. In Asian countries, where primates abound, monkeys have for a long time been regarded with various degrees of deference that, among Hindus in India, for instance, amounts to worship. In Europe and North America, where monkeys and apes are totally absent, no religious sect has attached divine significance to them and, in fact, the reverse has been the case, monkeys at various times having been regarded as the personification of evil and depravity, familiars of the devil. This image, however, is fading as a result of enlightened instruction in schools and the advances in naturalistic presentation of primates in zoos. The nonhuman primate is becoming generally accepted by laymen as an animal of peculiar interest to man with many amusing and endearing qualities.

Religious views toward primates

The qualities of primates, however, are less endearing to farmers and agriculturists in certain parts of the world. In South Africa, the chacma baboon (*Papio ursinus*) competes with domestic sheep for grazing lands and is an occasional predator of lambs; in West and Central Africa native crops are subject to daily assaults by forest-living monkeys; and, in India, macaques, which have been accorded a semi-sacred status, live alongside man in towns and villages and are parasitic upon him for their food and shelter.

Scientific interest in nonhuman primates, their structure at all levels and their way of life, is currently in the ascendancy. Their value as research animals increases year by year, so that at present over a quarter of a million wild monkeys are consumed annually by laboratories in the study of human diseases, in the production of vaccines, in the experiments of organ transplantation, in the testing of drugs and, even, for the clinical trials of new cosmetics. Clearly their scientific usefulness raises important problems of conservation of primate stocks in the wild. Other disciplines whose researches depend upon observations and upon experimentation with nonhuman primates include those of endocrinology, neurology, psychology, and sociology. Much is being learned as a result of such studies that is of great significance for man and his future betterment.

Size range and adaptive diversity. Members of the order Primates show a remarkable range of size and adaptive diversity. The smallest primate (in linear dimensions) is probably the dwarf or mouse lemur (*Microcebus murinus*) of Madagascar, which measures approximately 13 centimetres (about five inches) in head and body length; the most massive is certainly the gorilla (*Gorilla gorilla*), whose head and torso length may reach 100 centimetres (39 inches; the comparable dimension in man may exceed this figure, but the gorilla is considerably more robust). In terms of body weight, the range is even more striking. The pen-tailed tree shrew (*Ptilocercus lowii*) weighs on average 46 grams (1.62 ounces); the gorilla's weight may be more than 3,000 times as great, varying from 140 to 180 kilograms (about 300–400 pounds).

Size and weight

In terms of habitat, primates are tropical animals and occupy two major vegetational zones: the tropical forest and woodland–grassland vegetational complexes. Each of these zones has produced in its resident primates the appropriate adaptations, which are not remarkable for their

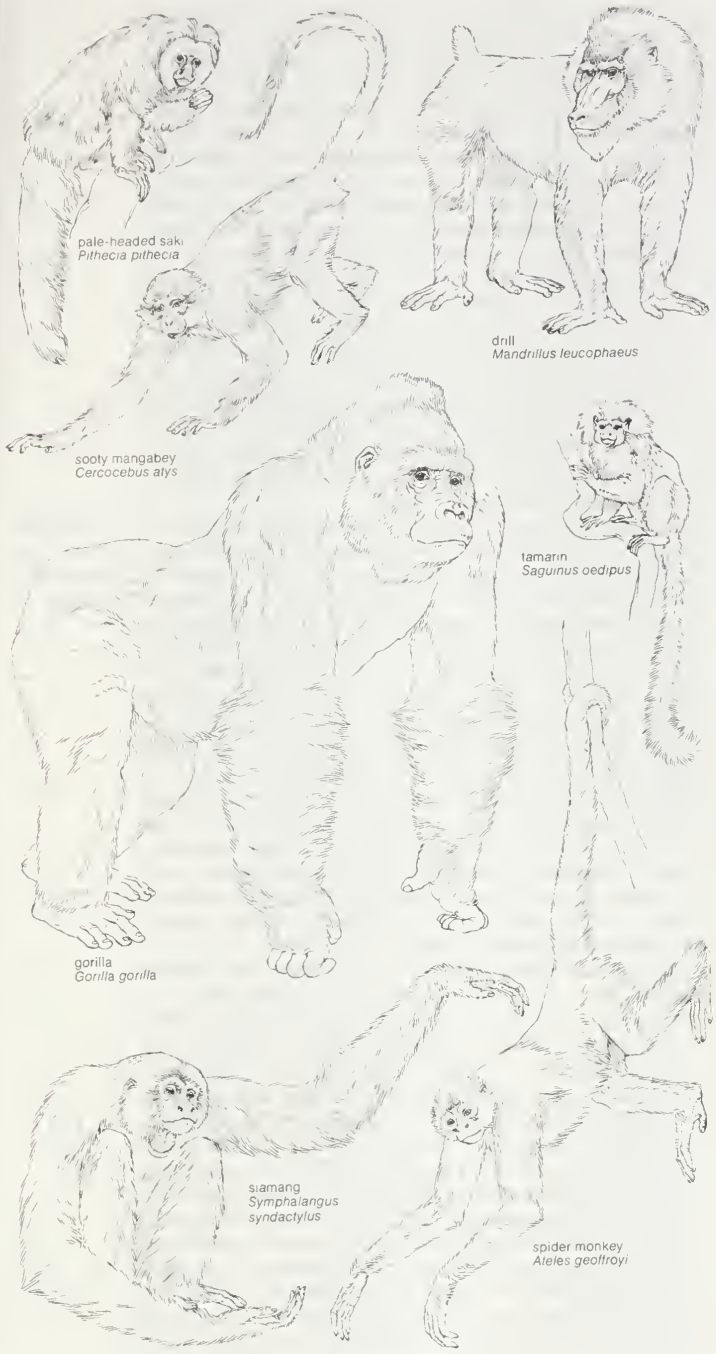

Figure 20: Body plans of representative anthropoids.
Drawing by R. Keane

diversity. There is perhaps more diversity of bodily form to be seen amongst forest-living species than among savanna inhabitants. One of the explanations of this difference is that it is the precise pattern of locomotion rather than the simple matter of habitat that governs overt bodily adaptations. Within the forest there are a number of ways of moving about. An animal can live on the forest floor or in the canopy, for instance, and within the canopy it can move in three particular ways: (a) by leaping—a function principally dictated by the hindlimbs; (b) by arm swinging (brachiation)—a function particularly of the forelimbs; (c) by quadrupedalism—a function equally divided between the forelimbs and the hindlimbs. On the savanna, or in the woodland-savanna biome, which substantially demands adaptations for ground-living locomotion rather than those of tree-living, the possibilities are limited. If bipedal man is discounted, there is a single pattern of ground-living locomotion, which is called quadrupedalism. Within this category there are at least two variations on the theme: (a) knuckle-walking quadrupedalism, and (b) digitigrade quadrupedalism. The former gait is characteristic of the African apes (chimpanzee and gorilla), and the latter of baboons and macaques, who walk on the flats of their fingers. After man, the Cercopitheeinae are the most successful colonizers of nonarboreal habitats.

The structural adaptations of primates resulting from locomotor differences are considered below in more detail, but they do not prove to be very extensive. Primates are a homogeneous group in terms of morphology, and it is only in the realm of behaviour that differences between primate taxa are clearly discriminant. It can be said that the most successful primates (judged in terms of the usual criteria of population numbers and territorial spread) are those that have departed least from the ancestral pattern of structure, but furthest from the ancestral pattern of behaviour. "Manners makyth man" is true in the widest sense of the word; in the same sense, manners delineate primate species.

Distribution and abundance. The nonhuman primates have a wide distribution throughout the tropical latitudes of Africa, India, Southeast Asia, and South America. Within this tropical belt, which lies between latitudes 25° N and 30° S, they have a considerable altitudinal range. In Ethiopia the gelada baboon (*Theropithecus*) is found living at altitudes up to 5,000 metres (16,000 feet). Mountain gorillas of the Virunga Volcanoes are known to travel across mountain passes at altitudes of more than 4,200 metres (13,800 feet) when travelling from one high valley to another. The howler monkeys of Venezuela (*Alouatta seniculus*) live at 2,500 metres (8,000 feet) in the Cordillera da Merida and in northern Colombia the dourocouli (*Aotus*) is found in the tropical montane forests of the Cordillera Central.

Temperate zone species

A few primate species occur naturally in temperate latitudes. The rhesus monkey (*Macaca mulatta*), for example, is found near Peking, and Japanese macaques (*Macaca fuscata*) are to be found on the Shimokita Peninsula, a hatchet-shaped promontory of the Japanese island of Honshu on latitude 41° N, where snow covers the ground for four or five months of the year. Macaques are particularly hardy animals and can withstand cold climates in the wild and captivity extremely well. The limiting factor to the occupation of temperate zones by monkeys is the winter food supply, combined with the short daylight hours available for foraging.

Primates in general are still plentiful in the wild; for the majority of common species there are few serious conservation problems at present. A number of species, particularly the orang-utan, the gorilla, some of the Madagascan lemurs, and some South American species, such as the golden marmoset, however, are in serious danger of extinction unless their habitats can be preserved in perpetuity and predatory habits of man kept under control.

NATURAL HISTORY

Reproduction and life cycle. The stages of the life cycle of primates vary considerably in duration. Among the most primitive members of the group, these stages are broadly comparable to those of other mammals of similar size. Higher in the phylogenetic scale they are substantially extended. The life span of a lemur is about 15 years, of a monkey 25–30 years, of a chimpanzee 40 years, and of man 70–75 years. The greatest differential between man and prosimians, indeed between the prosimians and apes and between apes and man, is in the duration of the infant and juvenile stages combined. The least differences occur in gestation period which, despite the general belief, can not be consistently correlated with adult body size. Gibbons, which weigh considerably less than macaques, have a 20 percent longer gestation period.

The clear trend toward prolongation of the period of juvenile and adolescent life is probably to be associated with the corresponding trend towards a progressive elaboration of the brain. The extended period of adolescence means that the young remain under adult (primarily maternal) surveillance for a long period, during which time the juvenile acquires, by example from its mother and peers, the knowledge that will allow it to become properly integrated as a fully adult member of a complicated social system. One might expect, therefore, a close correlation between the period of adolescence, the brain size, and the

complexity of the social system; and, insofar as the latter factor can be assessed, this appears to be the case.

Breeding periods. The reproductive events in the primate calendar are copulation, gestation, birth, and lactation. Owing to the long duration of the gestation period, these phases occupy the female primate (among higher primates anyway) for a full year or more; then the cycle starts again. The female does not usually come into estrus (physiologically receptive period) until the infant of the previous pregnancy is weaned.

The reproductive patterns of prosimians differ from those of anthropoids. Prosimians show one or more discrete breeding seasons during the year, during which time they may undergo more than one reproductive estrous cycle. The breeding seasons are separated by periods of anestrus, which in galagos are accompanied by changes in the skin of the vulva (the external organ of the genitalia), which closes over, completely sealing the vagina. In the Sudan estrus occurs only twice yearly in the African bush baby (*Galago senegalensis*), during December and August; but in captivity, breeding seasons may occur at any period in the year. In the wild, birth seasons are closely correlated with the prevailing climate, but in captivity under uniformly equable laboratory conditions, this consideration does not apply. In its native Madagascar the ring-tailed lemur (*Lemur catta*) has only a single breeding season during the year; conception occurring in autumn (April) and births taking place in late winter (August and September); but in zoos in the Northern Hemisphere a seasonal inversion of the birth period occurs in which it shifts to late spring and early summer. These examples suffice to indicate the influence of environmental factors on the timing of the birth seasons.

Reproductive cycles in the Anthropoidea continue uninterrupted throughout the year, though seasonality in births is characteristic of primate species living either outside the equatorial belt (5° north and south of the Equator) or at high altitudes in equatorial regions, where dry seasons and seasonal food shortages occur. Seasonality of births in macaques (*Macaca* species) has been documented in Japan, on Cayo Santiago in the Caribbean (where an introduced population thrives under semi-natural conditions), and in India. Observations on langurs in India and Ceylon, on geladas in Ethiopia, and on patas monkeys in Uganda have also demonstrated seasonality in areas with well-marked wet and dry seasons. Anthropoids within the equatorial belt display birth peaks rather than birth seasons. A birth peak is a period of the year in which a high proportion of births, but not by any means all, are concentrated. Equatorial primates such as guenons, colobus monkeys, howlers, gibbons, chimpanzees, and gorillas might be expected to show a pattern of births uniformly distributed throughout the year, but population samples are as yet too small to make this assumption. In captivity, under both laboratory and zoo conditions, anthropoids breed throughout the year with little evidence of seasonality. Even in man there is evidence of high birth peaks. In Europe, the highest birth rates are reached in the first half of the year, and in countries in the Southern Hemisphere in the second half. This may, however, be a cultural rather than an ecological phenomenon, for marriages in certain western countries reach a peak in the closing weeks of the fiscal year, a fact which undoubtedly has some repercussions on the birth period.

Distribution of births through the year

Gestation period and parturition. The period during which the growing fetus is protected in the uterus is characterized by a considerable range of variation among primate species, but shows a general trend towards prolongation as one ascends the evolutionary scale. The range of prosimians overlaps that of the anthropoids, which is never shorter than 140 days. Tree shrews, for example, have a gestation period of 41–50 days, lemurs 132–134 days, macaque monkeys 146–186 days, gibbons 210 days, chimpanzees and gorillas 250–290 days, and man (on the average) 267 days. Even small primates like bushbabies have a gestation period considerably longer than those of nonprimate mammals of equivalent size, reflecting the increased complexity and differentiation of primate structure compared with that of nonprimates. Although in primates there is a general trend towards evolutionary increase in body size, there is no absolute correlation between body size and the duration of the gestation period. Marmosets, for example, are considerably smaller than spider monkeys and howler monkeys but have a slightly longer pregnancy (howler monkeys 139 days; marmosets 140–150 days).

An extraordinary and somewhat inexplicable difference exists between the dimensions of the pelvic cavity and the dimensions of the head of the infant at birth in monkeys and man on the one hand, apes on the other. The head of the infant ape is considerably smaller than the pelvic cavity, so that birth occurs easily and without prolonged labor. When the head of the infant monkey engages in the pelvis the fit is exact, and labour may be a prolonged and difficult affair as it is in man, in whom similar conditions prevail. Human parturition, however, is generally a much more extended process than that of monkeys. Like the human infant, the monkey is born head first. Twin births are as rare in Old World monkeys and apes as they are in man, but certain New World monkeys (*e.g.*, marmosets) habitually produce twins.

The degrees of maturation and mother dependency at birth are obviously closely related phenomena. Newborn primate infants are neither as helpless as kittens, puppies, or rats, nor as precocial as the newborn gazelles, horses, and other savanna-living animals. With a few exceptions, primate young are born with their eyes open and are fully furred. Exceptions are the lowly tree shrews and mouse lemurs, which carry their young in their mouths in the manner of many mammals which bear altricial infants. Primate life being peripatetic, it is axiomatic that the infants must be able to cling to the mother's fur. The young of most higher primates have fully prehensile hands and feet at birth and are thus able to grasp the maternal fur without assistance; only man, chimpanzee, and gorilla need to support their newborn infants. In man this stage persists throughout the nursing period (six months or more), but in gorillas it lasts only four weeks and in chimpanzees for an even shorter period.

Condition of the newborn primate

It seems likely that the difference between the African apes and man in respect of postnatal grasping ability is related to the acquisition in man of bipedal walking. One of the anatomical correlates of the human gait is the loss of the grasping function of big toe, which is aligned in parallel with the remaining digits. Such an arrangement precludes the use of the foot as a grasping extremity. The human infant and, to a lesser degree, the gorilla infant must depend largely on its grasping hands to support itself unaided. The fact that man is habitually bipedal and that, consequently his hands are freed from locomotor chores, may also be a contributory factor; the human mother can move about and at the same time continue to support her infant. Selection for postnatal grasping, therefore, has not had the high survival value that it has in nonhuman primates in which the survival of the infant depends on its ability to hold on tightly. It is a well-known fact, of course, that newborn human infants can support their own weight, for short periods, by means of their grasping hands. Clearly adaptations for survival are not wholly lacking in the human species. Perhaps there are involved cultural factors which have the effect of suppressing natural selection for early infant grasping ability. The first may be that the social evolution of a division of labour between the sexes and a fixed home base has allowed the mother to park her infant with other members of the family as baby-sitters; the second that in more peripatetic communities, the invention of infant-carrying devices, such as the papoose technique of North American Indians, has made it unnecessary for the infant to support itself. Whatever the biological or cultural reasons, the human infant is less precocial than the young of any other primates.

Once the primate infant learns to support itself by standing on its own two (or four) feet, the physical phase of dependency is over; the next phase of psychological dependency lasts much longer. Man, metaphorically, is tied to his mother's apron strings for much longer periods than are the nonhuman primates. The reasons for this are discussed below. According to Adolph Schultz, the anthropologist whose comparative anatomical studies have

illuminated knowledge of nonhuman primates during the last 40 years, the juvenile period of psychological maternal dependency is 2½ years in lemurs, 6 years in monkeys, 7–8 years in apes, and 14 years in man.

Growth and longevity. The characteristic pattern of weight-growth curves of man is also shared by higher nonhuman primates such as chimpanzees (*Pan troglodytes*) and rhesus monkeys (*Macaca mulatta*). There seems little reason to doubt that similar curves will be found to exist in other higher primates not yet studied. It has been suggested that the growth curves of primates are closely akin to the basic curves of mammals in general.

The trend toward the prolongation of postnatal life as a characteristic of primates affects all postnatal life periods including infantile, juvenile, adult, and the period of senescence. The period which shows the least change in apes and man is that of gestation. The relative stability of the gestation period is a clear indication that, developmentally speaking, in the degree of structural complexity and cellular differentiation, there is little difference between apes and man. The differences that undoubtedly exist can probably be attributed to cultural factors. There is no reason to suppose that apes are not built to last equally as long as man; it is simply that the natural hazards of gorilla or chimpanzee life are not buffered by the blessings of civilization, except under conditions of captivity, in which case life spans of 40 years and more are known. The potential life span of the chimpanzee has been estimated at 60 years.

Average and potential life span

The characteristic growth spurts of human infants in weight and height also occur in nonhuman primates but start earlier in the postnatal period and are of shorter duration. Primates differ from most nonprimate mamals by virtue of a delayed puberty in both sexes until growth is nearly complete; in male macaque monkeys, as in man, the growth spurt precedes the onset of puberty. To postpone this latter event is of selective advantage because it ensures that the juvenile males in a primate society are not sexually competitive with adult males until they are large enough and strong enough to contribute fully to the responsibilities of the society in which they live by taking part, for instance, in defense against predators.

Locomotion. Primate locomotion, being an aspect of behaviour which arises out of anatomical structure, shows much of the conservativeness and the opportunism that characterizes the primates. Primates with remarkably few changes in their skeletons and musculature have adopted a bewildering variety of locomotor patterns. The "natural" habitat of primates—in the historical sense—is the canopy of the forest. Although many primates have adopted the ground as their principal foraging area during the day, given the opportunity, they return to the trees to sleep at night. Trees provide cover from the climate and protection from predators; they are of course also a source of food. Only the gelada (*Theropithecus gelada*), the hamadryas baboon (*Papio hamadryas*) of the mountainous regions of Ethiopia, and the chacma baboon (*P. ursinus*), which lives on the rocky coast of the Cape of Good Hope, South Africa, are ground sleepers; even these animals seek the protection of the cliffs and rocky precipices of their habitats at night. No primate sleeps totally unprotected; as a consequence of their relative immunity from predation, primates are heavy sleepers.

The essential arboreality of primates has guaranteed the relative uniformity of the locomotor apparatus. Even man, who has long since abandoned the trees as his principal lodging place, has only partially lost the physical adaptations for tree climbing; his hands remain in the arboreal mold. Only his feet have lost their primitive prehensility in adapting to bipedal walking. Primate locomotion can be classified on behavioral grounds into four major types (see Table 1). Within these major categories there are a number of subtypes, and within these subtypes there are an infinite number of variations between species and, by virtue of individual variability, within species. The differences between the four major categories lie principally in the degree to which the forelimbs and hindlimbs are used to climb, swing, jump, and run.

Locomotor types

Vertical clinging and leaping, for instance, is primarily a function of the hindlimbs, as is bipedalism, whereas brachiation is performed exclusively with the forelimbs. Quadrupedalism involves both forelimbs and hindlimbs, of course, although not to an equal extent. Some quadrupeds are hindlimb dominated; in others, the forelimb and the hindlimb are equally important. The hindlimb-dominated primates, such as the langurs and colobus monkeys, employ a large element of leaping in their movements, a less notable feature of the more generalized quadrupeds such as the species of the genus *Cercopithecus*. The quadrupedal category is inevitably somewhat of a grab bag, and the gaits included in it have not yet been studied critically. One subtype, here designated as slow climbing, differs profoundly from the other subtypes of the category, being somewhat ponderous and devoid of elements of leaping or jumping. The species in this category are all arboreal nocturnal prosimians.

As many authorities who have studied locomotion in free-ranging primate species have pointed out, the classifications of locomotion into categories is a somewhat artificial procedure. A chimpanzee shows a variety of different gaits according to the circumstances of the environment, and brachiation may form only a minor part of its repertoire; this holds true also for the langurs and colobus monkeys, which are placed in the subtype Old World semibrachiation. Although the categories are phrased in behavioral terms, their implications are strictly anatomical. Brachiation is the mode of locomotion for which the animal is specifically adapted; the anatomical correlates of brachiation are quite unmistakable and can be determined equally as well in fossil bones as in living animals. A

Table 1: Locomotor Classification

category	subtype	activity	primate genera
Vertical clinging and leaping		leaping in trees and hopping on the ground	*Avahi, Galago, Hapalemur, Lepilemur, Propithecus, Indri, Tarsius*
Quadrupedalism	slow climbing type	cautious climbing—no leaping or branch running	*Arctocebus, Loris, Nycticebus, Perodicticus*
	branch running and walking type	climbing, springing, branch running and jumping	*Aotus, Cacajao, Callicebus, Callimico, Callithrix, Cebuella, Cebus, Cercopithecus, Cheirogaleus, Chiropotes, Lemur, Leontideus, Phaner, Pithecia, Saguinus, Saimiri, Tupaia*
	ground running and walking type	climbing, ground running	*Macaca, Mandrillus, Papio, Theropithecus, Erythrocebus*
	New World semibrachiation type	arm swinging with use of prehensile tail; little leaping	*Alouatta, Ateles, Brachyteles, Lagothrix*
	Old World semibrachiation type	arm swinging and leaping	*Colobus, Nasalis, Presbytis, Pygathrix, Rhinopithecus, Simias*
Brachiation	true brachiation	gibbon type of brachiation	*Hylobates, Symphalangus*
	modified brachiation	chimpanzee and orangutan type of brachiation	*Gorilla, Pan, Pongo*
Bipedalism		striding	*Homo*

purely behavioral classification, based on observations in the living, can have little value in palcontological diagnosis. It is quite arguable that although pure arm swinging is rare in Old World semibrachiators, it is nevertheless one of the principal survival mechanisms of the group, an adaptive advantage that in critical circumstances provides these species with an "edge" over their competitors. In some instances it may well be the case that the particular category is of evolutionary significance only. The gorillas, for instance, whose anatomy is that of a brachiator, in fact, seldom brachiate; adult males probably never do. Gorillas are large animals and bulk-food eaters, forced by their dietary demands to obtain their food on the ground; living gorillas have adapted to a terrestrial life by adopting a compromise gait in which they walk quadrupedally bearing their weight on the backs of their knuckles. This is a form of quadrupedalism (inasmuch as all four limbs are employed) but, once again, the anatomy of their bodies indicates that in past time gorillas (or their evolutionary forebears) were smaller animals which lived and moved in trees. The modern gorilla differs widely from its historical counterpart in behaviour but, structurally, its kinship with its arboreal ancestor is overtly apparent.

The relation of locomotion to habitat changes

Changes in climate and geography during the evolutionary history of primates may also have led to structural atavisms in the anatomy of living primates. Many chimpanzees now living in woodland-savanna conditions in Africa, where the trees are widely spaced and generally unsuitable for the classic arm swinging progress of a brachiator, have adopted a largely ground-living life. Like the gorilla, the chimpanzees are also knuckle walkers, but given an environment like that of a zoo with a cage specially designed with a plentitude of overhead bars and ropes, they brachiate freely and frequently. Habitat changes in the past undoubtedly account for many apparent anomalies in the locomotor classification of present-day primates.

The intermembral index

When the subject of primate arboreal locomotion is studied in evolutionary terms, through the medium of fossils, it becomes clear that locomotor categories are not discrete, but that they constitute a continuum of change from a hindlimb-dominated gait to a forelimb-dominated one. The best single indicator of gait, one that has the added advantage of being strictly quantitative, is the intermembral index. Briefly, the index is a ratio expressed as percentage of arm length to leg length; an index over 100 indicates relatively long arms. The intermembral index provides a model by means of which the locomotion of an early primate can be inferred by determination of the intermembral index of the fossil skeleton. Animals do not necessarily fall discretely into categories. Species with indices lying between those of clearly recognizable locomotor types represent transitional types, whose style of locomotion manifests features of both of the bracketing categories. Some lemurs have indices that fall between 65 and 75, but their gait is a combination of vertical clinging and quadrupedalism. The ring-tailed lemur in fact shows an intermediate form of behaviour; it is generally quadrupedal but, given the right environmental milieu, can be observed in vertical clinging and leaping. The South American spider monkeys (*Ateles*), whose index lies between 100 and 108, show a type of locomotion that contains the elements of both quadrupedalism and brachiation.

Applying the intermembral index to fossil primates, it has become apparent that the earliest primates living in the Eocene Epoch, from about 54,000,000 to 38,000,000 years ago, moved about in the manner of modern vertical clingers and leapers. Quadrupedalism was well-established during the Miocene Epoch (about 26,000,000 to 17,000,000 years ago) when the two major environmental types of quadrupedal gait—the terrestrial and the arboreal—were established, with indices in the region of 85–100 and 75–85, respectively. Brachiation, associated with a high intermembral index, was established as a way of arboreal life at the end of the Miocene and the beginning of the Pliocene.

The origin of bipedalism, which implies the appearance of manlike creatures, is indeterminate. There is direct evidence of bipedalism extending back 1,500,000 to 2,000,000 years, and certain indirect evidence (see below *Evolution and paleontology*) suggests that bipedalism might have evolved in a modified form some 10,000,000 to 14,000,000 years ago.

Locomotion of primates is an area of primate biology of great interest to scholars. It is not only that locomotion is a basic factor of primate life (primates must move to eat and must eat to live) but it is also an indicator of evolutionary progress. To study the origins of primate locomotion is to study primate evolution. Because of its immediacy for survival, natural selection has acted strongly on locomotor behaviour and the locomotor apparatus; changes in locomotor pattern may thus be said to provide principal milestones on the road to modern primates.

Bipedalism, far from being a unique possession of mankind, as is generally thought, is a basic possession of the order Primates. With one or two exceptions (one of which is the tree shrew, which may not even be a primate), all primates sit upright. Many stand upright without supporting their body weight by their arms, and some actually walk upright for short periods. The view that the possession of uprightness is a solely human attribute is untenable; man is merely one species among the 189 that constitute the order who has exploited the potential of his ancestry to his ineffable advantage.

Walking

Chimpanzees, gorillas and gibbons, macaques, spider monkeys, capuchins, and others are all frequent bipedal walkers. To define man taxonomically as "bipedal" is not enough; to describe him as habitually bipedal is nearer the truth, but habit as such does not leave its mark on fossil bones. Some more precise definition is needed. Man's walk has been described as striding, a mode of locomotion defining a special pattern of behaviour and a special morphology. Striding, in a sense, is the quintessence of bipedalism; it is a means of travelling during which the energy output of the body is reduced to a physiological minimum by the smooth, undulating flow of the progression. It is a complex activity involving the joints and muscles of the whole body in its performance and it is likely that the evolution in the human gait took place gradually over a period of 10,000,000 years or so.

The pattern of locomotion of man's ancestors immediately preceding the acquisition of bipedalism has long been a matter of controversy, and the question has not yet been resolved. The evidence derived from anatomical, physiological, and biochemical studies for the close affinity of chimpanzees and gorillas with man would imply that he evolved from a brachiating ancestry. But the many differences between the apes and man, particularly in the structure of the limbs and teeth, have persuaded the majority of leading anthropologists that the theory of a brachiating origin of man is untenable. The issue is still hotly debated, the more so since current immunological studies of serum proteins are tending to emphasize the recentness of the separation of pongid and hominid stocks (the lines that led, repectively, to apes and man) in phylogeny. An alternative to the "brachiating theory" must inevitably be some sort of "quadrupedal theory." Various authorities have proposed other solutions: semibrachiation (a form of quadrupedalism with emphasis on arm swinging), a formal quadrupedal gait, and even a form of locomotion similar to that of *Tarsius* and other clingers and leapers. At the present time, there is insufficient information to elucidate the phylogeny of man's bipedal gait. It can, however, be assumed that it must have involved a large measure of truncal uprightness, a good deal of leaping, and a sizable element of arm swinging. There is no living primate that demonstrates, precisely, this combination of locomotor characteristics, although the arboreal monkeys of the subfamily Colobinae theoretically fit the bill better than most.

Ecology and diet. Few primate species are found today in temperate latitudes. The limiting factors appear to be the general climate and the duration of the daylight hours. The higher the latitude, the greater is the fluctuation between summer and winter temperatures and the shorter are the hours of winter daylight. The combination of quiescent growth periods of fruits, leaves, and grasses, a frozen top soil, and a restricted diurnal period all make

conditions extremely hard for monkeys, which depend on foraging in the trees, on the ground, or under it for their food supply. No monkey lives, or has ever lived, in the zones of permafrost, but it is probable that in times past they flourished in temperate regions. Without the harassment of man, monkeys no doubt could have survived in the temperate zones; their foraging, albeit condensed into a temperate-zone day of seven hours or so, would have supplied them with the food they required, providing they were free to forage without the threat of human persecution. Dietary adaptability of primates is greater than realized. On the Shimokita Peninsula of the Japanese Island of Honshu and in the Shiga Mountains of the same island, Japanese macaques survive from late November until April on incredibly meagre rations. The diet of these monkeys, during the months when snow covers the ground and when the last remaining summer seeds and leaves have vanished, is bark and the fleshy cambium layer that lies beneath it. The Japanese macaques, cold and hungry, ride out the worst that winter, at the latitude of 41° N, offers. Near Moscow, several species of African primates have been kept for several years in outdoor facilities in which winter temperatures go well below −18° C (0° F). It is true that they are well provisioned but, nevertheless, it is almost incredible that a tropical species should be sufficiently adaptable and possess adequately effective homeostatic mechanisms to survive in this degree of climatic adversity. Ruggedness of this sort is a primate characteristic, a survival mechanism that operates in the worst conditions, and one which provides a clue to the real reason for the primacy of the primates among mammals.

Resistance to cold

Diet. The diet of primates is a factor of their ecology that, during their evolution, has clearly played an important role in their dispersion and adaptive radiation as well as in the development of the teeth, jaws, and digestive system. Diet is also closely related to locomotor pattern and to body size.

The principal food substances taken by primates may be divided into vegetable (fruits, flowers, leaves, nuts, barks, pith, seeds, grasses, stems, roots, and tubers) and animal (birds, birds' eggs, lizards, small rodents and bats, insects, frogs, and crustacea). The flesh of larger mammals (including primates) is not listed as an important item of nonhuman primate diet, although it is taken by certain species such as baboons and chimpanzees in special circumstances that are not yet fully understood.

While in many mammalian groups, diet is selective and specific to the order, among primates it is difficult to establish any hard and fast rules. Although there are decided preferences for certain food items, catholicity is more characteristic than specificity. Generally speaking, primates are omnivorous, as the physiology of their digestive system attests. Relatively few examples of dietary specialization are to be found. The so-called leaf-eating monkeys, a sobriquet that embraces the whole of the subfamily Colobinae, are by no means exclusively leaf eaters and according to season include flowers, fruit, and seeds in their diet. The howler monkeys of the New World have a similar dietary preference.

Broadly, however, certain overall dietary preferences are discernible. The leaf-eating langurs have already been mentioned. The apes (other than the gorilla) are substantially fruit eaters; the percentages of fruit in the diet of the gibbon and the three great apes are as follows: gibbon 62 percent, orang 50 percent, chimpanzee 67 percent, and gorilla 2–15 percent.

Many of the smaller nocturnal prosimians such as tarsiers, galagos, dwarf lemurs, sportive lemurs, the aye-aye, slender lorises, and the South American night monkey are substantially insectivorous.

The larger diurnal prosimians (*e.g.*, typical lemurs, the sifaka, and the indri) and the large nocturnal prosimians (the Asian slow loris and the African potto) are more vegetarian, including both fruit and leaves in their menu. It seems apparent that size, rather than activity rhythm, governs the nature of the primate diet. The small marmosets of the South American genus *Callithrix* have exclusively diurnal rhythms and are insectivorous, while the slightly larger, but equally diurnal, tamarins (*Saguinus*) are more omnivorous.

The most widespread monkey populations are those of the subfamily Cercopithecinae. Many ground-living species are included in this group, the members of which are notable for the extreme catholicity of their diet; meat eating as a regular pattern, however, has not been reported among them.

Size in relation to food habits. In evolutionary terms, increase in size has probably played a large part in determining the direction of primate evolution. Fossil evidence of early primates of the Paleocene (about 65,000,000 years ago) suggests that these were small, forest-living creatures, not yet specialized as tree climbers. Their bodily form suggests that they possessed the build and the gait of squirrels. Their molar teeth bore high, pointed cusps but were neither as tall nor as pointed as those of the insectivore-like ancestors of the preceding Cretaceous epoch, whose molars were ideally adapted for cracking the hard, chitinous exoskeletons of insects. This fact suggests that the reduction of the molar cusps was associated with the adoption of a fruit-eating habit. Although this has some validity as a generalization, it should not be taken too literally. All primates include insects in their diet and there are many almost exclusively insectivorous forms, which have reduced the height and acuity of their molar cusps. Increasing body size, a trend which is clearly apparent throughout primate evolution, would have been associated with the adoption of supplementary sources of food. Insect eating is a laborious way for a large animal to obtain nourishment unless it happens to possess the extensible tongue of those mammalian "vacuum cleaners," the anteaters.

The shift from insect to fruit eating

An increase in size and the gradual addition of bulk foods to the diet would, in turn, have affected the habitat and the pattern of locomotion of primates. Fruit eating is more easily accomplished in trees than on the ground and this growing preference amongst primates may have been accompanied by the tree-climbing habit. Once such a habit was established, natural selection would have operated to espouse the suitable physical adaptations which would facilitate such a behaviour. Suitable adaptations in this case would have been the facility to climb, leap, and balance in trees.

It is noteworthy that during evolution the development of a prehensile foot preceded that of a prehensile hand. Vertical clinging primates such as the tarsiers or small squirrel-like quadrupeds like the marmosets and tamarins—all of which have prehensile feet, but not prehensile hands—by remaining small, have never been subject to the same evo-

From J.R. Napier and P.H. Napier, *A Handbook of Living Primates* (1967). Academic Press

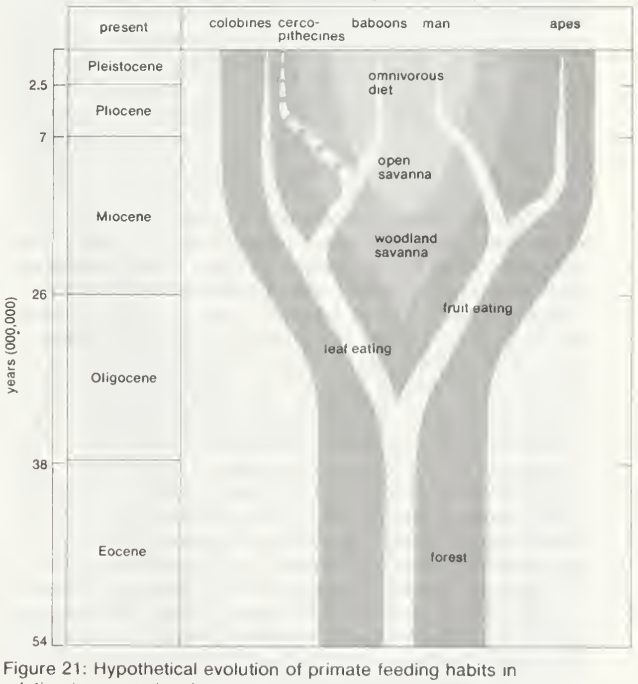

Figure 21: Hypothetical evolution of primate feeding habits in relation to vegetational areas.

lutionary pressures that have impinged on larger primates. A large arboreal primate without prehensile hands is at a considerable disadvantage in moving about in the canopy of trees, but a small one suffers little disadvantage. Amid the large and firm branches, size is no particular hazard, but at the periphery of the crown, where the fruit is most abundant and the branches are slender and flexible, the risk of falling is increased. It is, therefore, likely that the combination of an increase in body size, associated with the inevitable shift towards a bulk diet, led first to the evolution of a grasping hand, then to the appearance of a prehensile hand, and finally to an opposable thumb. Four prehensile extremities are more effective than two in defying gravity.

Such adaptations of the forelimbs would have had the effect of equalizing the role of the limbs. The limbs of vertical clingers are functionally disparate, the lower pair being dominantly propulsive, the upper, secondary and purely supportive. The limbs of quadrupeds, on the other hand, are more homogeneous, both pairs having a propulsive function during running. Thus, it would seem that the transition in locomotor grade between vertical clinging and leaping and quadrupedalism came about as adaptation to increased body size. Size, diet, ecology, locomotion, and anatomical structure provide a constellation of causes and effects that are critical factors in the evolution of the primates.

Effect of forest stratification. An aspect of primate ecology that has not yet been fully investigated is the effect of the stratification of forests on the adaptations (particularly the locomotor adaptations) and on the speciation of primates. In recent years it has become apparent that forests are not simply a random consociation of trees but are an ordered system of plants under the control of climatic, photobiotic, and edaphic (soil) factors.

Forest structure and traffic ways

The chief physiognomic features of rain forests, the ancestral home of primates and the principal habitat (in numerical terms) of nonhuman primates today, are the evergreen broad-leaved trees that, collectively, form a closed canopy, so opaque to sunlight that the forest floor is in perpetual twilight. Epiphytes and thick-stemmed lianas drape the trees, linking one crown to another and providing aerial pathways for monkeys to pass from tree to tree through a continuum of interlacing branches, a three-dimensional maze that provides home, restaurant, shopping districts, and highways for primates. Three strata of the canopy of rain forests are usually recognized by botanists: an understory, a middle story, and an upper story. The understory is often "closed," the crowns of the constituent trees overlapping one another to form a dense, continuous, horizontal layer. The middle story is characterized by trees that are in lateral contact but do not overlap; and the highest story by tall trees, some 50 metres (160 feet) or more, which form a discontinuous layer of umbrella-shaped crowns. The occasional "emergent" forest giant may tower above the highest layer of the canopy. There is some evidence, much of it conflicting, that zonation of forest primates occurs within the forest canopy. The stratification of forest is extremely variable and the number of layers tends to diminish from three to two in secondary forest, dry deciduous forest, and montane forest; and from two to one as temperate zone, tropical woodland, or montane woodland supervenes.

Tropical grasslands, or savannas, are also the homes of primates in Africa and Asia; no savanna-living primates exist in South America. Tropical grasslands comprise a mixture of trees and grasses. The proportion of trees to grass varies directly with the rainfall; areas of high seasonal rainfall support single story woodlands of tall trees while lush grasses form the ground vegetation; but where rainfall is both seasonal and low, the trees consist of stubby xerophilous (dry-loving) shrubs and short, tussocky grasses. The principal primate fauna of the savanna biome are the ground-living species; in Africa, the grivet (*Cercopithecus aethiops*), baboons (*Papio* species), and the patas monkey (*Erythrocebus patas*); and in Asia the macaques (*Macaca* species) and the Hanumān langur (*Presbytis entellus*).

Tropical montane forests or tropical rain forests at high altitude also abound in primates in Africa, Asia, and South America. In equatorial Africa certain primate species have colonized the montane-savanna regions, or moorlands, where the rugged mountainous terrain and seasonal food scarcity support herds of geladas and hamadryas baboons. These high mountaineers of Africa have no ecological counterparts in Asia or South America.

As a measure of the physiological adaptability of primates it may be noted that various populations have at different times been subjected to relocation in alien environments by man. Some of these expatriates are the green monkeys (*Cercopithecus sabaeus*) of St. Kitts in the West Indies, the mona monkeys (*C. mona*) of Grenada, the macaques on Mauritius, and the Barbary apes (*Macaca sylvana*) of Gibraltar.

FORM AND FUNCTION

Distinguishing features. The basis of the success of the order Primates is the relatively unspecialized nature of their structure and the highly specialized plasticity of their behaviour. This combination has permitted the primates throughout their evolutionary history to exploit the wide variety of novel ecological opportunities that have come their way. Although there are a few highly specialized species among the lower primates (the aye-aye, the tarsier, the potto, and the lorises, for instance), the higher primates, the anthropoids, are extremely conservative in their structure; morphologically speaking, they have maintained a position in the evolutionary midstream and have avoided the potential stagnation of specialized life near the bank. Specialization is not always a liability; in times of environmental stability the specialized animal enjoys many advantages, but in a rapidly changing world it is the less specialized animals that are more likely to survive and flourish.

The importance of a large brain

The plasticity of primate behaviour is largely a function of the brain. The primate brain is distinguished by its relatively large size compared with the size of the body as a whole; it is also notable for the complexity and elaboration of the cerebral cortex, the function of which is to receive, analyze, and synthesize the incoming impulses from the sense organs and to convert them into appropriate motor actions, which in turn constitute behaviour.

It has been observed that there is no distinguishing feature which characterizes all primates except a negative one—their lack of specialization. St. George Mivart defined the order Primates in the following terms:

> . . . an unguiculate, claviculate, placental mammal with orbits encircled by bone; three kinds of teeth at least at one time of life; brain always with a posterior lobe and a calcarine fissure; the innermost digits of at least one pair of extremities opposable; hallux with a flat nail or none; a well-developed caecum; penis pendulous; testes scrotal; always two pectoral mammae.

When these criteria are examined one by one the inevitable conclusion is reached that, singly, none of these characters is unique to primates nor do all primates demonstrate every single character. Collectively, however, more primates than nonprimates show this particular constellation of characters. Perhaps a more meaningful way to look at primate characteristics is in the form of evolutionary trends. This approach is quantitative, inasmuch as it is recognized that not all adaptations are developed in primates to the same degree. A list of evolutionary trends with behavioral connotations is also a somewhat more functional inventory than Mivart's essentially morphological one and, furthermore, is more applicable to the study of fossil primates.

Binocular vision

Primates are essentially arboreal animals whose limbs are adapted for climbing, leaping, and running in trees. Active arboreal life requires the mechanical assistance of a long tail and sensitive, grasping hands and feet with opposable thumbs and big toes, to aid in climbing and to ensure stability on slender branches high above the ground. Active arboreal locomotion also requires a much more accurate judgment of distances than life on the ground; this is facilitated by the development of stereoscopic vision, the anatomical basis of visual judgments in depth. The forward-facing eyes of primates are adaptations for this type of visual precision. A highly developed sense of smell is not nearly as important for animals leading

an arboreal life as it is for those on the ground. Primates thus have a much reduced olfactory mechanism; noses are shorter, the turbinal (or scroll) bones of the nose are reduced in number and complexity compared with most nonprimate mammals.

Primates, being on the whole omnivorous animals, have evolved a multipurpose dentition; incisors to cut, canines to pierce and tear, and molars and premolars to crush and grind. Such a dental arrangement equips its possessor with the power to cope with many different sorts of food—insect food, vegetable food, or flesh—and provides a major contribution for the generalized way of life that is so characteristic of the order.

A basic adaptation for the primate way of life (including the unique specialization of man—upright walking) is verticality of the trunk. Above the level of the tree shrews, the ability to hold the body upright is a universal primate possession; indeed paleontological evidence indicates that truncal uprightness was a primate characteristic as far back as the early Eocene, some 54,000,000 years ago.

Above all, the principal evolutionary trend of primates has been the elaboration of the brain, particularly of that portion of the cerebral hemispheres known as the neopallium or neocortex. A neocortex is characteristic of higher vertebrates, such as mammals, which operate under the control of multiple sources of sensory input. In many mammals the olfactory system dominates the senses and the cerebral hemispheres consist largely of paleocortex—the "smell brain"—of lower vertebrates. The arboreal habit of primates has led to a dethronement of the olfactory sense and the accession of a tactile, visually dominant sensory system. This evolutionary trend has resulted in the dramatic expansion and differentiation of the neocortex.

General structure. *Vertebral column and posture.* All primates retain a clavicle or collarbone (lost in many mammalian groups), a separate radius and ulna in the forearm, and a separate tibia and fibula in the lower leg. The single exception to this is the tarsier, in which the fibula becomes fused to the tibia.

The primate vertebral column shows a basic mammalian pattern of components including an "anticlinal" vertebra, situated in the mid-thoracic (upper-back) region of the spinal column and marking the transition between the forelimb and hindlimb segments. In a galloping greyhound the anticlinal vertebra is at the apex of the acute curve of the back. An anticlinal vertebra is characteristic of all quadrupeds and is seen in all primate families except the hominids and the pongids, whose posture is upright or semi-upright. The evolutionary trend in the vertebral column is toward shortening the lumbar, sacral, and caudal regions. Extreme shortening in the lumbar region, with complete loss of the caudal (tail) vertebrae, occurs in gibbons, the great apes, and man. Prehensility of the tail is a specialization of certain New World monkeys, but appears also for a brief period in the infants of many Old World monkey groups, in which it provides an important mechanical aid to survival.

Hands and feet. With two exceptions, all primates have retained five digits on hand and foot. The exceptions are the spider monkeys of South America and the colobus monkeys of Africa, which have lost or reduced the thumb. This appears to be an adaptation for locomotion, the rationale for which is not fully understood at present.

All (except tree shrews) possess prehensile (grasping) hands, and (except man) prehensile feet. The hands of Anthropoidea show a greater range of precise manipulative activity than those of Prosimii. Prosimians lack the functional duality of the hands of anthropoids. Duality in hand function has been described for man and nonhuman primates in terms of precision and power grips. The power grip of prosimians is very well developed but the precision grip is lacking. Among Anthropoidea, the New World monkeys show a considerable advance over prosimians in tactile sensitivity but they possess less functionally effective hands in prehensive terms than Old World monkeys. The critical component of the prehensile hand in terms of skilled manipulation is the opposable thumb: a thumb, that is to say, that is capable of being moved freely and independently. The movement of opposition is a rotary movement in which the thumb, swinging about its own axis, comes to face the under or palmar surface of the tips of the fingers. The opposable thumb is the basis of the precision grip which, though present to some extent in all primates, is particularly highly developed in man. Opposability is present to some degree or other in most primates but varies considerably in its functional effectiveness as an instrument of fine manipulation. The baboons and man are pre-eminent in this respect. The apes, having short thumbs and long fingers, are handicapped in relation to delicate manual dexterity but are adept in the coarser elements of hand use, particularly in relation to tree climbing and branch swinging.

Power versus precision grips

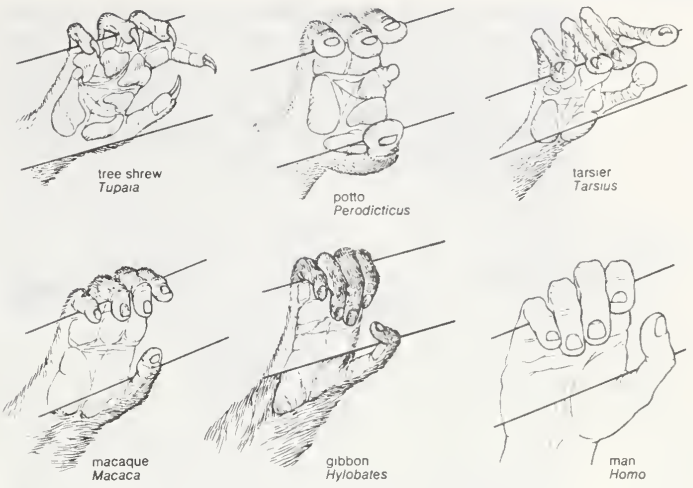

Figure 22: Shape and function of the hand in certain primates.
Drawing by R. Keane

Teeth. A dentition with different kinds of teeth (heterodonty)—incisors, canines, and cheek teeth—is characteristic of all primates and indeed of mammals generally. Heterodonty is a primitive characteristic and primates have evolved less far from the original pattern than most mammals. The principal changes are a reduction in the number of teeth and an elaboration of the cusp pattern of the molars.

The primitive mammalian dental formula is assumed to have been $\frac{3\,.\,1\,.\,4\,.\,3}{3\,.\,1\,.\,4\,.\,3} = 44$ teeth (the numbers being the numbers respectively of pairs of incisors, canines, premolars, and molars in the upper and lower jaws). No living primate has retained more than two incisors in the upper jaw and only in tree shrews is the primitive number of three incisors retained in the lower jaw. The incisors are subject to considerable variation in prosimians. Characteristically, the upper incisors are peglike, one or other pair often being absent; in the lower jaw the incisors show a peculiar conformation which has been likened structurally and functionally to a comb. The dental "comb" of prosimians is composed of the lower canines and lower incisors compressed from side to side and slanted forwards; the dental comb appears to be primarily a device for grooming the fur. Canines are present throughout the order, but show remarkable variation in size, shape, projection, and function. Characteristically the teeth of cercopithecines have a function in the maintenance of social order within the group as well as an overtly offensive role; their function as organs of digestion is relatively unimportant. They are large and subject to sexual dimorphism, being larger in males than females. Man's canines are small and are almost wholly dental in function, with no size differences between the sexes.

Evolutionary reduction of the cheek teeth

The trend in the evolution of the cheek teeth has been to increase the number of cusps and reduce the number of teeth. Both molars and premolars show this tendency. No living primate has four premolars; prosimians and New World monkeys have retained three on each side of each jaw, but at the anthropoid level two premolars are the invariable rule. The primitive premolars are uniform in shape and are unicuspid, but in primates the most posterior premolar tends to evolve either one or two extra

cusps (molarization), an adaptation providing an extended tooth row for a herbivorous diet. In species with large upper canines, the most anterior lower premolar assumes a peculiar shape known as sectorial, functioning as a hone for the scythelike canine. In man, whose canines are small and unremarkable, the first and second premolars are identical in shape and two-cusped.

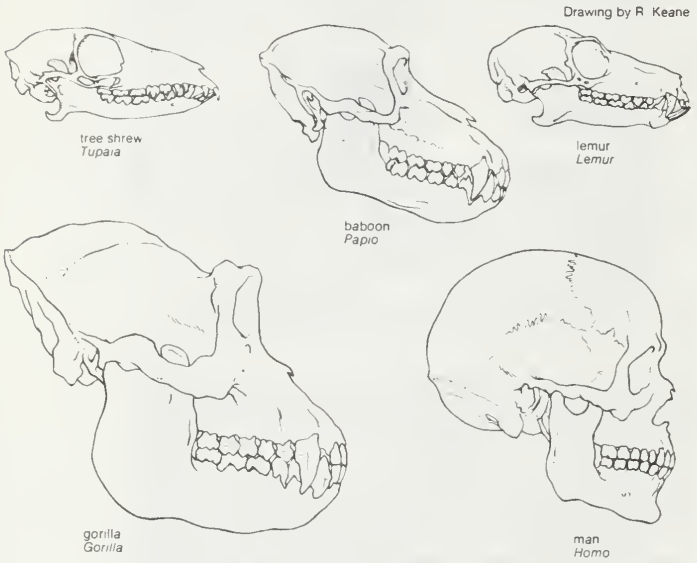

Figure 23: Skulls and teeth of primates.

The trend in the morphology of the molars has been to increase the primitive three cusps to four or five. The apes and man are more specialized in this feature than are the monkeys or the lower primates, having four cusps on the molar crown in the upper jaw and five cusps on the lower. A further tendency has been to reduce the molar series from three to two in both jaws, principally in the lower.

Snouts, muzzles, and noses. The reduction of the snout in primates is a correlate of the diminution of the olfactory sense (see below *Sensory reception*). To a great extent visual acuity and manual dexterity have replaced the sensitive, inquiring nose found in so many nonprimate mammals. A marked reduction in the complexity of the "scroll" bones of the nose, the richness of the innervation of the olfactory mucous membrane, and the sensitivity of the moist tip of the nose—the rhinarium—is associated with the reduction in length of the primate snout. Although the trend in primate evolution is towards a dethronement of the primacy of the sense of smell, there are still some good snouts to be seen in those lower primates, that retain a naked moist rhinarium attached to the upper lip.

Prosimians depend for many aspects of their social and reproductive behaviour on olfactory signals which are effected by means of special scent glands distributed in different regions of the body but congregated principally in the anal and perineal regions. Marking behaviour, the placing of scent at various points in the environment, is a prominent feature of the prosimian repertoire of communication. Marking behaviour ceases to be of much importance above the prosimian level, and in anthropoids the structures by which olfactory signals are given and received are diminished. Monkeys, apes, and man, though they may be lower down the scale of olfactory excellence than prosimians, rely in considerable measure on the sense of smell; all higher primates, for instance, including man, sniff at unfamiliar items of food before placing them in the mouth.

The platyrrhine–catarrhine division

The shape of the nose of higher primates is one of the most reliable means of distinguishing Old World monkeys from New World monkeys at a glance. In New World monkeys or Platyrrhines (platyrrhine means "flat nosed") the nose is broad and nostrils are set wide apart, well separated by a broad septum, and point sideways; in Catarrhines (catarrhine: "downward nosed") the nostrils are set close together, point forwards or downwards, and are separated by a very narrow septum.

Some Old World monkeys, particularly those that have adopted a ground-living way of life, such as baboons, mangabeys, and the mandrills of the subfamily Cercopithecinae, appear to have re-adopted a long snout during their evolution. This structure, however, is not primarily olfactory in function but seems, rather, to be more closely related to the large size of the jaws and the prominence of the canine teeth; it should be considered a dental muzzle rather than an olfactory one.

Sensory reception and the brain. Among mammals in general, the olfactory system is the primary receptor for environmental information; consequently the brain of most mammals is dominated by the olfactory centres. In primates the sense of smell is considerably less important than the well-developed visual system and highly refined sense of touch. The primate brain is enlarged in the specific areas concerned with vision (occipital lobes) and touch (parietal lobes), thus taking a characteristic shape throughout the higher primates.

Touch. The skin of the primate hand is well adapted for tactile discrimination. Meissner's corpuscles, the principal receptors for touch in hairless skin, are best developed in the apes and man, but can be found in all primates except the tree shrew: structurally correlated with a high level of tactile sensitivity are certain anatomical features of the skin of the hands and feet, such as the absence of pads on the palms and soles, characteristic of mammals in general, and the presence of a finely ridged pattern of skin corrugations known as dermatoglyphics (the basis for fingerprints).

Eyes and vision. The evolutionary trend towards frontality of the eyes has not proceeded as far in the prosimian as in the anthropoid families. Tree shrews retain set of the eyes like that of the primitive ancestor, the central axis of each bony orbit being 140° apart. In lemurs this angle is considerably less, 60°–70°, and in the anthropoid families of apes and monkeys the divergence has been reduced to 20°. It should be noted that the axes of the eyeballs (as distinct from the bony orbits) in apes and monkeys are, in fact, parallel.

Colour vision

Colour vision is of considerable advantage to arboreal animals living on fruits and insects. Species that have both rod and cone receptors in their retinas include all of the Anthropoidea with the exception of some of the nocturnal species (*Aotus*, the night monkey of South America, for example), and the family Lorisidae and some of the Lemuridae among the prosimians. Rods are the more primitive retinal cells and respond to low intensity light, while cones, which respond to high light intensity, have a greater resolving power, and thus provide for a finer type of visual discrimination. Cones, moreover, are adapted for colour discrimination.

Nervous integration. The elaboration of touch and vision supplements the senses of smell, hearing, and taste, providing the primate with a sensory armament of great range and flexibility. The primate central nervous system is sufficiently refined to deal with the elaborate bombardment of environmental information reaching it. Association areas provide the connections between the input and output centers of the brain—the motor and sensory cortex. Association areas are the memory banks where the memory of past experience is encoded in the infinitely complicated plexiform arrangement of the neurons, the

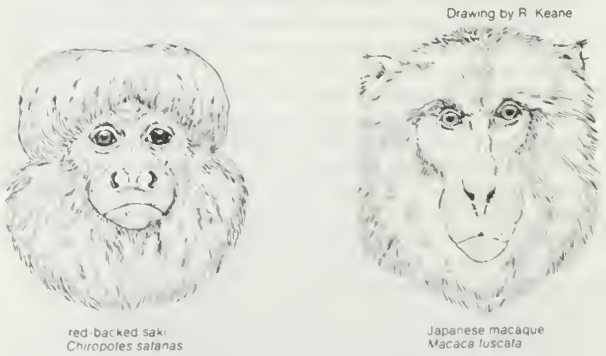

Figure 24. Head of New World monkey (saki) compared with head of Old World monkey (macaque).

brain cells, and their processes. All sensory impulses reaching the cortical centers of the central nervous system are routed through the association areas for conditioning, as it were, before reaching the effector side or output side where the appropriate response is initiated in the cells of the motor cortex. The more highly developed the association areas of the brain are, the more specific and appropriate is the behaviour and the more versatile is the animal in facing environmental demands.

The brain. The principal evolutionary trend in brain development has been towards elaboration. The neocortex of higher primates possesses highly developed associative functions, an aptitude for receiving, analyzing, and synthesizing the sensory input from visual, olfactory, auditory, gustatory, and tactile receptors and converting them into the appropriate motor responses.

Relative versus absolute brain size

The brain of Anthropoidea is larger, both absolutely and relatively, than that of prosimians. For instance, the weight of the simplest anthropoid brain, that of a marmoset, is three times greater than the brain weight of the bush baby, a prosimian of comparative size. This quantitative increase, in part, is attributable to the elaboration of the regions of the neocortex concerned with tactile and visual sensitivity; and in part to the elaboration of the intrinsic pathways connecting one part of the brain with another. The large brain of man is attributable not so much to an increased nerve cell content as to an increase in the size of the nerve cells and to a greater complexity of the connections linking one cell to another.

The external form of the anthropoid cerebral cortex is characterized by a complicated pattern of folds and fissures (sulci and gyri) in the brain surface. The fissural pattern is seen in its simplest form in the marmosets, but in the larger and more advanced members of the New World monkey infraorder, the capuchins (*Cebus*) for instance, the cerebrum is richly convoluted. Gyri and sulci are well marked in Old World monkeys and in the apes, the complexity of the pattern closely approximating the tortuous mazelike pattern seen in man.

Reproductive system. *Male and female genitalia.* The functions of the individual organs of reproductive systems are fairly uniform throughout the primates, but in spite of this physiological homology there is a remarkable degree of variation in minor detail of organs between groups, particularly in the external genitalia, which, by their variation, provide a morphological basis for the reproductive isolation of the species. There could be no more effective barrier to mating between different species than incompatability of the male and female sex organs.

Among the characteristics of the primate order as listed by Mivart, the penis is described as "pendulous" and the testes as "scrotal." In contrast to other mammals, the primate penis is not attached to the abdominal wall but hangs free. The testes, with a few exceptions among the prosimians, in which they are withdrawn seasonally, lie permanently in the scrotal sac. In all primates except modern man (there is no evidence one way or the other regarding early representatives of the genus *Homo*), tarsiers, and some South American monkeys, the penis contains a small bone called the baculum, a typically mammalian character. The uterus of female primates shows all grades of transition between the two-horned (bicornuate) uterus, typical of most mammals, to the single-chambered (simplex) uterus of the higher primates and man.

Variations between primate taxa are demonstrated most strikingly by the glans penis, the scrotum, and perineum of the male, and the clitoris and the labial folds of the female vulva. The length and form of the clitoris, which when elongated mimics the penis, as in spider monkeys for instance, is a potent source of confusion in determining the sex of certain New World primates. The coloration of the male scrotum in forest-living primates, particularly of the genera *Cercopithecus* and *Mandrillus,* shows an infinite range of variations and provides a species-recognition signal of considerable effectiveness.

The external appearance of the genitalia undergoes seasonal variation in a number of primates. In the male, swellings of the testis and colour changes of the scrotum occur, and, in the female, swelling and coloration of the vulva and perineal region herald ovulation, sometimes most obtrusively. Turgidity and excessive vascularity of the tissues of the perineum are probably characteristic of all mammals, but there are certain primate species in which this engorgement reaches monstrous proportions, notably baboons, mangabeys, some macaque species, and chimpanzees. Regions other than the primarily genital areas may also be affected by the hormones circulating at certain periods of the reproductive cycle. For instance, in the gelada baboon, the skin on the front of the female chest, which normally bears a string of caruncles resembling the beads of a necklace, becomes engorged and brightly coloured. A German zoologist, Wolfgang Wickler, has suggested that this is a form of sexual mimicry, the chest mimicking the perineal region. The observation that geladas spend many hours a day feeding in a sitting posture provides a feasible, Darwinian explanation of this curious physiological adaptation.

Mimicry of bottom by chest colours

Placenta. The placenta, a characteristic of all Eutherian mammals, is a vascular structure that permits physiological interchange of blood and body fluids between the mother and the fetus and the breakdown products of the fetal metabolism; it also provides a two-way barrier preventing the passage of some, but not all, noxious substances and organisms such as bacteria and viruses from one individual to the other and is the source of hormones such as estrogens.

The placenta is a flat discoid-shaped "cake" in man, some of the other higher primates, and the tarsier. In many monkeys it is bidiscoidal, having two linked portions. The placenta is intimately attached on its outer surface to the endometrium, the lining of the uterus, by fingerlike processes (villi) that embed themselves in the endometrium where the vascular connections between the two circulations are achieved. The connection between fetal and maternal circulations appears as two distinct types among primates, a distinction which is believed to have had an important effect on the evolution of the order. In the first type (epitheliochorial), found in the prosimian suborder, several cellular layers separate the maternal and fetal bloodstreams, thus limiting the passage of molecules of serum proteins. In the second type, hemochorial placenta, the relationship is much more intimate, there being no fetal and maternal cellular layers separating the two circulations, and serum proteins can easily pass. A hemochorial type of placentation is found in tarsiers, apes, monkeys, and man.

The placenta is shed at birth in all primates, and, in all other than civilized man, is eaten by the mother.

EVOLUTION AND PALEONTOLOGY

Renewed interest in primate origins. Beginning in the 1950s there was a notable expression of interest in primate paleontology. Since then, hardly a year has passed without the announcement of some new major discovery. New sites have been opened up and old discoveries redescribed and reallocated. New techniques in geological dating, in palynology (the study of fossil pollen), in paleoclimatology and paleoecology and in the archeological interpretation of fossil sites, have helped to lift primate paleontology into the forefront of the life sciences and have aroused public interest to an unprecedented level. The popularity of all aspects of the evolution of man is reflected, for instance, in the spate of books covering this field published during this period.

Important recent sites of primate fossils

The African continent has contributed the greatest share of significant early finds—Rusinga and Songhor in Kenya, Olduvai in Tanzania, and Sterkfontein, Kromdraai, Swartkrans, Makapan in South Africa are names with which every anthropology student is familiar. Later, the names Omo, Kanapoi, Lothagam, Napak, Moroto, Laetoli, and Hadar—all East African sites of hominid and pongid discoveries in the 1970s and '80s—became equally well known.

Elsewhere, pieces of this colossal worldwide jigsaw have been discovered in Europe, notably in Hungary, France, and Italy; in the Siwālik Hills of northwest India; in the ever prolific middle Eocene Bridger Beds of North Amer-

ica; and in Colombia and Bolivia. These latter discoveries were particularly welcome because of the poverty of fossils of New World monkeys.

While new discoveries have clarified the human story, older ones, that had only served to cloud it, have been repudiated. Piltdown man was shown unequivocally to be a fake in 1953; *Oreopithecus* of Monte Bamboli, Italy, has been relegated to a family remote from human ancestry, and Galley Hill Man in England has been shown to be a recent intrusion (a burial) into middle Pleistocene gravels. The questionable finds from the remoter geological period of the Eocene and Oligocene have also been re-examined, with the result that a number of confusing fossils have been dismissed. *Anagale*, long thought to be a fossil tree shrew, is now regarded as a small carnivore; others, such as the supposed tarsioid-anthropoid annectent form, *Parapithecus fraasi*, have been reallocated within the order Primates.

Progress in constructing the phylogeny of higher primates and man has been bedevilled by a number of controversies concerning taxonomy and nomenclature, and, as a result, internal disagreements have developed which mitigate against the sort of international cooperation that is essential for so vast a project as the construction of a human phylogeny. New-school and old-school taxonomists have come into conflict. But with the rapid advances in genetics, in the new concepts of biological species and in population anthropology, a fresh equilibrium is slowly being acquired, as the pendulum swings between the reactionary "lumping" of such taxa as genera and the traditional "splitting," in which every new discovery was provided with a new generic name. The most extreme example of taxonomic lumping in primate paleontology was in a 1965 revision by E.L. Simons and D.R. Pilbeam of the Miocene–Pliocene genus *Dryopithecus;* from the 28 genera recognized prior to 1965, the authors recommended the recognition of three genera only: *Dryopithecus, Ramapithecus,* and *Gigantopithecus.* All the rest were absorbed into the three genera, a result initially satisfying but not yet subjected to the test of time.

The primate fossil record. *Cretaceous.* The known range of the primate order was extended back from the middle Paleocene to the Late Cretaceous (about 75,000,000 years ago) by the discovery in Montana of one premolar and four molar teeth, representing two species of insectivore-like primates that were assigned in 1965 to a new genus, *Purgatorius.* This diagnosis is based on the characters of four molar and one premolar tooth and is not by any means universally accepted.

Paleocene. The best known early primate species, of which, *inter alia,* a complete skull and a partial postcranial skeleton are available, belongs to the genus *Plesiadapis* from the Paleocene (about 60,000,000 years ago) of Cernay, France, and Colorado. The skull shows a number of dental specializations including procumbent rodentlike incisors in the upper and lower jaw and the absence of antemolar teeth, but the molar teeth show the unequivocal primate affinities of this species. Rodent affinities have been suggested for *Plesiadapis,* but most authorities agree that it is a primate, however aberrant.

Eocene. The known Eocene fossil families include the Tarsiidae (tarsiers), the Adapidae, considered probable ancestor of lemurs and lorises, and the Omomyidae, possible ancestors of the monkeys and apes.

Possible ancestors of the lemurs

The family Adapidae contains two North American genera, *Notharctus* and *Smilodectes,* which are well represented in the fossil deposits of the Bridger Basin, Wyoming. *Adapis,* a closely related genus, was widely distributed in Europe, as were *Anchomomys* and *Pronycticebus. Notharctus* and *Smilodectes* are not thought to be antecedent to living lemurs, principally on zoogeographical grounds, since egress from the North American continent for tropical species was effectively cut off by ecological changes soon after the beginning of the Eocene (about 54,000,000 years ago). *Notharctus* was not unlike the modern lemurs in size and general appearance. On both morphological and zoogeographical grounds, *Adapis* and *Pronycticebus* or *Anchomomys* could have provided the stem from which the living lemurs and lorises evolved.

Figure 25: Eocene fossil lemur *Notharctus.*
Drawing by R. Keane

Representatives of the Omomyidae have been found in North America, in Europe, and in Asia. According to American paleontologist Elwyn L. Simons, the Omomyidae are probably the key family for tracing the phylogeny of the higher primates, the apes and monkeys. The family was common to North America and Eurasia, a fact which reinforces the presently held view that omomyids provided the stock from which New World monkeys and Old World monkeys, apes, and man arose. Their principal claim to antecedency (other than the circumstances of their zoogeography) is the dental formula: $\frac{2 \cdot 1 \cdot 3 \cdot 3}{2 \cdot 1 \cdot 3 \cdot 3} = 36$ teeth (18 pairs).

The Eocene Tarsiidae, represented by the European species *Necrolemur antiquus,* found in the Quercy deposits of France, are likely to contain the ancestor of the modern genus *Tarsius.* The tarsier is indeed a "living fossil" in the best sense of that overworked term. What is known of the skull and skeleton of *Necrolemur antiquus* indicates that it was almost identical with that of the living *Tarsius.*

Oligocene. Information on primate evolution during the Oligocene Epoch (about 38,000,000 to 26,000,000 years ago) rests principally on discoveries in three areas—Burma, Texas, and Egypt, and by far the most important is Egypt. From the Fayum region of the Sahara, from the upper levels of the Qatrani Formation, has come the first evidence of the emerging Anthropoidea. A number of different genera have been described from the Fayum, including *Apidium, Propliopithecus, Oligopithecus, Parapithecus, Aeolopithecus,* and *Aegyptopithecus.* The Fayum, indeed, seems to be the cradle of the Old World anthropoids. Simons has indicated that the possible ancestors of Old World monkeys (*Parapithecus, Apidium*), of gibbons (*Aeolopithecus*), of apes (*Aegyptopithecus*), and even of man (*Propliopithecus*) are all represented in the fauna. Unfortunately, apart from fragmentary scraps of limb bones, there are no postcranial bones to help. From the evidence provided by the possible forerunners and probable descendants of the Fayum primate fauna, however, it is reasonable to assume that quadrupedalism was becoming established as the typical locomotor pattern, and that vertical clinging and leaping, the characteristic gait of the Eocene forebears of the fauna, was probably retained by at least some of the genera represented at this site.

Rooneyia, an important transitional form

Of unusual interest is the recent discovery of the cranium of a North American omomyid called *Rooneyia,* it is of particular note in view of a belief that primates had disappeared from North America by the late Eocene times. *Rooneyia* is also of considerable interest in itself. The

skull possessed a mixture of primitive (prosimian) and advanced (anthropoid) features, precisely the combination that might be anticipated in a transitional form between lower and higher primates.

Miocene. The Miocene Epoch is probably the most fruitful of all for paleoprimatology. During the 19 million years of its duration (beginning about 26,000,000 years ago), dramatic changes in geomorphology, climate, and vegetation took place. The Miocene was a period of volcanism and mountain building, during which the topography of the modern world was becoming established; of particular relevance to the story of primate evolution are the vegetational changes resulting from the orogenic ones. Grasses, known since the early Tertiary Era, flourished in the new conditions and in many areas that were previously forested. Grassland is known regionally by such names as savanna, llanos, prairies, etc. A new type of primate—the ground inhabitant—came into being during this period. The generalized nature of the bodily form of primates, combined with their specialized brain, made possible this critical step.

In the last few decades considerable additions to the knowledge of ape and human evolution have accrued from Miocene fossil beds in East Africa and Europe.

In Europe further discoveries of the gibbon-like genus *Pliopithecus* and the gorilla-chimp-like genus *Dryopithecus* have been made. *Pliopithecus* remains from Neudorf-an-der-March in Czechoslovakia have provided a remarkably complete picture of the habits of the Miocene apes, which, on this evidence, appear to have possessed bodily forms of a quadruped with morphological overtones of incipient brachiating specializations. Perhaps most interestingly of all, *Pliopithecus,* with its retention of numerous platyrrhine or New World monkey characters, emphasizes the phylogenetically conservative nature of anthropoid evolution.

In East Africa the excavations of the inshore islands and of the Kenyan shores of Lake Victoria by L.S.B. Leakey and a number of colleagues have illuminated man's knowledge of the evolution of the African great apes and have set up provocative questions regarding the origins of man. The *Proconsul* group (relegated to subgeneric status within *Dryopithecus* by the revision of Simons and Pilbeam) is known from three fossil species of ape, *Proconsul major, P. nyanzae,* and *P. africanus.* All three species are represented by a large number of jaw and facial fragments, but the only complete skull, discovered in 1948, belongs to *P. africanus.* Though complete, it was somewhat distorted by pressure of the surrounding rocks during fossilization. Subsequent reconstruction revealed a skull more monkey-like than apelike in its contours, an appearance which belied the unquestionably chimpanzee-like affinities of its teeth. The form of the skull and braincase of *P. africanus,* along with the forelimb skeleton, which is known in great detail for this species, indicates a body form that most closely resembles that of living monkeys. An American anthropologist, Sherwood L. Washburn, has described these creatures as "dental apes." The monkey-like characteristics of the *Dryopithecus* (*Proconsul*) group reflect the recency of the separation of the monkey and ape stocks of the Old World.

Proconsul africanus has been suggested as a possible common ancestor for apes and monkeys, but the general consensus is that *P. africanus* was already too specialized dentally to fit such a role. Be this as it may, there is no doubt that this Miocene fossil ape provides a very reasonable "model" for such an ancestor.

In East Africa two species of fossil gibbons, *Limnopithecus,* have also been discovered, closely related, if not generically identical, to the fossil "gibbon" of European deposits termed *Pliopithecus.* The taxonomic status of these fossils as "gibbons" is somewhat uncertain.

Appearance of hominids

It is towards the end of this turbulent epoch that the first probable ancestral hominids appear in the fossil record. *Ramapithecus punjabicus* was discovered in 1934 by an American paleontologist, G.E. Lewis, in the Siwālik Hill Miocene deposits in northwest India. Lewis tentatively expressed the view that *Ramapithecus* was a hominid, but the scientific climate of the period was not propitious for claims that seemed to imply such remote anteeedents for man; as a result Lewis' pereeptiveness was largely ignored. Recently, Simons and Pilbeam have resurreeted Lewis' specimen and have demonstrated its hominid characteristies. At Fort Ternan in East Africa, meanwhile, Leakey found what at present appears to be another specimen of *Ramapithecus,* but of a different speeies and called by him *Kenyapithecus wickeri.*

It was also from the late Miocene that the first unequivocally ground-living monkey came to light. Attributed to the living subfamily Cereopithecinae of Old World monkeys, these speeimens of *Mesopithecus pentelici* demonstrate the transition between the aneestral monkey type (today represented by the leaf-eating monkeys or Colobinae of Africa, India, Ceylon, Malaya, Burma, and Southeast Asia) and the newly evolved type of ground-living monkey epitomized by *Macaca* or *Papio.* In its known features of skull and posteranial skeleton, *Mesopithecus* is broadly equivalent to the macaque monkeys.

First ground-living monkey

Pliocene. The Plioeene Epoch (from about 7,000,000 to 2,500,000 years ago) was very similar to the present in terms of its geomorphology and elimate. Discounting the effects of the reeent influeence of man on the distribution of forest and savanna in the tropies, the face of the land cannot have differed mueh from the aspeet it presents today. Thus, one would expect that during the Pliocene (bearing in mind the effectiveness of environmental selection) essentially modern forms of primates would have made their appearance, but perhaps the most famous of the Plioeene fossils was far from "modern." *Oreopithecus* was first discovered, fragmentarily, in brown eoal deposits in Italy in the middle of the 19th eentury. The most recent discovery of a complete, though paper-thin, skeleton (so grossly has it been compressed) in Tuscany has demonstrated the power of the environment acting upon the genetic structure, in once again reproducing the trade marks of two of the "inevitable" trends of primate evolution, brachiation, and bipedalism. *Oreopithecus* possessed a number of dental and bony characters that are typically hominid; it also possessed limb characteristics that are typically pongid. The canines were relatively short, the face was abbreviated, and the pelvis was broad. The foot showed charaeteristics assoeiated with bipedal walking as did the vertebral column (all hominid characters), yet the arms were long and the fingers long and curved. The limb proportions are those of a brachiator (pongid characters). Finally, a number of characters of this confusing hominoid typieally reflect those found in Old World monkeys. The present eonsensus of attitude towards this composite primate is that it is best segregated within the superfamily Hominoidea but in a family of its own, the Oreopithecidae. That the end of the *Oreopithecus* story has not yet been heard is certain; in the meantime the Tuscany fossil stands as a memorial to the primate order, the order which, of all of the class Mammalia, is most subject to environmental adaptation by virtue of its behavioral plasticity.

Few fossils referable to the ape family are known during the Pliocene, and monkey families are scarcely better known. *Libypithecus* and *Dolichopithecus,* both monkeys, were probably ancestral cercopithecines that still retained some features of their colobine aneestry; but neither genus ean be placed in a precise ancestral relationship with modern members of this subfamily.

Pleistocene. The Pleistoeene, which on faunal evidence is estimated to have started 2,000,000 to 3,000,000 years ago, is the epoch of hominid expansion (see EVOLUTION, HUMAN: *Classes of Hominidae*). Knowledge of nonhuman primates is surprisingly sketchy. No ape fossils are known until relatively recent times and monkeys have been identified in only a few regions in Africa and even fewer in Asia; *e.g., Cercopithecoides* (a colobine-like form), *Gorgopithecus, Dinopithecus,* from South African deposits (forms of the living genus *Papio*); and *Simopithecus* (a giant, ancestral forerunner, according to one authority, of the present-day genus, *Theropithecus,* the gelada) from Olduvai Gorge and South Africa. It is possible that the *Papio-Theropithecus* divergenee can be pushed well back into the Pliocene.

One genus of the Pleistocene that is neither ape nor

The special case of *Gigantopithecus*

monkey in the sense that these taxa are interpreted today is *Gigantopithecus*. The romantic story of the discovery of the gargantuan molar teeth of *Gigantopithecus blacki* by von Koenigswald, the Dutch paleontologist, in a Chinese pharmacy has often been told. The boldness of the move that erected a new genus on such apparently slender grounds has been amply justified by the subsequent discovery of several massive jaws from Kwangsi in South China and attributed to this genus. The most recent discovery is of an enormous jaw in the Dhok Pathan deposits of the Siwālik Hills of India. Possibly dating back to the middle Pliocene, this discovery provides a respectably long period of existence for this aberrant giant-toothed hominoid genus. Clearly *Gigantopithecus bilaspurensis* was a member of the family Pongidae with divergent dental specializations that were possibly adaptive for foraging in grassland where tree products were unavailable and ground products available but hard to get. *Gigantopithecus* was a fossil ape that fell by the wayside on its way up to hominid status, a victim, possibly, of overspecialization.

CLASSIFICATION

Distinguishing taxonomic characters. The identifying characters of the primate order have already been discussed above. The point has been made that no single morphological characteristic distinguishes this group exclusively from other mammalian taxa. For instance, while it is possible to make the generalization that primates bear flat nails on the ends of their fingers and toes, it is not strictly accurate, for species such as the tree shrews, the marmosets, and the tamarins have either overt claws (tree shrews) or modified claws (marmosets and tamarins). One can also aver that primates characteristically possess two pectoral mammae, but it must be pointed out that the aye-aye (*Daubentonia madagascariensis*) has its nipples sited in the inguinal region (lower lateral region of the belly) and that mouse lemurs and tree shrews have multiple sets. Generalizations regarding opposability of the thumb, a "classic" primate character, are particularly vulnerable since some marsupials possess this trait and some primates do not. Examples of the generalized nature of primate specializations are too numerous to mention here. At first sight, big toe opposability provides a more promising diagnostic feature but, as with other features, there are exceptions to the rule, man for instance; moreover, it occurs in nonprimates.

Features and exceptions

As F. Wood Jones said in his book *Man's Place Among the Mammals:* "There is no single [characteristic] which constitutes a peculiarity of the Primates: for a primate animal may only be diagnosed by possessing an aggregate of them all." It was with this precept in mind that Sir Wilfrid Le Gros Clark introduced his list of evolutionary trends of primate evolution in 1959, which is amplified below:

1. The preservation of a generalized structure of the limbs with a primitive pentadactyly [*i.e.*, containing five digits] and the retention of certain elements of the limb skeleton (such as the clavicle) which tend to be reduced or to disappear in some groups of mammals.
2. An enhancement of the free mobility of the digits, especially the thumb and big toe (which are used for grasping purposes).
3. The replacement of sharp compressed claws by flattened nails, associated with the development of highly sensitive tactile pads on the digits.
4. The progressive abbreviation of the snout or muzzle.
5. The elaboration and perfection of visual apparatus with the development to varying degrees of binocular vision.
6. Reduction of the apparatus of smell.
7. The loss of certain elements of the primitive mammalian dentition, and the preservation of a simple cusp pattern of the molar teeth.
8. Progressive expansion and elaboration of the brain, affecting predominantly the cerebral cortex and its dependencies.
9. Progressive and increasingly efficient development of those gestational processes concerned with the nourishment of the foetus before birth. (From W.E. Le Gros Clark, *The Antecedents of Man;* © 1959 Edinburgh University Press.)

Two further evolutionary trends may be added to the list:

10. Progressive development of truncal uprightness leading to a facultative (opportunistic) bipedalism.
11. Prolongation of postnatal life periods.

From J.R. and P.H. Napier, *A Handbook of Living Primates* (1967).

A British zoologist, R.D. Martin, has criticized many of these evolutionary trends as irrelevant as determinants of primate origins. In his view, many of them are either symplesiomorph characters (primate characters inherited from an ancestral mammal and therefore nonspecific for primates) or convergent characters (characters that have been acquired by many groups of primates in response to the environmental effects of natural selection). The disputed trends of primates, nonetheless, comprise characters that are of considerable significance for primate classification. Martin's point is that such characters are of little use in distinguishing the order Primates from other placental orders. Martin argues that the inadequate nature of the current definitions of primates is the principal reason why, when so much behavioral and structural evidence points to the opposite conclusion, the tree shrews (Tupaiidae) are presently included in the order. This may well be so. But until the true synapomorph characters (characters of independent acquisition) are identified by extensive comparative studies of all of the relevant characters of primates and nonprimates, there is little justification for arbitrary disenfranchisement of the tree shrews. "Possession is nine-tenths of the law," a principle that, as in this instance, supplies the highly desirable element of stability to zoological nomenclature.

Annotated classification. It is apparent that the taxonomy of primates is in a very fluid condition; but this state of affairs is wholly preferable to the virtual stagnation that existed during the first half of the present century. In view, therefore, of the likelihood of further major revisions taking place during the next decade that may well reveal the fallacies of certain current concepts, the informational content of this section is best served by a conservative, rather than a radical, approach to primate classification. Thus, the most widely accepted current classification is here followed, while fully admitting that it is not wholly adequate. In order to avoid some of the descriptive complications, derived from an imperfect classification, the following scheme outlines the distinguishing taxonomic characters of order, suborders, and families; intermediate taxa, such as infraorders and superfamilies, are omitted.

ORDER PRIMATES

Distinguished by the possession of a hallux (first toe) and a pollex (thumb), one or both opposable; eyes frontally placed on the face, orbit ringed by bone and, in higher members of the group, closed posterolaterally by bone. Brain relatively large. Most of the fingers and toes bear nails, not claws. Number of teeth 18 to 36; canines prominent but dentition as a whole not highly specialized. Diet omnivorous; body weight from about 100 grams (a few ounces) to 180 kilograms (400 pounds), more or less. Twelve Recent families, 55 genera and 197 species; 8 extinct families. Extinct groups are indicated by daggers (†).

†Suborder Plesiadapoidea

†Families Phenacolemuridae, Carpolestidae, and Plesiadapidae

Middle Paleocene to lower Eocene; North America and (except Phenacolemuridae) Europe; collectively, more than a dozen genera.

Suborder Prosimii

Usually quadrupedal and plantigrade, but some species show vertical clinging in trees and saltation on the ground; all have long tails (except *Indri*). Very small to medium in size; substantially insectivorous, but fruit- and leaf-eating common; activity rhythm nocturnal or crepuscular. Suborder characterized by possession of long or longish snouts, naked rhinarium, and naked tethered upper lip (except *Tarsius*); facial vibrissae (whiskers) present. Specialized sublingual fold, often serrated, below tongue. Eyes large, fully frontally facing in *Tarsius*, but somewhat divergent laterally in others; bony orbits not fully closed posterolaterally. Teeth characterized by special arrangement of lower incisors and canines to form a dental "comb," except in *Tarsius* (structure absent) and in *Tupaia* (canines take no part in comb); upper incisors usually small and peglike. Hallux and pollex more or less opposable, tips of all digits bear flat or flattish nails (except in *Tupaia*), second digit of hindlimb bears toilet (grooming) claw. Placenta epitheliochorial and nondeciduate (except *Tarsius*). One or more pairs of nipples. Single births are the rule.

Family Tupaiidae (tree shrews)

Small animals with elongated body and long bushy tail (sca-

ly with terminal tuft in *Ptilocercus*). Short limbs, with fore longer than hind. Long pointed snout. Relatively large brain (compared with nonprimates) with diminished olfactory representation; turbinal bones of nasal region of skull not well developed. Tympanic ring within middle ear cavity. Primitive dental pattern, with 3 pairs of lower incisors, protuberant and arranged as modified "dental comb"; cheek teeth primitive in form. Digits of hands and feet bear claws; pollex is incipiently divergent, but nonopposable; hallux, nonopposable. Both arboreally and terrestrially adapted species occur within the family. Head and body length 10–24 cm (3.9–9.4 in.), tail 12–14 cm (4.7–5.5 in.); 5 genera, 17 species; India and Southeast Asia and Philippines.

†*Family Adapidae (Notharctidae)*

Lower to upper Eocene; Europe, Asia, and North America; about 10 genera.

Family Lemuridae (lemurs)

Size very small to medium; tail longer than head and body length combined; hindlimbs considerably longer than forelimbs; tail more developed in subfamily Lemurinae than in the other subfamily Cheirogalinae. Coat colours highly variable; one species, *Lemur macaco*, shows sexual dichromatism (males black, famales rufous). Tympanic bullae large, tympanic ring contained within middle ear cavity (contrasting with Lorisidae). Cutaneous glands on forearm and upper arm serving marking functions in *L. catta* and *Hapalemur griseus;* absent from other species. Dentition typical of Prosimii, including "dental comb" and reduced upper incisors (absent in *Lepilemur*). Diurnal (*Lemur, Hapalemur*) or nocturnal. Births seasonal; twins common in *Microcebus*. Head and body length 13–46 cm (5.1–18.1 in.), tail 17–56 cm (6.7–22 in.); 6 Recent genera; about 14 species (some possibly extinct); restricted to Madagascar.

Family Indriidae (indri, sifaka, and avahi)

Arboreal animals with exceptionally long limbs, associated with specialized locomotor habit of vertical clinging and leaping. Skull with somewhat downwardly facing foramen magnum, short facial skeleton and very large auditory bullae. Dentition atypical of Prosimii; lower canines absent, first premolar somewhat caniniform, 2 premolars only. Anatomy of stomach and cecum, particularly, specialized in association with a bulky vegetarian diet. Activity rhythm nocturnal (*Avahi*) or diurnal (*Propithecus* and *Indri*). Fossils from Pleistocene. Three living genera, 4 species; Madagascar.

Family Daubentoniidae (aye-aye)

Arboreal, nocturnal family comprising single species *Daubentonia madagascariensis*. Hand specialized by markedly elongated and attenuated third digit. Dentition anomalous: central incisors reduced to single large pair having long roots and a rodent-like function; canines absent, premolars absent in lower jaw and reduced in upper. Symphysis between right and left halves of mandible is fibrous, a condition unique among the primates. Single inguinal pair of nipples. Madagascar.

Family Lorisidae (galagos, lorises, angwantibo, and potto)

Arboreal and nocturnal. Two major locomotor types comprise family: vertical clingers and leapers (subfamily Galaginae) and slow quadrupedal climbers (Lorisinae), the former possessing excessively long hindlimbs, and the latter subequal limbs. Tails short or absent in Lorisinae and long in Galaginae. Second digit of hand reduced, extremely so in Lorisinae (particularly *Perodicticus* and *Arctocebus*) and first digit of hand and foot disproportionately large. Skull globular in form with little protrusion of facial region. Tympanic bullae large, short external auditory canal with tympanic ring sited at junction of middle and external ear. Orbits large, with little lateral divergence. Dentition typical of suborder. Omnivorous (with large insectivorous element). Family comprises 5 Recent genera with about 12 species; Africa, Asia (Lorisinae); Africa (Galaginae).

†*Family Anaptomorphidae*

Upper Paleocene to middle Eocene; North America and Europe; about 10 genera.

†*Family Omomyidae*

Upper Paleocene to lower Oligocene; North America, Europe, and Asia; about 20 genera.

Family Tarsiidae (tarsiers)

Arboreal and nocturnal. Hindlimbs almost twice the length of forelimbs. Hands with 5 digits, fingers surmounted by circular digital pads and backed by tiny triangular nails; thumb opposable, but in a fashion distinct from other Prosimii. Head of femur cylindrical (not spherical as in all other Prosimii except *Galago*), and tibia and fibula fused in lower third (unique to *Tarsius*). Skull characterized by enormous, frontally directed orbits, incompletely closed posterolaterally; nasal space much compressed. Foramen magnum (opening for spinal cord) directed downwards. Short external auditory canal; middle ear with prominent bulla and tympanic ring, sited as in Anthropoidea. Dentition unlike typical prosimian pattern, lacking dental comb; central lower incisors absent; molars sharp-cusped tuberculo-sectorial. Placentation is hemochorial, discoidal, deciduate, as in Anthropoidea. Single young usually produced. One genus, 3 species; Southeast Asia.

†*Family Microsyopidae*

Lower to upper Eocene; North America and Europe; 4 genera.

Suborder Anthropoidea

Quadrupedal, brachiating or bipedal in gait. Diurnal in habit (except night monkey, *Aotus*). Omnivorous in diet. Tail present or absent, varying in length from species to species, prehensile in some. Size ranges from very small (*Saguinus* and *Callithrix*, the tamarins and marmosets) to very large (*Gorilla* and *Homo*.) Faces show varying degrees of protrusion, most marked in the baboons and mandrills and least developed in man. Neurocranium relatively large and with or without sagittal or nuchal crests or both; foramen magnum directed downwards and backwards. Orbits frontally facing and fully closed posterolaterally; nasal cavity narrow. Dentition comprising 30–36 teeth, canines are well developed except in man. Hands and feet prehensile; thumb semi-opposable or fully opposable (except in certain platyrrhine species). Hallux widely abductable (capable of being rotated inward) and capable of prehension in all species except man; flat nails on fingers and toes (except Callitrichidae); specialized toilet claws absent. Two pectoral mammae only. Placenta hemichorial, discoidal, and deciduate. Lengthy gestation period and extended life periods (compared with Prosimii) characterize the suborder. Suborder contains two geographical groups: New World monkeys and Old World monkeys; 6 families and 35 genera; both the tropical and subtropical zones of New and Old World.

Family Callitrichidae (tamarins and marmosets)

Small animals, diurnal, arboreal, and mainly insectivorous. Quadrupedal gait, hindlimbs being 25 percent longer than forelimbs. Thumb nonopposable, but hallux fully abductable; all digits bear modified claws (tegulae) except hallux, which has a flat nail. External nostrils face forwards and sideways (platyrrhine condition); nasal septum broad. Coat colour highly variable between species including wholly black and wholly white forms; one species (*Leontopithecus rosalia*) golden; distinguishing external features include a variety of ear tufts and a diversity of mustaches. Skull long and ovoid in shape with bulging occiput; tympanic bulla present; external auditory canal absent. Dentition consists of 32 teeth (36 in *Callimico*) with 3 premolars and only 2 molars. Tamarins are distinguished from marmosets by long lower canines which project beyond incisors; in marmosets canines and incisors are the same length. Head and body length 13–37 cm (5.1–14.6 in.), tail 20–39 cm (7.9–15.4 in.); weight about 100–700 gm (3.5–24.7 oz). Five genera, 15 species; South America.

Family Cebidae (New World monkeys)

Larger in size than Callitrichidae, with ears more or less naked externally. All digits bear flattened or curved nails; thumb imperfectly opposable. Gait quadrupedal. Prehensile tail present in *Ateles, Alouatta, Brachyteles,* and *Lagothrix*. Bony ear formation as in Callitrichidae. Nose typically platyrrhine. Dentition of 36 teeth; molars quadrangular and quadricuspid, and canines moderately developed in both sexes. Head and body length about 24–70 cm (9.4–27.6 in.; tail usually of same magnitude), weight about 600 to 10,000 gm (1.3 to 22 lb); 11 genera, 29 species; southern Mexico to Brazil.

†*Family Parapithecidae*

Lower Oligocene; North Africa; 2 genera.

Family Cercopithecidae (Old World monkeys)

Medium to large in size. Arboreal or terrestrial. Characterized by naked callosities covering expanded ischial bone of pelvis. Quadrupedal, plantigrade, or digitigrade in gait; hindlimbs longer than forelimbs in most species, but in ground-adapted forms limbs are nearly equal. Thumb present in all genera (except *Colobus*) and functionally opposable. Cheek pouches present in subfamily Cercopithecinae and concerned with temporary storage of food; in subfamily Colobinae pouches are absent but stomach is sacculated in association with a predominantly leaf-eating diet. Tail length variable from very long (Colobinae) to very short or absent (some Cercopithecinae). Muzzle more or less prominent. Noses with external nasal opening facing forwards and downwards or directly downwards ("catarrhine" condition); internasal septum narrow (as contrasted with Callitrichidae and Cebidae). Skull of anthropoid type but without auditory bulla; external auditory canal present. Dentition of 32 teeth; canines large in males, moderate in females; first lower premolar sectorial, molars quadricuspid with transverse linking crests (bilophodonty). Head and body length about 32–

110 cm (12.6–43.3 in.); tail, when present, 2–100 cm (0.8–39.4 in.); weight about 0.7–30 kg (1.5–66 lb); 13 genera, 72 species; Africa, India, China, Japan, and South East Asia.

Family Hylobatidae (gibbons and siamang)

Demonstrate highly specialized form of locomotion called brachiation. Arboreal, tailless catarrhines with forelimbs twice length of hindlimbs. Hands exceptionally long and prehensile; deep cleft between first and second digits; thumb fully opposable by means of unique mechanism at carpo-metacarpal (basal thumb) joint, associated with a specialized musculature. Ischial callosities as in Cercopithecidae but developing late in life. Well developed laryngeal (vocal) sac in *Symphalangus*. Skull of typical anthropoid form, orbits large, forwardly directed and having a well-buttressed lateral margin; strong brow ridge; sagittal and nuchal crests rare; mastoid processes absent. Long sabre-like canines equally developed in both sexes; molar cusp pattern similar to that of the Pongidae and Hominidae. Chromosome diploid number: 44. Head and body length about 40–64 cm (15.7–25.2 in.); weight 4–13 kg (8.8–28.6 lb); 2 genera; *Hylobates* (6 species) and *Symphalangus* (1 species); Southeast Asia.

Family Pongidae (great apes: gorilla, chimpanzee, and orangutan)

Arboreal or ground living. Locomotion consists of brachiation and a modified form of quadrupedalism, called knuckle walking. Characterized by total lack of tail, relatively long forelimbs, elongated hands, and short but fully opposable thumbs. Brain relatively large compared with body size and showing well marked cerebral fissuration. Permanent dentition 32 teeth: incisors large and spatulate, particularly in upper jaw; canines large and conical, particularly in males; well-marked diastema present between upper lateral incisors and canines. Molars large; quadricuspid in upper jaw and quinquicuspid in lower; cusps arranged in so-called "*Dryopithecus*-pattern"; enamel much wrinkled in *Pongo;* third molar relatively small in *Pan*. Skull bears sagittal and nuchal crests in adult males (but rare in *Pan*). Ischial callosities usually absent (*cf.* Cercopithecidae, Hylobatidae). Thorax widest transversely (*cf.* Cercopithecidae); pelvis expanded in iliac region; lumbar vertebrae reduced in number (*cf.* Cercopithecidae). Life periods extended compared with New and Old World monkeys. Chromosome diploid number: 48. Family includes three genera: *Gorilla, Pan, Pongo. Distribution:* Africa and Southeast Asia.

Family Hominidae (man and fossil relatives)

Ground-living, hairless, omnivorous and bipedal. Hindlimbs longer than forelimbs (contrasting with Pongidae and Hylobatidae). Thumb fully opposable and hand capable of both precision grip and power grip; big toe aligned with other toes, foot nonprehensile. Brain relatively large and highly fissured. Neurocranium expanded particularly in parietal and frontal regions; Mastoid process of periotic bone present from birth. Facial skeleton nonprotrusive and strongly flexed relative to cranial base. Dentition of 32 teeth: canines small and blunt, lying flush with occlusal plane; premolars bicuspid; molars small, low, bearing rounded cusps; last molar in upper and lower jaw frequently unerupted. Postcranial skeleton shows adaptations to upright posture particularly in vertebral column, pelvis and lower limb. Chromosome diploid number: 46. Life periods (including growth period and life expectancy) extended as compared with Pongidae. Head and body length about 80 to more than 130 cm (31.5–51.2+ in.); total length (height) about 130 to over 220 cm (51.2–86.6 in.); weight from about 40 to more than 120 kg (88–264 lb); one Recent species, *Homo sapiens;* distribution world-wide.

Critical appraisal. The classification of the primates by George Gaylord Simpson is the most widely used list today. Since it was published in 1945 a number of revisions at family level and below have been incorporated; the higher categories have remained unchanged, although they have been the subject of considerable criticism and doubt. W.C. Osman Hill's classification, which, with modifications, follows R.I. Pocock's list published in 1918, has not enjoyed a wide popularity, in spite of the success of "Primates," Hill's monumental treatise on the order. Hill excludes the tree shrews from the primates altogether; he also removes the tarsioids from among the lemurs and lorises and places them with the monkeys and apes. A compromise view between the classifications of Simpson and Hill has been proposed by American paleontologist Alfred S. Romer. Romer also omits the tree shrews from the order and gives the tarsioids equal status with lemurs and lorises, Old World monkeys, New World monkeys, and apes in a separate subordinal group. It seems likely that before very long Romer's classification, or one closely similar to it, will become generally accepted. Reference to the annotated classification given above (based on Simpson's) will indicate how ill-fitted is the living genus *Tarsius* to share subordinal status with the prosimians.

Problem of the tarsiers

Several revisions of lower taxa (genus and species) have been proposed in recent years which are proving generally acceptable. It has been suggested that *Cynopithecus niger,* the Celebes black "ape," be included within the synonymy of *Macaca,* in which case this species therefore becomes *Macaca nigra.* Also widely accepted is inclusion of *Comopithecus* (the hamadryas baboon) in the synonymy of *Papio* (the common baboon), but opinions differ as to whether the hamadryas and the common baboon are not better considered a single species in view of the good evidence of hybridization in the wild. Synonymy of the genus *Mandrillus* with *Papio* has also been suggested, largely on the evidence of molecular data from blood protein studies, but has not found much support. Less controversial is the conclusion, based on field evidence, that the three generally accepted species of savanna monkeys (*Cercopithecus aethiops, C. sabaeus* and *C. pygerythrus*) actually comprise a single polytypic species, *C. aethiops.*

Less universally acclaimed is the suggestion by Simpson that the structural and behavioral differences between the chimpanzee and the gorilla are insufficient to justify continued generic separation. According to this view, which has some support, *Pan,* having nomenclatorial priority, should include two species, *Pan troglodytes* (chimpanzee) and *Pan gorilla* (gorilla). At a symposium on the Old World monkeys held in 1969, the synonymy of *Nasalis* (the proboscis monkey) with *Simias* (the Pagai Island langur) and *Rhinopithecus* with *Pygathrix* was recommended but, as yet, is by no means universally accepted. Field, museum, and laboratory work has led to numerous changes in classification of primates by subspecific level that need not concern us here. (J.R.N.)

Edentata (armadillos, sloths, anteaters)

Edentata, an order of mammals, includes 31 living species distributed among the armadillos, true anteaters, and tree sloths, as well as eight extinct families of ground sloths and armadillo-like animals. The living families and six of the extinct families comprise the suborder Xenarthra. A second suborder, Palaeanodonta, consists of two extinct families. The entire evolutionary history of the edentates is restricted to the Western Hemisphere and the majority of the living species occur today in South America.

GENERAL FEATURES

Edentata means lacking teeth, though in reality only the true anteaters are toothless. The majority of edentates have simple, peglike cheek teeth that lack enamel; canine-like teeth do occur in some forms. Certain armadillos may have as many as 100 teeth. Edentates possess specialized traits, such as reduced dentition, a long sticky tongue, powerful, clawed, forefeet, associated with their insect diets. They also have primitive traits, such as the possession of five toes on the hindfeet, a simple uterus, and small, uncomplicated brain, which place them close to the primitive stock that gave rise to the infraclass Eutheria, which includes all placental mammals.

Primitive traits

A persistent myth holds that any kind of armadillo, in defense against enemies, can roll itself into an impregnable armour-plated ball. In fact, only the three-banded armadillo (*Tolypeutes tricinctus*) is able to perform this feat. Most armadillos contort themselves into a reasonable facsimile of a ball, but some only slightly increase the convexity of the dorsal shell (carapace) while flattening against the ground. Individuals of some species flee to burrows or attempt to burrow right on the spot but may freeze and feign death when flight and rapid excavation are somehow prevented. Misconceptions about other edentates also exist. The toothless, weak-jawed anteaters seem to be sucking in ants and termites through a small tube, when, in fact, it is the sticky product of the greatly enlarged submaxillary glands covering the lengthy extensible tongues that facilitates the capture of these insects. The

slow-moving arboreal sloths, typically depicted as moving upside down along a branch, really spend only about 10 percent of their time moving at all.

The armadillos and anteaters are important ecologically, helping to control many kinds of abundant insects, especially ants and termites. Armadillos feed on some carrion and thus play a small part in cleaning up the environment. Although some armadillos may become agricultural pests, and the armour of several species is made into purses and other curios, edentates are generally of little economic importance. Generally, the greatest interest in edentates lies in their bizarre appearance.

Size range

Living edentates range in size from the tiny pink fairy armadillo or "lesser pichiciego" (*Chlamyphorus truncatus*) of Argentina, measuring about 16 centimetres (6.3 inches) in length and weighing little more than 100 grams (3.5 ounces), and the slightly larger two-toed or silky anteater (*Cyclopes didactylus*), just over 37 centimetres (14.6 inches) long and weighing about 325 grams (11.5 ounces), to the 60-kilogram (132-pound) giant armadillo (*Priodontes giganteus*), nearly 1.5 metres (five feet) long, and the giant anteater (*Myrmecophaga tridactyla*), which weighs up to 25 kilograms (55 pounds) and may be over two metres (6.6 feet) in length. Among extinct forms, an Oligocene armadillo, *Prozaedyus proximus,* had a skull under eight centimetres (3.1 inches) in length and was only somewhat larger than the smallest of the living armadillos. The Pleistocene ground sloth, *Megatherium americanum,* was six metres (20 feet) long and was larger than a modern elephant; a Pleistocene glyptodon (*Doedicurus clavicaudatus*) was more than four metres (13 feet) long and 1.5 metres (five feet) high. Both flourished in South America about 500,000 years ago.

Anteaters, tree sloths, and armadillos are strikingly different in appearance, but within each of these families, there is only a modest diversity of structure. The toothless anteaters vary from strictly arboreal to terrestrial forms that are characterized by progressively more elongate tubular mouths. The arboreal species have only two (*Cyclopes*) or three (*Tamandua*) clawed toes on the forefeet, whereas the terrestrial giant anteater has four. In addition, the arboreal species have prehensile tails. At a casual glance, the two genera of herbivorous (plant-eating) tree sloths (*Bradypus, Choloepus*) differ from each other in general appearance only in the number of toes on the forefeet (two in *Choloepus* and three in *Bradypus*) and in pelage coloration. The armadillos (Dasypodidae) are distinguishable on the basis of relative size and on the distribution, flexibility, and pattern of the bony shields that form their body armour.

Figure 26: Edentate body plans.
Drawing by J.C. Barbens

The anteaters, essentially a tropical family, occur from northeastern Argentina and northern Uruguay to the extreme northern part of the state of San Luis Potosí, Mexico. Tree sloths are restricted to forests from northern Rio Grande do Sul, Brazil, to southeastern Honduras. Armadillos are found from the northern part of the province of Santa Cruz, Argentina, to south-central Kansas. Most living edentates are fairly common in their preferred habitats, although several species have disappeared from parts of their range largely because of habitat destruction and excessive hunting by man. These endangered species include the giant anteater, the three-toed sloth (*Bradypus torquatus*), the three-banded armadillo, the giant armadillo, the pink fairy armadillo, and Burmeister's armadillo (*Burmeisteria retusa*).

NATURAL HISTORY

Behaviour. Anteaters eat termites, ants, and occasionally other insects. They may forage in trees (two-toed), on the ground (giant *Myrmecophaga*), or in both situations, as does the lesser anteater (*Tamandua tetradactyla*). Their prey is usually located by smell, the sense of which is better developed in these animals than are those of eyesight and hearing. With the long, powerful forceclaws, the anteaters rip open anthills and termite mounds, into which they then insert their long sticky tongues. The tongue, covered with prey and debris, is then drawn into the tubular mouth. When frightened, the giant anteater usually flees at a slow clumsy gallop, but if forced it will fight, using its claws to rip the enemy. *Cyclopes and Tamandua* also use their foreclaws for defense, anchoring themselves to a branch with their prehensile tails. When alarmed, these two emit shrill calls.

Anteaters travel solitarily or as mother and young and do not seem to have permanent resting places. The giant anteater chooses a secluded spot such as a hollow log or the abandoned burrow of some other animal and then curls up to rest, with its long bushy tail covering its head and body. The arboreal anteaters find shelter in trees. The two-toed and lesser anteaters are mainly nocturnal, but the giant anteater is both nocturnal and diurnal. In areas remote from civilization, the giant anteater is most active during the day, whereas in heavily populated regions it is primarily nocturnal.

Food habits of sloths

Tree sloths are strictly herbivorous, but the absence of enamel on their teeth suggests that the group perhaps was once insectivorous. The lack of enamel could pose serious problems relating to tooth wear for animals eating such abrasive food as vegetation. The difficulty, however, is alleviated by continuous growth of the teeth, which have an outer covering of hard cement. As is typical of herbivores, tree sloths have large multichambered stomachs in which the slowly digesting plant material steeps. Constantly filled, the stomach and its contents constitute about 30 percent of the sloth's body weight. A meal may take up to a week to digest. Every two to eight days, the sloth descends to the foot of its home tree and passes a large amount of excrement.

The diet of the two-toed sloth consists of a variety of leaves, stems, and fruits. The three-toed sloth, on the other hand, eats only the leaves of the cecropia tree. The sloth locates its food by touch and smell and then hooks a branch with its curved claws and pulls it to the mouth. Although colour vision is present, the eyesight and hearing of sloths are not very well developed, and they orient themselves mainly by touch.

In the wild, the hair of the sloth's body is inhabited by algae, which flourish in the jungle humidity. A variety of mites, beetles, and small moths live as commensals (harmless companions) in the hair, feeding on the algae.

Tree sloths are normally solitary creatures and spend the days and most of the nights sleeping. The little time that remains is spent eating, resting, and moving. This "laziness" contributes greatly to their survival, because their diurnal sleeping posture (hanging from a branch with feet bunched together and head tucked in on the chest) and their coloration give them the appearance of a bunch of dead leaves, rendering them virtually invisible. At night, when they are active, their slow movements do not attract the attention of nocturnal enemies. In addition, sloths have a thick skin and the ability to tolerate strong poisons and severe injuries.

When angered or otherwise disturbed, the three-toed sloth utters a high-pitched cry that sounds like "ai," whereas the two-toed sloth snorts and hisses. Normally, sloths are docile and in the presence of danger remain still, relying on their protective coloration to conceal them. If molested, however, they bite savagely and strike out furiously with the sharp foreclaws.

Burrowing by armadillos

Armadillos are primarily nocturnal, spending the daylight hours in their burrows, in expanded nest chambers lined with grasses and leaves. The burrow is also used for the escape from enemies and as a food trap. When using a burrow, in an emergency, some species are able to flex their bony back plates and brace with the feet in such a manner as to become firmly wedged in the tunnel and virtually impossible to pull out. When in danger away from a burrow, armadillos will draw in their feet and lie so that the edges of their armour touch the ground, or will run, burrow rapidly, or even defend themselves with their claws. The three-banded armadillo can roll itself into a ball with feet inward and the head and tail protected by special shields. If captured, an armadillo usually reacts by "playing dead," either stiffening or relaxing, but in either case remaining perfectly still for a brief period. If this course of action does not result in release, the captive armadillo begins kicking vigorously, often facilitating escape. Several kinds of sounds are reported to have been made by fleeing or otherwise agitated armadillos. The peludos (three species of *Chaetophractus*) make snarling sounds, the mulita (*Dasypus hybridus*) repeatedly utters a guttural monosyllabic sound reminiscent of the rapid fluttering of a human tongue, and other species emit a series of grunts or buzzes when alarmed.

The act of burrowing involves the forelimbs, hindlegs, and tail. The heavy claws on the forefeet are used for scraping and loosening the dirt, pushing it toward the rear. The hindlimbs throw the dirt out behind while the tail elevates the rear end of the animal so that the hindlegs may kick more freely. In this manner, burrows from 0.6 to six metres (two to 20 feet) long, from 0.3 to 1.5 metres (one to five feet) underground and with as many as 12 entrances, may be constructed in a relatively short period. Occasionally, other small animals share these burrows. In North America, rabbits (*Sylvilagus*) and cotton rats (*Sigmodon*) have been found living in the burrows of the nine-banded armadillo.

Armadillos eat insects, mollusks, frogs, small reptiles, carrion, and some plant material and will burrow underneath an animal carcass to obtain maggots and other insects. An acute sense of smell enables some armadillos to detect grubs and other insects up to 12 centimetres (nearly five inches) below the surface of the earth. The peludo is reputed to make conical holes with its snout in the earth in search of food. It first inserts its snout and then rotates its body so that it literally drills the hole. It is able to hold its breath under such circumstances for up to four minutes. Armadillos have relatively good hearing and vision.

Locomotion. The giant anteater walks with a shuffling gait bearing the weight of its foreparts on the side of the fourth (outermost) digit on the front foot. When hard pressed, this species breaks into a slow, clumsy gallop. It is also a good swimmer. The tamandua walks rather clumsily on the sides of its forefeet when on the ground, in a manner similar to that of the giant anteater. The tamandua is an agile climber, aided both by its foreclaws and hindclaws and by its prehensile tail. Two-toed anteaters are strictly arboreal and are thus very strong climbers. They also have a prehensile tail.

The claws of tree sloths, which are quite similar to those of their terrestrial forebears, have become adapted to a strictly arboreal life. On the ground, a tree sloth is nearly helpless and cannot move at all unless there is something to grasp, then it is able to drag itself along with its claws. Most of the time sloths simply hang upside down, but when they do move they use a slow hand over hand motion both on horizontal and upright branches. Interestingly enough, they are excellent swimmers.

Bipedalism in armadillos

Generally, armadillos walk on the tips of the claws of their front feet and on the soles of the hindfeet; occasionally, they rear up and walk bipedally on their hindlegs. They trot with a stiff-legged gait. At a gallop, some species can outdistance a man. Because of their heavy dermal armour, armadillos have a specific gravity so high that they would normally sink in water. To overcome this problem, they gulp quantities of air that give them the buoyancy needed for swimming. Under some circumstances, armadillos seemingly take advantage of their specific gravity and cross small streams simply by walking under water on the bottom.

Habitat. Edentates occur in a variety of habitats, in temperate, subtropical, and tropical environments. Giant anteaters are found in savannas and in wet forests, where they feed either at night or in the day, ripping the terrestrial mounds of termites and ants apart with their powerful foreclaws. Lesser and silky anteaters are both arboreal, the latter totally so. Lesser anteaters prefer tropical forests, parklands, and, to a lesser extent, savannas, in which they forage mostly in trees on ants, termites, and various other insects. They are predominantly nocturnal but may be active at twilight as well. Silky anteaters, which are nocturnal, are found in tall humid tropical forests usually high up in the trees, where they feed almost exclusively on termites. The herbivorous tree sloths occur only in dense tropical rain forests. Armadillos frequent grasslands, parklands, open and even thick forests. They may live largely in subterranean burrows (pink fairy armadillo) in grasslands or dig burrows for temporary shelter in forests (*Dasypus* species). The shape of the burrow entrance is often diagnostic of the cross-sectional shape of the owner; the nine-banded armadillo (*Dasypus novemcinctus*), for example, which has a high rounded carapace, digs a nearly circular entrance. The six-banded armadillo (*Euphractus sexcinctus*), which is compressed from top to bottom, digs a burrow with an entrance that is wider than it is high. The habitat preference of the three commonest armadillos in Uruguay illustrates the ecological diversity of this group. *Dasypus hybridus*, the smallest of the species, prefers grassland and most of its burrows are found there. The six-banded armadillo burrows near streams in open woodlands and grasslands where it occasionally overlaps with the former species and with the nine-banded, which most frequently makes its burrows in woodlands.

Reproduction. The gestation period of those edentates for which it is known ranges from 65 days in the hairy armadillo (*Chaetophractus villosus*) to 263 days in the two-toed sloth. The protracted gestation period of the sloth is attributed to delayed implantation. The very early embryo, consisting of but a few cells, lies free in the uterus without developing further for several months, before becoming imbedded in the uterine wall, at which time normal embryonic growth recommences. Anteaters and tree sloths normally bear single young. Most armadillos give birth to one or two young, although some species demonstrate polyembryony (the birth of from two to 12

Delayed implantation

identical young, which develop initially from a single fertilized ovum) and delayed implantation (attachment of the ovum to the uterine wall after a variable delay period). The nine-banded armadillo has both of these phenomena. The delayed implantation is seasonal, the stages occurring at fixed times of the year, related to environmental influences. In the Northern Hemisphere, young of this species are born in March and April. Breeding occurs between June and September, but, regardless of when breeding occurs, implantation is delayed until November and the postimplantation pregnancy is between November and March. Delayed implantation is presumably beneficial because birth does not take place until spring, when food is plentiful.

Little information is available on the birth and early life of many edentates. A recent study of the two-toed sloth (*Choloepus didactylus*) revealed that the young is born as the mother hangs upside down. The baby emerges head first and face upward, and, as soon as its forelimbs are free, it grasps the abdominal hair of the mother and pulls itself up on her chest. The mother may assist in birth by pulling on the young. Subsequently, the female breaks the umbilical cord with her teeth.

The young sloth's eyes and ears are open at birth. It suckles for about five months but does not leave the mother until the ninth month, when adult proportions, but not size, have been attained. Adult size is reached at from two and one half to three years. Young anteaters also cling to their mothers for several months to a year after birth. The giant anteater rides on its mother's back, the two-toed anteater on its mother's tail.

Armadillo young are born with soft leathery skins, which harden as they grow older. In the six-banded armadillo, the eyes do not open for several days after birth, but in the nine-banded armadillo, the young are born with their eyes open. Young armadillos are able to walk when only a few hours old. In the nine-banded armadillo, physical maturity is achieved at six months, but females do not have their first litter until they are two years old. In captivity, the giant anteater has lived 14 years, the two-toed sloth 19 years, the peludo 15½ years, and the three-banded armadillo 11 years.

FORM AND FUNCTION

External appearance. Anteaters (Myrmecophagidae) have elongate heads; tubular muzzles with no teeth; and long, sharp claws. Their toes vary in number from two to four on the forefeet and from four to five on the hindfeet, depending on the species. The thick coat of the giant anteater is gray with lateral white-bordered blackish stripes, and the hair is long and straight, especially on the characteristically stiff bushy tail. Tamanduas, or lesser anteaters, have short hair, which is usually cream-coloured to brownish, with a black vestlike area over the upper thorax. The entire underside of the tail, as well as the tip, is naked. The two-toed anteater (*Cyclopes*) has soft silky fur, usually golden yellow in colour. In this species, only the underside of the prehensile tail is naked. Males and females are of approximately equal size in *Cyclopes* and *Tamandua*, but males are much larger in *Myrmecophaga*. All anteaters have enormously developed salivary glands that supply the sticky saliva that covers their long extrusible tongues.

The shaggy pelage of tree sloths grows from the belly toward the back on the body and toward instead of away from the body on the limbs (*i.e.*, downward, when the animal is suspended beneath a branch), thus facilitating the shedding of rain. Tree sloths have pale faces with darker eye rings. The body hair is yellowish to brownish, but the individual hairs are fluted and contain a growth of algae that gives a greenish cast to the entire animal, especially in the rainy season. In the drier conditions of captivity, the algae die and the animal loses the natural coloration. The legs are long, with the forelimbs longer than the hindlimbs, and are designed for suspension of the body rather than for "column-like" support.

Algae on tree sloths

Armadillos are characterized by a dorsal bony carapace made up of scapula (shoulder), dorsal, and pelvic shields, separated by a series of movable bands. A bony cephalic (head) shield is also present. The tail is typically armoured as well, except in the naked-tailed armadillos of the genus *Cabassous*. The body hair is greatly reduced, but some, such as the pink fairy armadillo, have dense fur on their sides and underparts. A sparse growth of hair also occurs among the bony plates of all species.

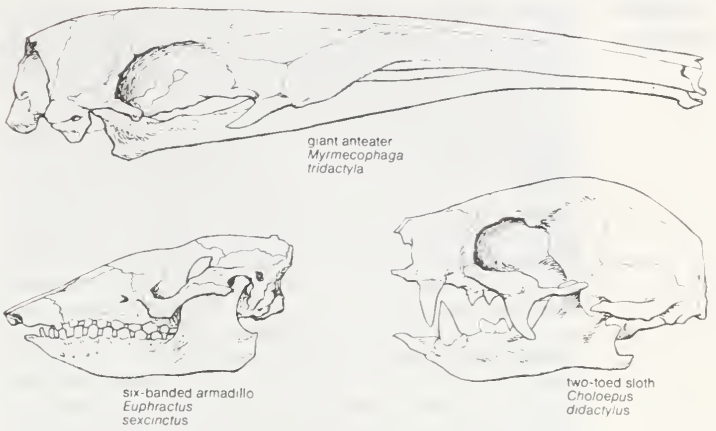

Figure 27: Edentate skulls.
Drawing by J.C. Barberis

Specializations of internal anatomy. Female edentates have a common urogenital sinus (*i.e.*, both reproductive and excretory functions involve a single chamber) and a simple uterus (a single uterine cavity rather than a branching two-chambered organ). The placenta (the uterine connection between the mother and embryo) is discoid in shape. In other words, the actual areas between which gases, food, and nitrogenous wastes are exchanged are restricted to a single disc-shaped region. The placenta is also deciduous; *i.e.*, it is shed at the time of birth. Females have one or two pairs of mammary glands that are located just lateral to the "armpits," on the chest or on the abdomen. In males, the testes are abdominal and the length of the penis is associated with the degree of difficulty encountered in copulation. In tree sloths, where the partners hang abdomen to abdomen, it is quite small, whereas in armadillos, in which the carapace prevents the partners from getting very close to one another, the penis is long and pendulous.

In general, edentates have poor temperature control. Definitely related to the conservation and manipulation of heat are the extensive anastomoses (fusions) of the veins and arteries (termed retia mirabilia) in the limbs and tails of most species. These structures conserve heat, transferring heat from the arterial components carrying warm blood outward along the limbs to the veins lying adjacent for return to the trunk. At the same time, the appendages are cooled.

Tree sloths are heterothermic (*i.e.*, have imperfect control of body temperature) and under experimental conditions their body temperature, normally ranging between 28° and 35° C, may drop to 20° C. At this temperature, the animals become torpid. Temperature control is likewise relatively poor in armadillos. The fact that it builds a subterranean leaf-lined nest has aided the nine-banded armadillo in the northward expansion of its range into the United States. Nonetheless, many individuals of this species perish during severe winters.

EVOLUTION AND PALEONTOLOGY

The ancestry of the order Edentata is believed to be rooted in some unknown but probably generalized insectivore (order Insectivora). The oldest known members of the two presently recognized suborders of edentates were already too specialized for either group to have given rise to the other. Members of the extinct suborder Palaeanodonta, a group restricted to North America, by the time of their first appearance in the fossil record had already developed specializations that eliminate them as possible direct ancestors of the suborder Xenarthra, which flourished throughout the Tertiary in the then isolated South American landmass.

The palaeanodonts, which lived from the late Pale-

The palaeanodonts

ocene until the beginning of the Oligocene, comprised two families, Metacheiromyidae and Epoicotheriidae. The most completely preserved form in the former family is *Metacheiromys*, an archaic mammal about 45 centimetres (17.7 inches) in length, reminding one somewhat of an armadillo lacking armour. This animal possessed an assemblage of clearly edentate traits, including the near absence of teeth (except for the enlarged bladelike canines), long compressed foreclaws, and a slight inward twist of the wrist, which is typical of virtually all members of the order. Other metacheiromyids did not show the strong development of the canines. *Palaeanodon*, known from the upper Paleocene and probably ancestral to *Metacheiromys*, had a series of four or five peglike cheek teeth that lacked enamel. The Epoicotheriidae, which had a skull that in outline is reminiscent of that of a small armadillo, were apparently small aberrant forms, highly specialized for a fossorial (digging) livelihood. When the palaeanodonts passed from the scene at the end of the Oligocene, they left no descendants.

The second suborder, Xenarthra, by far the more successful group of edentates, enjoyed an evolutionary history independent from that of the palaeanodonts because North and South America were separated throughout most of the Tertiary, not becoming rejoined until the Pliocene. Contemporaneous with the earliest palaeanodonts of North America was the first South American xenarthran, *Utaetus*, already recognizable as a primitive armadillo and thus sufficiently advanced to eliminate any possibility that known palaeanodonts might be directly ancestral to xenarthrans. The fact that primitive armadillos are the first known members of the suborder strongly suggests that the other xenarthran families are in some way derived from the Dasypodidae.

The Tertiary radiation of edentates in South America resulted in several more or less separate lineages, which are conveniently arranged in three infraorders. The first of these infraorders, Loricata, includes the armadillos (Dasypodidae) and their relatives, the extinct glyptodonts (Glyptodontidae) or so-called turtle armadillos, distinguished from the former especially by their possession of a rigid carapace. Armadillos flourished in South America in the Tertiary and were abundant by the Miocene. In the Pleistocene, some species had moved northward as far as what is today the central United States.

Fossil armadillos

Four distinctive lines developed in the Dasypodidae, comprising the subfamilies Dasypodinae, the Stegotheriinae, the Pampatheriinae, and the Chlamyphorinae (including only the living genera *Chlamyphorus* and *Burmeisteria*). The Dasypodinae includes most of the living genera of armadillos as well as *Utaetus*. The fossil members of this group varied in size from that of a small contemporary armadillo to animals as large as the South American Pliocene form *Macroeuphractus* that had a skull nearly 28 centimetres (11 inches) long. The head and body of the latter must have been almost two metres (6.6 feet) long. The fossil members of this subgroup all seemed to favour invertebrates in their diets, but they probably ate carrion and some plant material as well. This distinguished them from the extinct Stegotheriinae, a subfamily whose members were highly specialized for a strictly insectivorous diet. *Stegotherium* of the lower Miocene of South America had an elongate anteater-like skull with much reduced cylindrical cheek teeth.

The Pampatheriinae, known from the late Miocene to the Pleistocene, was a group characterized by great size. At least one form, *Pampatherium*, a nearly complete skeleton of which was recovered from a Pleistocene deposit in Texas, was nearly as large as a rhinoceros. This animal and its closest relatives were apparently adapted to an herbivorous diet. Both insect- and plant-eating groups are thus included among the true armadillos.

The genus *Peltephilus* and several other closely related genera of aberrant armadillo-like creatures have been placed in their own family, Peltephilidae, because, among other characteristics, they possessed at least one pair of hornlike protuberances on the muzzle. These animals, which appeared in the Oligocene and disappeared in the Pliocene, were apparently specialized for flesh eating.

(Left) Ground sloth (*Megatherium*) and (right) glyptodonts (*Doedicurus*). Painting from fossil skeletons by Charles R. Knight.

By courtesy of Field Museum of Natural History, Chicago

The glyptodonts (Glyptodontidae) evolved from primitive armadillos, first appearing in the fossil record in the Eocene with the genera *Glyptatelus* and *Lomaphorelus* but remaining relatively uncommon until the beginning of the Miocene. Subsequently, they experienced a radiation of their own and by the Pleistocene several kinds had spread into North America. Throughout their history, they demonstrated an increase in size culminating in the Pleistocene giant, *Doedicurus*. They became extinct before the end of that epoch.

The giant glyptodont

The second infraorder, Pilosa (hairy) includes the sloths, both the living arboreal forms (Bradypodidae) and the fossil ground dwellers of the families Megatheriidae, Megalonychidae, Mylodontidae, and Orophodontidae. There are no fossils of tree sloths, but they appear to be structurally related to the ground sloth families Megatheriidae and Megalonychidae. The oldest fossils of ground sloths belong to the Megatheriidae and come from Oligocene deposits in South America. By the early Miocene, primitive members of this group were rather common. One form, *Hapalops*, although typical of that time, was of relatively small size for a ground sloth. It had a slender body about 1.3 metres (4.5 feet) in length and had five toes with developed claws on both its forefeet and hindfeet. *Hapalops* had a moderately elongated skull with slender premaxillae (bones of the upper jaw), and a process resembling a spout that protruded from the lower jaw and may have supported horny plates for cropping. This animal had five upper teeth and four lower teeth in each jaw, the first upper pair of which resembled canines. The small Pleistocene ground sloth *Nothrotherium* apparently was a descendent of *Hapalops* and the two comprise a branch of the Megatheriidae, which throughout its history was given to small size. This stock differed greatly from the main stem of the family, which had no specialized "canines" and had the two inner toes reduced, represented by the Pleistocene *Megatherium*, a massive ground sloth larger than an elephant.

The megalonychids, although related to the megatheriids, were distinguished from them by their definite caninelike teeth and lack of the spoutlike process on the lower jaw. The megalonychids ranged in size from one island-dwelling animal no bigger than a domestic cat to the mainland ox-sized *Megalonyx*. Both the Megalonychidae and the Megatheriidae reached southern North America by the Pleistocene, but they became extinct on the Continent at the end of the epoch. Some megalonychids invaded the West Indies, however, and experienced a minor radiation in Hispaniola, Puerto Rico, and Cuba. One or more species may have flourished there to within a few hundred years of the present.

Distinct from the megatheriid–megalonychid line of ground sloths were the Mylodontidae, which first appeared in the Oligocene; from the Pliocene until their extinction at the end of the Pleistocene, they were the dominant South American group of ground sloths. The mylodonts

Mylodonts

differed from the other ground sloths in their partially developed upper canines, reduced first toe of the hindfoot and rounded ossicles (bony tubercles) in their skin. The mylodonts followed the trend of other ground sloth families toward great size and awkwardness, which in this group culminated in the Pleistocene giant, *Glossotherium,* which was the size of a large ox. As with other xenarthran groups in the Pleistocene, the mylodonts extended as far north as the southwestern United States.

The other family of ground sloths, the Orophodontidae, is known only from the Oligocene of South America. This briefly-lived side group is represented by *Orophodon* and *Octodontotherium,* both of which were rather small sloths that do not seem to have left any descendants.

The final infraorder, Vermilingua, comprising the anteaters (Myrmecophagidae), has not been found in the fossil record any earlier than the Miocene. The fossil myrmecophagids, as represented by the Pliocene form *Palaeomyrmedon,* were already completely toothless and presumably well adapted to an insectivorous diet. The Myrmecophagidae first appeared in South America in the early Miocene and apparently only fairly recently have spread to Central America.

CLASSIFICATION

Distinguishing taxonomic features. The degree of development of certain sets of structural characteristics taken in concert defines the Edentata and its subgroups. None of these features is univerally distributed throughout the order. The most important are as follows: (1) in addition to the normal zygapophyses (protuberances), the occurrence of supplementary articular surfaces called xenarthrous articulations between the arches of sequential posterior trunk vertebrae; (2) development of certain projections of the scapula bone, or shoulder blade, called the acromion and coracoid processes; (3) articulation of the ischium bone of the pelvis with the proximal caudal (tail) vertebrae, forming an elongate sacrum; (4) length and massiveness of limb bones; (5) fusion of distal limb bones; (6) hyperdevelopment of claws; (7) development of forefeet and hindfeet; (8) a skull characterized by a small brain housed in a long tubelike brain case, typically with a reduced premaxilla (*i.e.,* elongate palate), often an incomplete zygomatic arch, and a reduction in number of teeth and their enamel covering.

Annotated classification. The classification presented here combines those proposed by the two paleontologists R. Hoffsteter and Alfred S. Romer. The features given below are only those that distinguish each group from the others. Groups indicated by a dagger (†) are known only as fossils.

ORDER EDENTATA

Placental mammals with reduced dentition, often lacking enamel; heavily clawed forelimbs for burrowing. Coracoid process of the scapula more strongly developed than in other eutherian mammals. About 31 recent species.

†Suborder Palaeanodonta

Fossil only. Bony carapace and the xenarthrous articulations on the vertebrae lacking; no fusion between the ischium and caudal vertebrae; simple teeth, usually single-rooted and lacking enamel; slight inward twist to the forelimbs.

†*Family Metacheiromyidae.* Upper Paleocene to lower Eocene. Small, lightly built edentates with sharply pointed somewhat laterally compressed canines; postcanine teeth reduced or lacking; armadillo-like feet with 4 to 5 digits; the lateral digits reduced, the inner greatly so. North America.

†*Family Epoicotheriidae.* Lower Eocene to lower Oligocene of North America. Very small burrowing edentates, with a domed skull having a depressed snout and possessing a zygomatic arch; having 6 slightly differentiated cheek teeth, nearly cylindrical, lacking enamel, and single-rooted.

Suborder Xenarthra

Some extinct and all living edentates; all with xenarthrous posterior trunk vertebrae. Lack teeth or have only poorly differentiated cheek teeth, lacking enamel and having single roots. Fusion (symphysis) between the ischium and the anterior caudal vertebrae in all except the 2-toed anteater (*Cyclopes*).

Infraorder Loricata

Bony plates covered with horny plates, forming a protective carapace over the trunk.

Family Dasypodidae (armadillos). Lower Eocene to Recent in South America; Pleistocene to Recent in North America; forests, savannas, and plains; primarily in the tropics and subtropics.Teeth more than $\frac{6}{6}$ (6 above and below on each side); top and sides of the body covered with horny scutes over a bony, flexible carapace.

†*Family Peltephilidae.* Upper Oligocene to lower Pliocene (questionably) in South America. Teeth $\frac{2}{2}$; short, broad skull; hornlike structures on the head armour.

†*Family Glyptodontidae* (glyptodonts). Mid-Eocene to Pleistocene in South America; upper Pliocene to Pleistocene in North America. Fusion of bony plates on the back into a solid turtle-like carapace; teeth $\frac{8}{8}$ with 3-lobed pattern.

Infraorder Pilosa

Incomplete zygomatic arch (bony ridge below eye); 4 or 5 simple cheek teeth; expanded acromion, which unites with the coracoid region.

†*Family Orophodontidae.* Oligocene in South America. Bilophodont teeth, $\frac{5}{4}$, made of a mass of compacted dentine; highly specialized astragalus (ankle bone). Small to medium body size.

†*Family Megalonychidae* (ground sloths). Upper Pliocene to Pleistocene in South America; middle Pliocene to Pleistocene in North America; Pleistocene in West Indies. Ground sloths. Large canine-like teeth in the upper and lower jaws and no spoutlike terminus on the lower jaw.

†*Family Megatheriidae* (ground sloths). Upper Oligocene to Pleistocene in South America; Pleistocene in North America. Partial development of upper "canines"; spoutlike terminus on the lower jaw.

†*Family Mylodontidae* (ground sloths). Upper Oligocene to Pleistocene in South America; Pleistocene in North America. Distinguished by a partial development of upper "canines," triangular-shaped cheek teeth, and a hindfoot with the 1st toe reduced.

Family Bradypodidae (tree sloths). South and Central America; tropical forests; no fossil record. Dental formula of $\frac{5}{4.5}$; 6 to 9 cervical vertebrae.

Infraorder Vermilingua

Toothless and hairy edentates.

Family Myrmecophagidae (anteaters). Lower Miocene to Recent in South America; Recent in Central America; tropical forests and savannas. Teeth lacking; tubular mouth with a small terminal opening.

Critical appraisal. The edentates are a natural assemblage of several seemingly rather diverse groups. Given that the oldest known representatives of the palaeanodonts and the xenarthrans are too advanced for either to be ancestral to the other, it would be of great interest to find the common ancestor of both groups, as well as the insectivore precursor of this ancestor. To date, no good fossil candidates have been unearthed in either category.

Authorities disagree on the relationships and degree of distinctness of some groups of fossil edentates. The palaeanodonts are believed by some to be closer to the Old World pangolins (order Pholidota) than to the New World edentates. The armadillo-like *Pseudophorodon* from the upper Oligocene of South America is sometimes placed in its own family but is considered here to belong in the Peltiphilidae. The palaeopeltids, known especially from polygonal plaques of bone, are considered by some to have been aberrant glyptodonts but are considered by Romer to have been the distinct superfamily Palaeopeltoidea. The unusual Miocene ground sloth *Entelops,* due to the presence of teeth on the premaxillary bone, is sometimes separated from the Mylodontidae as sole member of the family Entelopsidae.

Relationship of sloths and anteaters

The degree of relatedness of sloths and anteaters has been the subject of disagreement. It has been shown that despite certain adaptations of the front limbs and digestive tract for insect eating, anteaters are close to the most primitive xenarthran edentates in many characteristics of the forefeet and hindfeet. Hofstetter has suggested that the evolutionary lines that produced the modern Myrmecophagidae and Bradypodidae separated early and that, therefore, the two families are not closely related but should be placed in separate suborders.

The origin of the tree sloths and the relationship of the currently recognized two genera is a question of some

interest. As mentioned above, the two genera may be independently derived from two extinct families of ground sloths. *Choloepus* shows affinities to the megalonychids, and *Bradypus* is more like the megatheriids.

At one time, the Old World scaly anteaters or pangolins (order Pholidota) and the South African aardvarks (order Tubulidentata) were included in the Edentata. The adaptations for an insectivorous diet that these two groups seem to have in common with the New World anteaters and the armadillos are most assuredly a result of convergent evolution and not a reflection of any close phylogenetic relationship. (J.C.B.)

Lagomorpha (rabbits, hares, pikas)

The terrestrial mammals of the order Lagomorpha include the relatively well-known rabbits and hares and also the less frequently encountered pikas, or mouse-hares. Rabbits and hares characteristically have long ears, a short tail, and strong hindlimbs that provide a bounding locomotion. In contrast, pikas have shorter, rounded ears, no external tail, and less well-developed hindlimbs associated with scampering locomotion.

GENERAL FEATURES

Wild lagomorphs are small to small-medium in size, ranging from the smallest pikas, about 150 millimetres (5.9 inches) in length and 100 grams (3.5 ounces) in weight, to the largest hares, 700 millimetres (27.6 inches) and 4.5 kilograms (10 pounds). Wild rabbits range between pikas and hares in size, while some varieties of domestic rabbit may reach up to seven kilograms in weight.

Nearly worldwide in distribution, lagomorphs are absent only from most of the Southeast Asian islands, Australia, New Zealand, Madagascar, southern South America, and Antarctica. Humans have introduced rabbits and hares into areas outside their original ranges for purposes of sport and to provide a readily available food supply. The natural range of the Old World or European rabbit, *Oryctolagus cuniculus,* appears to have been southwestern Europe and North Africa; however, in Roman times this species was often introduced to islands, where it flourished, and spread north and east, partly following human agricultural activities, reaching Britain in Norman times. More recently, *Oryctolagus* was introduced for sport and food into New Zealand and Australia, where the absence of native predators and other factors soon led to its becoming an agricultural pest and a threat to some of the native fauna. In North America several species of the cottontail rabbit, *Sylvilagus,* have shown an increase in abundance and a broadening of range in areas disturbed by human activity and settlement.

Economic importance of lagomorphs

Wild lagomorphs are popular with hunters for sport as well as for food and fur. Domestic rabbits, all descendants of *O. cuniculus,* are raised for meat and skins, the latter of which are used both as pelts and for making felt. Domestic rabbits make good and relatively undemanding pets. Their attractive appearance and quiet manners have made them favourite characters with children's storytellers. On the other hand, wild rabbits and hares locally may become pests, depleting vegetation available to domestic grazers or damaging young trees and orchards, especially in winter. The problem becomes especially acute in areas where human populations have removed the natural predators of lagomorphs. Attempts have been made to control Old World rabbit populations in western Europe and Australia by introducing the viral disease myxomatosis, which exists naturally in populations of certain South American rabbits of the genus *Sylvilagus,* but in some areas the rabbits have developed resistance to the disease. Use of this virus in controlling rabbit numbers has been fought by some humane organizations because of the distressing symptoms of the disease. Pikas, usually found in areas remote from human activity, have little economic importance.

NATURAL HISTORY

Rabbits and hares occupy a wide variety of habitats, including grassland, desert, forest, marsh, brushland, and tundra. They are found in mountains up to elevations of 4,900 metres above sea level. Rabbits frequent areas where cover is readily accessible and do not venture far from it. Some rabbits dig their own burrows, whereas others use burrows dug by other mammals. Although most rabbits are solitary, some live in pairs. The Old World rabbit, *O. cuniculus,* usually is gregarious, forming breeding colonies known as warrens, with extensive burrow systems. The Mexican volcano rabbit, *Romerolagus,* maintains runways through dense vegetation. Although rabbits are typically terrestrial, two North American species of *Sylvilagus,* the marsh rabbit and the swamp rabbit, take readily to water when necessary. Hares tend to live in more open areas than do rabbits. They are solitary and do not use burrows but rest and take shelter in shallow depressions made in soil or vegetation. Pikas are found in northern steppes, semideserts, some forests, and scrub thickets of Asia and in rocky terrain, especially on rock debris on slopes; they range in mountainous areas to 6,000 metres (19,700 feet) in northern and central Asia and western North America. Steppe-dwelling pikas construct and inhabit burrows in flat areas. Rock-dwelling pikas usually seek shelter among rocks and boulders. Some pikas are colonial, whereas others are solitary and may exhibit some degree of territorial behaviour.

Vocalizations

Rabbits and hares are customarily nonvocal, making cries or screams only when frightened or injured. One rabbit, the South African red "hare" *Pronolagus,* is known to utter a warning call. Pikas are highly vocal, having a whistle or bark and a chattering call, reflected in such common names as whistling hare and piping hare. The voice is used in giving alarm signals and in maintaining territorial boundaries. Mountain hikers or climbers frequently hear their calls and may see these attractive little creatures sunning themselves on rocks and going about their daily activities.

Rabbits and hares are active mainly from dusk to after dawn, whereas most pikas are active during the day. All lagomorphs are plant eaters, grasses and soft vegetation being their dietary staples, but they may also eat twigs and bark, especially in winter. Arctic hares are known to break through crusted snow with their forelimbs to feed on the buried vegetation. Rabbits and hares are not known to store food, but pikas store and cure piles of vegetation for use during the winter. Some pikas cut grasses, carry them to the pile, and allow the vegetation to dry before adding more, whereas other pikas actually turn the contents of a pile to aid in the curing. Pikas that live among rocks first pile the vegetation in the sun and open air before moving it under the shelter of rocks for the winter. Steppe-dwelling pikas pile their hay in the open. By contrast, however, other pikas may store hay not in piles in the open but in crevices in trees, stumps, and among rocks. Some of the Asian pikas unwittingly supply hay for domestic livestock during the winter.

Some lagomorphs regularly reingest fecal pellets (coprophagy). Two kinds of pellets are produced: dry and hard, and soft and moist. The latter variety, which appear to contain both vitamins and metabolic products, are eaten, in most cases directly from the anus. The nutritional effect of this practice has been compared to that of rumination among cows.

Rabbits and hares differ from one another in the condition of their young at birth. Young rabbits are born and cared for in a nest; they are naked, blind, and relatively helpless at birth. Hares are born in the open; they are furred, have open eyes, and can run shortly after birth. Confusion of the terms "rabbit" and "hare" in common parlance is shown by such popular names as "jack rabbit" for a hare and "Belgian hare" for a variety of domestic rabbit.

Reproductive potential

The reproductive abilities of rabbits are proverbial. Rabbits and hares usually produce several litters during each breeding season, two or three litters being common among hares and three to six among rabbits. The gestation period ranges from about 28 days in rabbits to 47 in hares, and litter size is usually between two and eight. A female cottontail rabbit from an early spring litter can produce offspring by the end of the summer at age 10 weeks. In contrast to most mammals, female rabbits and hares are

usually larger than males. Reproductive cycles of pikas are less well known than those of rabbits and hares. Their breeding season occurs in late spring and summer, with a gestation period of approximately 30 days. Litter size normally ranges from two to six, and two or three litters may be born each year. In some pikas, the newborn young are only lightly furred, have eyes and ears closed, but can move about after about eight days.

Lagomorphs, especially hares and rabbits, are important elements in many food chains. They are preyed upon by a variety of carnivores, both mammals and birds, who rely upon them as dietary staples. Wolves, foxes, bobcats, weasels, predatory hawks, and owls all take their toll. More northerly species of rabbits and hares frequently exhibit cyclic fluctuations in numbers, which are reflected in the cycles of the carnivores dependent upon them. The snowshoe hare–snowy owl cycle is one of the prominent ones. Pikas are preyed upon by various carnivores, among which weasels and birds of prey are probably most important.

Externally most rabbits and hares are not dissimilar from one another, the main variation occurring in length of ear and strength of hindlimb. The coat is usually brownish or reddish brown above and lighter to white below. An exception to this coloration is found in the Arctic hare, in which the winter coat is pure white with only the eartips dark. In more northerly representatives of the Arctic hare, individuals retain this colour pattern all year, whereas more southerly forms of it may become grayish or buff-coloured. In other northern hares, the varying hare (*Lepus timidus*) of Eurasia and the snowshoe hare (*L. americanus*) of North America, the winter coat is white and the summer coat brown. Some varying hares in Ireland and snowshoe hares from the Pacific Coast do not become white in winter. The most unusual coloration in a modern rabbit occurs in the Sumatran rabbit *Nesolagus,* which has brown stripes on its buff-gray pelage and a bright red rump and tail. Pikas are usually brownish to reddish above and somewhat lighter below.

Lagomorphs illustrate adaptation to particular habitats in an interesting gradational series of features for detection of, and escape from, enemies. At one end of the series are the long-eared, wary, and alert hares, inhabitants of open country, which detect enemies at considerable distance and rely for escape on their strengthened hindlimbs and bounding locomotion that takes them up to 80 kilometres (50 miles) per hour. Rabbits, shorter eared and with weaker hindlimbs, do not react to such distant threats and are scamperers or bounders who do not venture far from cover. They are quick over short distances but lack the endurance of hares. With still shorter ears and relatively weaker hindlimbs, pikas live in areas in which a quick scamper takes them the short distance that usually separates them from secure cover.

FORM AND FUNCTION

Dentition

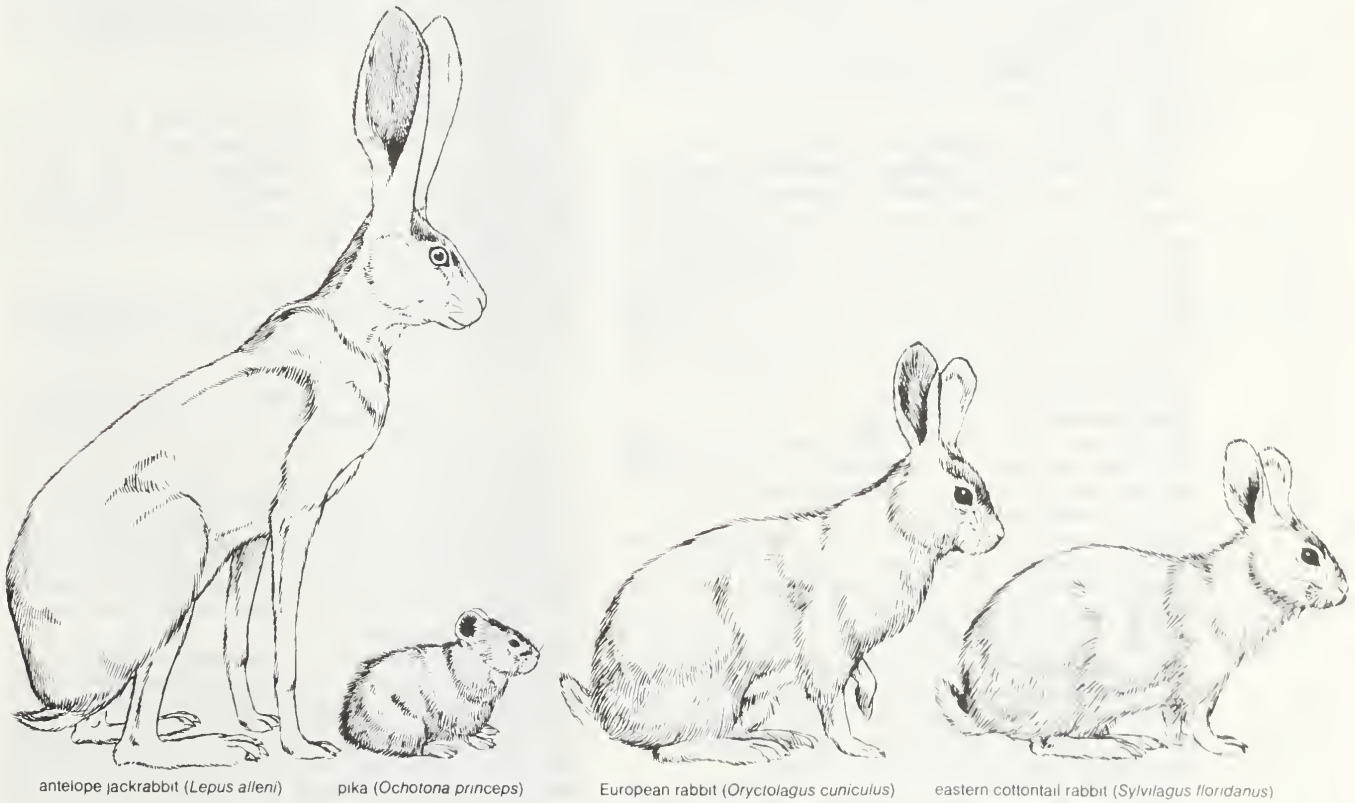
Lagomorphs are well adapted to a herbivorous diet. Like rodents, they have well-developed incisors that grow continuously from the roots, while they are worn down at the cutting edges. These teeth are extremely effective for severing plant stems and for gnawing on bark. The very mobile lips each consist of two lobes, which meet behind the chisel-like incisors when the mouth is closed. There are no canine teeth, a gap (diastema) showing where they might have been. Cheek teeth farther back in the jaw are also ever growing, wearing away as they grind abrasive vegetation. The upper tooth rows are more widely separated than the lower rows, and chewing is done with a transverse movement. The chewing muscles of the jaws, though strong, are less well developed than in rodents.

Vegetation passes through the long small intestine, which has a spiral valve (like a wood screw), providing a much greater surface area for digestion of food and absorption of nutriment. A large pouch, or cecum, located at the point of attachment of the large intestine contains bacteria that aid digestion and that produce the nutritional soft fecal pellets.

Skeletal adaptations for speed and agility are evident and are discussed as taxonomic characters in the *Annotated classifications* section, below. The bones of the hindlimb are fused where they move against the anklebone (calcaneum), affording strength and leverage employed in bounding or scampering locomotion. Lagomorphs move about as if they walked on their toes (digitigrade locomotion). There are five digits on the forefoot and four or five on the hindfoot.

EVOLUTION, PALEONTOLOGY, AND CLASSIFICATION

The order Lagomorpha appears to have originated in northern Asia, probably by the end of the Paleocene (about 55,000,000 years ago), and has been relatively



antelope jackrabbit (*Lepus alleni*) pika (*Ochotona princeps*) European rabbit (*Oryctolagus cuniculus*) eastern cottontail rabbit (*Sylvilagus floridanus*)

Figure 28: Diversity among lagomorphs.

The summer fur (left) of the snowshoe hare (*Lepus americanus*) blends with the browns of woodland and prairie. A mottled effect, created by white hairs gradually replacing the brown, is similar to patches of new snow, while the white winter coat (right) is completely camouflaged in a snowy landscape.

The National Audubon Society Collection/Photo Researchers (left) Charlie J. Ott (right) Leonard Lee Rue

stable morphologically throughout the approximately 40,000,000 years since the end of the Eocene, when its fossil record first becomes well documented. Lagomorphs seem to have established early in their history the patterns of dental and skeletal development that were to change, for the most part, only by gradual advances in the basic pattern. Within the order several trends can be observed from more primitive to more advanced lagomorphs: development of ever-growing cheek teeth, simplification of the pattern of the occlusal surfaces of the upper cheek teeth, and shortening of the shaft of the lower incisor where it passes back into the jaw. When dealing with fossil forms, often known only from fragments of jaws and teeth, the most useful characters that differentiate taxa are ordinarily found in the structure of the anterior two upper, and anterior lower, premolars. Presence or absence of the last upper molar may also be important, as may the pattern of the upper cheek teeth. When preserved in fossils, structure of palate and of lower jaw also provide characters that assist in determining affinities.

Evolutionary trends

The family of rabbits and hares (Leporidae) entered North America by the end of the Eocene and underwent most of its Middle Tertiary development there. By the Pliocene (about 7,000,000 years ago) it had become reestablished in Asia and had moved also into Europe. The leporids now extend throughout those ranges and down to the tip of South Africa and as far south as northern Argentina in South America.

The pika family (Ochotonidae) spread from Asia to Europe, where they developed into a number of types in the Middle Tertiary. One of these lines persisted until the late Pleistocene or early modern times (about 1,000,000 years ago) on Corsica and Sardinia. Other ochotonid branches reached Africa and North America in the Middle Tertiary. The extant genus *Ochotona* appeared in Asia in the Pliocene and spread from there, reaching western Europe and eastern North America in the Pleistocene. The current range of the genus represents a considerable reduction from that during the Pleistocene.

Distinguishing taxonomic features. Within the order Lagomorpha living members of its two extant families are clearly separable on morphological grounds, the differences being in skull, jaw, and dental structures, as well as in postcranial morphology.

Morphological trends in the rabbits and hares include increase in arching of the skull, correlated with the development of bounding locomotion and of a relatively upright posture of the head; reduction in the ability to perform lateral movements, caused partly by fusion of bones and partly by modifications related to specialization for anteroposterior movements; strengthening of the hindlimbs and pelvic girdle; and elongation of the limbs distally. Pikas lack these skeletal modifications and are adapted rather for a scampering locomotion.

Annotated classification. In older classifications lagomorphs were usually placed in the order Rodentia. Both rodents and lagomorphs are gliriform mammals; that is, they have enlarged, ever-growing incisor teeth that function as effective tools for gnawing. Under this scheme, the lagomorphs were the suborder Duplicidentata, and the true rodents the suborder Simplicidentata. Early workers, however, recognized many features separating these suborders. For one, there are two pairs of upper incisors in lagomorphs (thus the name Duplicidentata) as opposed to one pair of upper incisors in rodents (Simplicidentata). It is now known that lagomorphs and rodents have long separate histories and that even their earliest representatives did not closely resemble one another. Accordingly, it is more accurate and currently generally accepted to classify the two groups as distinct orders. Lagomorpha and Rodentia. The following classification is the one in general use.

ORDER LAGOMORPHA

Small to medium-sized mammals with two pairs of upper incisor teeth, one pair large, ever-growing, and grooved, in front of a pair of small, peglike incisors, and one pair evergrowing lower incisors. In skull the jawbone, or maxilla, pierced or with open lacework laterally; palatal bone with large, deep-cut openings and relatively short bridge. Of muscles used in chewing, masseter muscles not greatly enlarged, temporalis muscle reduced, pterygoid muscles well developed. Twelve extant and approximately 35 known extinct genera are included in three families, one extinct (†).

†Family Eurymylidae

Late Paleocene and (?) Eocene. This extinct family of two genera known only from northern Asia may or may not be closely allied to the other two families of lagomorph. Several anatomical features, such as the presence of only two pairs of upper premolars, show that it was not directly ancestral to later lagomorphs, but it may have been near a group from which later lagomorphs originated.

Family Leporidae (rabbits and hares)

Late Eocene to Recent. Almost worldwide. Distinguished by elongated ears, hindlegs much longer and stronger than forelimbs, often greatly strengthened, and short external tail. Most anterior premolars unlike others in pattern, the following two premolars similar; usually three upper and three lower molars in each jaw, reduced to two upper molars in *Pentalagus;* shafts of upper cheek teeth extend upward into socket in bony capsule (orbit) surrounding eye. Skull with jawbone having open lacework of bone laterally; bony process present over orbit. The palate has one pair of large deep-cut holes; bony palate with longer maxillary and shorter palatine components. Tendency toward arching of skull in profile, related to increasingly upright posture of head. Clavicle rudimentary. Strong, well-developed lumbar region of back, and strong pelvic girdle for articulation with hindlimb and attachment of limb muscles. Five digits on forefoot and on hindfoot.

The subfamily Palaeolaginae is an extinct group that includes primitive Old and New World forms. Descendants of the Palaeolaginae were the extinct Archaeolaginae, including most North American Middle Tertiary forms as well as a group that reached Eurasia in the Pliocene. The most advanced leporids are in the subfamily Leporinae, which includes all living leporids (11 genera), including the American *Sylvilagus*, the Old World *Oryctolagus*, *Lepus* of the Northern Hemisphere,

Romerolagus of central Mexico, *Pentalagus* of the Ryukyu Islands south of Japan, *Bunolagus* and *Pronolagus* of South Africa. Other leporids showing some relatively primitive characters are *Nesolagus* of Sumatra and *Brachylagus* of the western United States. The subfamilial divisions are based partly on the pattern of the most anterior upper and lower premolars, which seem to be valid indicators of leporid relationships. Size 25 to 70 centimetres (9.8–27.6 inches).

Family Ochotonidae (pikas)

Oligocene to Recent. Asia and western North America. Distinguished by short, rounded ears, hindlegs slightly longer than forelimbs, no external tail. Three upper premolars exhibit three different patterns; two upper and three lower molars in each jaw in modern forms, ranges from three upper and lower molars in each jaw to two in each jaw in fossil forms. Shafts of upper teeth curve outward into arch of the zygomatic bone beneath eye socket. Skull with single large opening in each jawbone, other holes present in some fossil forms. Bony process over orbit absent in modern ochotonids but present in some fossils. On palate one or two pairs of deep-cut holes; bony palate with larger palatine component and smaller maxillary component. Skull typically more flattened than in leporids. Well-developed clavicle. Five digits on forefoot and four on hindfoot. One extant genus, *Ochotona,* and 14 or 15 extinct genera. Size 15 to 28.5 centimetres (5.9–11.2 inches).

Critical appraisal. Perhaps the most important unanswered question in lagomorph classification is that of affinities to other mammals. Part of the difficulty is that the fossil record from the Early Tertiary of Asia is incomplete for large parts of the Paleocene and Eocene. The Eurymylidae, known from some Paleocene and possibly Eocene deposits in Asia, have some characters similar to those later lagomorphs but other characters showing that they were not the direct ancestors of later forms. Other fossil mammals now known from the Paleocene of Asia may represent forms related to eurymylids. The evidence is incomplete, but perhaps eurymylids and these possibly allied forms were in a generally ancestral position to leporids and ochotonids. The wider affinities of this possibly ancestral group to other mammals are not yet clear. No transitional forms are known between the eurymylids and later lagomorphs, which had attained their distinctive characters by the late Eocene. Earlier attempts to arrive at the solution to the problem of lagomorph affinities often emphasized similarities between various primitive herbivorous animals, such as the condylarths, and primitive lagomorphs. These similarities, however, are probably due to the presence, in both groups, of morphological characters common to primitive mammals in general.

Relationships with other mammals

A further point causing some difficulty in studies on fossil leporids and ochotonids is the assignment of various primitive forms to one family or the other. The problem is especially acute when the fossil record is based only on a few teeth or jaw fragments. Morphologically these primitive forms seem to be intermediate between the two families.

Some differences of opinion exist in regard to the subfamilial classification of leporids. Some students of these animals have taken the step of subdividing leporids into several families. Other problems in the classification of modern leporids are matters of specific assignment of various populations. A sound subfamilial arrangement for the ochotonids has not yet been established. (M.R.D.)

Rodentia (rats, mice, beavers, squirrels, guinea pigs, capybaras)

The rodents, or Rodentia, are the most abundant order of mammals. At present, over a quarter of the families, 35 percent of the genera, and 50 percent of the species of living mammals are rodents. Probably an even higher percentage of individuals are rodents, for they tend to be small animals with dense populations. They are one of the few groups of animals that flourish in close association with men. Some, such as squirrels, live independently but fairly successfully near humans. Others, such as the house mouse (*Mus musculus*) and black and Norway rats (*Rattus rattus* and *R. norvegicus*), have adapted themselves to human civilization, and live everywhere that man does. These two rats (and the Polynesian rat, *Rattus exulans,* of Australia and Oceania) have travelled in ships and boats of all sizes, and have populated the entire habitable world, especially near human habitations.

GENERAL FEATURES

All rodents possess one pair of upper and one of lower incisors, growing throughout life, with the enamel restricted to a band on the front side of the teeth. Behind this is a large gap (diastema) followed by two to five cheek teeth. The jaw articulation is so arranged that when the cheek teeth are in use, the incisors do not meet, and vice versa. The incisors grow continuously, and must be worn off equally fast, or the whole gnawing mechanism is ruined. Because of the necessity to abrade these incisors, rodents spend a considerable amount of time gnawing hard objects.

Generally rodents are small. Some mice and dormice are among the smallest of living mammals, adults being as small as 75 millimetres (three inches) long, including the tail, and weighing as little as 20 grams (0.7 ounce). The largest living rodent is the South American capybara (*Hydrochoerus hydrochoeris*), reaching over 1.3 metres (four feet) in length and as much as 50 kilograms (about 110 pounds) in weight. A fossil rodent recently described from Uruguay is reported to have had a skull as large as that of a bull and a body bulk as large as that of a wild boar.

Size range

Rodents are of major economic importance, primarily as consumers of the grains that are the basic foodstuff for

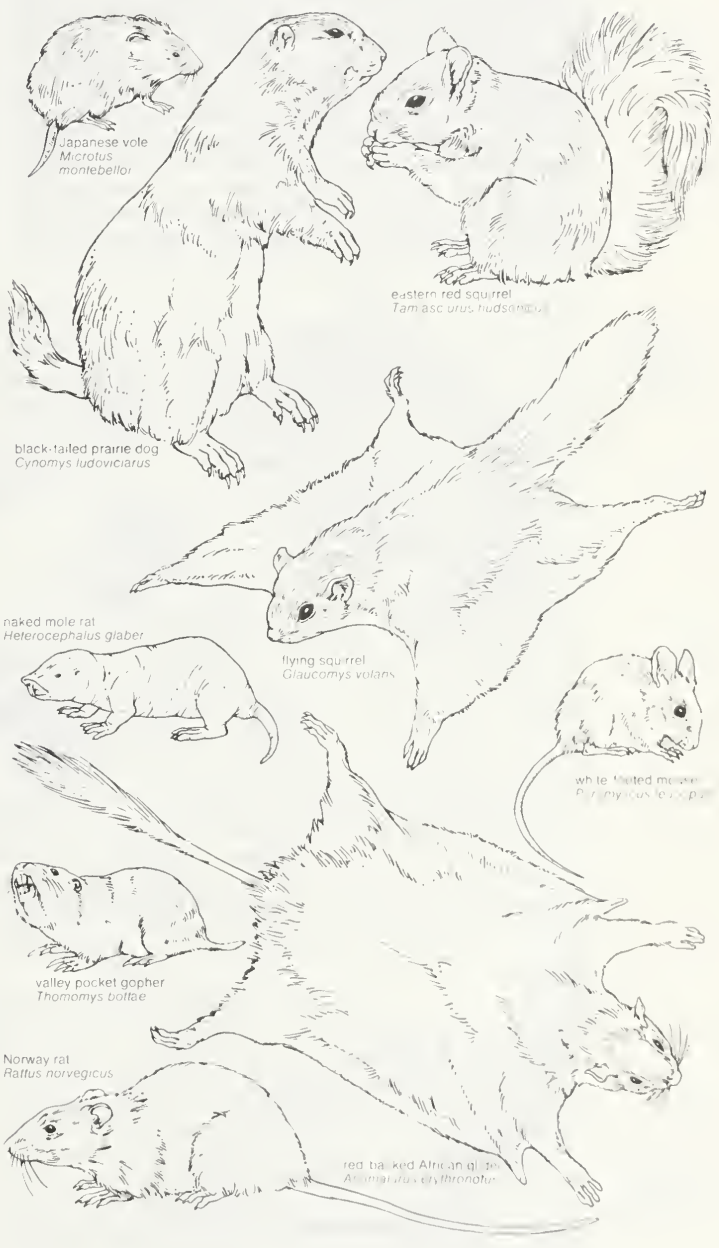


Figure 29: Range of body-plan variation of Rodentia.

man. It has been estimated that rats and mice destroy up to one-third of grain crops under conditions of heavy infestation. Burrowing rodents may damage root crops. The muskrat (*Ondatra zibethica*) and nutria (*Myocastor coypus*), introduced into Europe as fur sources, have escaped and spread over much of Europe between the Baltic and the Alps. Their burrows, particularly in canal banks, have been a major source of damage to the drainage system, most especially in The Netherlands. A number of rodents serve as reservoirs for human diseases, such as bubonic plague, tularemia, scrub typhus, and others. The plague that ravaged Europe during the mid-14th century was transmitted by fleas from rats to humans.

Several rodents (beaver, muskrat, chinchilla, nutria, squirrel) produce fur useful to man. All but beaver and squirrel have been domesticated for this purpose. Albino mice and rats, hamsters, and guinea pigs are widely used as laboratory animals for biological and medical purposes. Guinea pigs were domesticated by the Incas for food; a few kinds of rodent have been raised as pets.

Distribution of rodents

Rodents occur naturally in all parts of the land where there is an adequate food supply and are found in essentially all terrestrial habitats. They range from well above the Arctic Circle to the southern tips of Africa and South America and were the only terrestrial placental mammals, other than bats, to reach Australia before the arrival of man. Many rodents have successfully adapted to difficult environments such as deserts. Many rodents have broad climatic tolerances, an example being the North American porcupine, which is found from the Arctic Circle to central Mexico and from the Atlantic to the Pacific. Most are quadrupedal scamperers, but they generally have much freedom of use of their forefeet in manipulating food; many are burrowers, spending most of their life underground; some are ricochetal, leaping on their hind legs; flying squirrels use skin membranes to glide from one tree to another; a few (beaver, muskrat, water vole, nutria) have become amphibious in habit, living in freshwater streams and ponds; and a number of South American rodents are cursorial (running) animals.

IMPORTANCE TO MAN

Destruction of crops and foodstuffs. The most important rodents, from the point of view of economic damage, are the Norway and black rats, with the house mouse close behind them. It has been frequently estimated that the rat population of the United States is approximately equal to the human population. A population of over 1,000 rats per acre (2,470 per hectare) on an Iowa farm has been reported. Population explosions of house mice occurred in the Central Valley of California in 1926–27 and 1941–42. During the former, the mouse population was estimated to have reached over 80,000 per acre (198,000 per hectare).

Population explosions

Remarkable population explosions of voles (*Microtus*) and wood mice (*Apodemus*) are well known in western Europe, recurring every few years. In France from 1790 to 1935 there were at least 20 mouse plagues, some lasting several years. Estimates of abundance are highly inaccurate, but there are reports of 8,000 voles per acre (19,800 per hectare) and 15 to 20 vole burrows per square metre (13 to 17 per square yard) in peak conditions. There was a population explosion of voles and wood mice over much of Germany beginning in late summer of 1917 and lasting through 1918. Damage to crops was serious; clover was the favourite food; winter rye and wheat, sugar beets, and potatoes also were destroyed in many areas. During the winter, the voles invaded barns and farm buildings, destroying all kinds of stored food. In 1932–35 voles and lemmings were in epidemic proportions in over 104,000 square kilometres (40,000 square miles) of what was then the southern U.S.S.R. This resulted in extensive damage to wheat and other field crops and to orchards.

Rats will eat almost anything that humans eat. Perhaps the most serious damage is to the seeds of grain plants, both before and after harvesting. Grain stored on farms is often not only eaten by rats but also rendered unsuitable

Figure 30: Range of body-plan variation of larger Rodentia.

for human consumption by being mixed with rat droppings. Food that has reached warehouses in cities is also eaten by rats, and here the excess of damage over the amount actually consumed is even greater. It is estimated that rats damage about twice as much grain as they eat. About 23 kilograms (50 pounds) of grain are required to support a rat for a year, so the total cost is about 70 kilograms (150 pounds) per rat per year. Rats sometimes demonstrate a fondness for animal food and have been known to kill several hundred baby chickens in a single night. Eggs are frequently eaten, and even full grown hens, baby pigs, and lambs may be killed. Rats will also follow a farmer in the planting season and dig up newly planted seeds.

Depredation by rats

Rats also do extensive damage in searching for food or in making nests. They gnaw holes to gain entrance to barns, warehouses, or houses, or through walls once they are inside. Clothing, upholstered furniture, and other textiles are gnawed to provide nest-building materials. In areas of cities where extensive quantities of garbage and other refuse are available, the rat populations may exceed the human populations, and rat infestation is one of the commonest complaints of slum dwellers. Such rats are very apt to bite sleeping humans, especially children, and fatal attacks on babies have been known to occur.

The house mouse has food preferences similar to those of the Norway rat but is not as abundant nor as large. Other rodents are much less likely to attack stored supplies of human food, but they do eat considerable quantities before harvesting. This is true of such forms as voles, field mice, and squirrels. The seeds of both wild and domesticated grasses are a major food source for large numbers of wild rodents. Because of the quantities of these that are eaten, such animals are often considered a major threat by grazing interests, but the benefit that rodents give by collecting seeds into underground store houses, where they may later sprout and grow into new plants, certainly comes close to balancing any damage they cause to man's interest.

The role of rats in the "Black Death"

Transmission of diseases. *Plague.* Rodents serve as reservoirs for a number of diseases that may be transmitted to humans by arthropod agents. The most devastating of these is bubonic plague. This disease is fundamentally a disease of rodents, especially rats, transmitted from one rodent to another by an intermediate host, the flea, which also serves to transmit the disease to humans. An epidemic (called a "pandemic" because of the totality of infection in the human population) that seems to have been plague spread over Europe in the 6th century AD. If this epidemic was indeed plague, it must have involved an unusual rodent host because it antedated the arrival of *Rattus* in Europe. The epidemic known as the Black Death originated in Mesopotamia about the middle of the 11th century, and spread to Europe, particularly in the 14th century, being accompanied by the spread of rats throughout the Continent. It has been estimated that 25,000,000 people died of that pandemic of the plague in Europe. The latest pandemic originated in southwestern China in the late 19th century and was spread all over the world by the rat populations of oceangoing ships. Plague is controlled by controlling rat populations, particularly those on ships, and preventing shipborne rats from reaching land. Although plague epidemics have been brought under control, there still remain numerous foci of infection.

The plague bacillus (*Pasteurella pestis*) can infect a variety of other rodents, and foci have been established among native rodents other than *Rattus* in many parts of the world. This disease is referred to as "sylvatic plague" to distinguish it from the basically urban occurrence of ratborne plague. Over 80 species of ground-living and burrowing rodents are known to be involved in sylvatic plague, including ground squirrels, some cricetids (*e.g.,* voles, lemmings, muskrats), several murids (*e.g.,* Old World mice), and a few others, including guinea pigs.

Tularemia. Tularemia is primarily a disease of lagomorphs (rabbits and hares) and secondarily of rodents. It has been reported from all parts of the United States, and seems to have spread from there to many other parts of the world. Among rodents, it is carried by ground squirrels, tree squirrels, prairie dogs, chipmunks, muskrats, and beavers, and is transmitted largely by ticks.

Rickettsial diseases. Three rickettsial diseases—murine typhus, Rocky Mountain spotted fever, and tsutsugamushi disease—involve rodents as reservoirs. Murine typhus, which is much less severe than epidemic typhus, is transmitted to man by fleas, primarily from *Rattus*. It is probably almost universal in tropical and subtropical areas. Rocky Mountain spotted fever, which apparently originated in the northwestern United States, has spread over much of that country, and very similar if not identical diseases are found in Mexico, South America, and Africa. It is transmitted to humans by tick bites, and is presumably endemic in a considerable number of rodents as well as other animals. The cottontail rabbit is believed to be a major reservoir animal. Tsutsugamushi disease, or scrub typhus, is transmitted to humans by the bite of a rat mite. It is found in the East Indies and Southeast Asia. The reservoir seems to be primarily rodents of the genus *Rattus*. A variety of other diseases of lesser importance are transmitted to humans from a reservoir in rodents, largely *Rattus,* by rat bites, ticks, or in other ways.

Damage by burrowing and gnawing. Rodents have been accused, in many parts of the world, of damage to agricultural interests because of their burrows. Cattlemen in the western United States supported campaigns to poison prairie dogs (*Cynomys*) because horses or cattle might (and occasionally did) break their legs in prairie-dog holes. But perhaps the most striking case of damage from rodent burrows has been caused by the American muskrat, introduced into European fur farms, from which it escaped as early as 1905, spreading widely over much of Europe, from Great Britain and Brittany to the Ukraine. It burrows in the banks of streams, and has caused damage especially by making burrows in the banks of drainage ditches, canals, and in dikes.

The ever-growing incisors of rodents need to be used regularly on hard substances to wear them off. This need results in the gnawing of lead pipes or telephone transmission cables, or the making of holes in boxes, walls, and stored inedible items.

Rodents as valuable furbearers

Benefits derived from rodents. *Trapping for furs.* The beaver (*Castor canadensis*) was extremely important in the development of the western United States and Canada, the trappers of the first two-thirds of the 19th century being primarily interested in beaver skins. Most of the initial exploration of the West was performed by beaver trappers. The beaver skin became the basic unit of currency over much of the western United States. The trapping was so extensive and effective that beavers were exterminated over much of the area, but they are making a slow recovery under current conditions of protection. The fur of the chinchilla (*Chinchilla laniger*) was of such value that these rodents were almost exterminated in Argentina. Muskrat and nutria have also been extensively hunted for their fur.

Rats in the laboratory. Among the best laboratory mammals, for all types of biological, medical, and psychological investigation and for testing of new drugs, are the laboratory rats and mice, normally albino strains of wild species of the Norway rat and the house mouse. Guinea pigs (*Cavia cobaya*) are also widely used. There are a number of other laboratory rodents of lesser importance, of which the Syrian or golden hamster (*Mesocricetus auratus*) is the most widely used. Some strains of rats are nearly unique among nonhuman animals in being susceptible to dental caries, and most of the experimental work on tooth decay has been performed on them.

ECOLOGY AND NICHE RELATIONSHIPS

The basic scampering rodent

Habitat and locomotion. The most typical members of the order are the small, ground-living rodents, of the type generally called rats or mice, similar to what was probably the ancestral condition for the order. While these generally stay on the ground, most can climb shrubs and bushes with ease and many climb trees; among the smallest rodents, harvest mice climb stalks of wheat to reach the seeds on which they feed. This central generalized adaptive type of rodent, the scamperer with limited burrowing or arboreal adaptations, includes the family Muridae (Old World rats

and mice, now worldwide), the family Cricetidae (field mice, wood rats, voles, lemmings, muskrats, to name a few; found in most parts of the world other than Australia), some Sciuridae (the ground squirrels and chipmunks), the nonleaping members of the New World family Heteromyidae (pocket mice); some South American rodents (degus, spiny rats, and chinchilla rats), and the South African rock rats (Petromuridae). Although there are many adaptive variants among the scampering rodents, there is a strong tendency for them to inhabit either open country or limited areas of woodland. Rodents of this type are found over essentially the entire land surface of the world. In most cases individual or family territories are set up, and intruders are successfully kept at bay by a variety of threatening and defiant postures. Normally there is no actual combat. The territories are, of course, of varying size, related to the available food supplies and the size of the animals. Individual ground squirrels have been observed over a territory of 2,500 square metres (about 0.6 acre). Changes with time in the territories of chipmunks (*Eutamias*) indicate rather striking seasonal changes, with an increase in the area toward the end of the foraging season (perhaps to allow greater accumulation of food), and very little shift of the territory from one year to another. With few exceptions, these terrestrial rodents make burrows near the centre of the territory where they may spend as much as half of the time, where the young are born, and where the adults hibernate, in forms where hibernation occurs. Normally more young are produced than there is room for, and as a result there is extensive migration of subadult or young adult individuals. For most rodents, the lengths of these migrations are unknown, but it has been shown that muskrats will migrate as much as 30 kilometres (19 miles), including several kilometres cross-country, over a period of one to two weeks, looking for suitable new stream or swamp sites.

From occasional tree climbing it is a relatively short evolutionary step to an arboreal habitat, such as that occupied by the tree squirrels or, with an increase in size and decrease in rapidity of movement, by the New World porcupines. Tree squirrels are, essentially, scamperers that have developed the capability of holding on to bark with their claws. They are as much at home on the ground as in trees and show no special anatomic modifications for tree life. Their nests may be either in hollow trees or other sheltered places (*e.g.*, barns) or built of twigs and leaves among the smaller branches of trees. In Europe and adjacent parts of North Africa and Asia, the dormice (Gliridae) have similar habitat but spend an even larger part of their lives in the trees. Many murids and cricetids (rats and mice, in the broad sense) are about as fully arboreal in their habits as are the tree squirrels.

Gliding rodents

Scampering arboreal animals are faced with the necessity, from time to time, of moving rapidly from one tree to another and do so by leaping. It is generally agreed that gliding forms have evolved their skin fold (patagium), which assists them in gliding, as a direct adaptation to this type of habitat. Patagia have evolved, probably several times independently, among the Sciuridae (squirrels) of both the Old World (*Pteromys* and others) and North America (*Glaucomys*) and in the quite distinct and unrelated African family of scaly-tailed squirrels (Anomaluridae). The patagium of the anomalurids is supported at the anterior end by a long, slender cartilage, which has apparently evolved from the olecranon process of the ulna (the posterior bone of the forearm) at the elbow.

Larger, heavier arboreal forms such as the New World porcupines move slowly along the trunks and main branches of trees. One of these, in South and Central America, has developed a prehensile (grasping) tail that assists in climbing.

Burrowing rodents

A large proportion of the small, ground-living rodents construct underground nests, where the young are born and reared. Often there are adjacent chambers for food storage. In many cases two or more exits provide an opportunity for escape from predators. From ancestors such as this, many lines of rodents have evolved into habitual burrowers that make extensive subterranean tunnels and rarely or never come to the surface, foraging, feeding, mating, and raising their families underground. Among the numerous varieties of burrowing rodents are the prairie dogs, colonies of which were formerly abundant in the western United States. The mouth of the burrow is surrounded by a volcano-shaped mound of dirt, on which a prairie dog frequently sits upright, alert for potential enemies. The animal forages on the ground surface, returning to the mound or to the burrow to eat. Voles (*Microtus*) may make lengthy runways 50 to 75 millimetres (two or three inches) below the surface, arching up the ground surface over them. The pocket gophers (*Geomys* and *Thomomys*) are even more effective burrowers, throwing up mounds 30 centimetres (12 inches) or more across and spending most of their life beneath the ground. They use the incisors as well as the front legs in digging. During times of heavy snow, they may burrow through snow, feeding on plants above ground. Similar types of burrowing occur in the Old World mole rats (Spalacidae). An extreme form of burrowing is found in the African mole rats or blesmols (Bathyergidae), in which the incisors extend forward, with a fold of skin closing the mouth behind them, permitting their use as the primary digging tools, having replaced the forelimbs in this respect. The burrows of a single blesmol form a crisscross of tunnels, at several levels below the ground surface, that may occupy an area of a thousand or more square metres. All these burrowing forms have short, heavy limbs used in digging, short tails, and small eyes. In one genus of blesmol, *Heliophobius*, the eyelids have grown together so that the eyes do not form images. These animals remain permanently below ground. Many burrowing rodents are solitary, but a number of them live in colonies, unlike other members of the order.

Relatively few rodents have become large animals. Several of the South American caviomorphs have done so, however, and have evolved as quadrupedal terrestrial cursorial animals. Usually these have the claws modified into or toward hooves, reducing the number of toes on each foot to four or occasionally three and tending to make each foot symmetrical about the median plane. Among these are the capybara (the largest living rodent), nutria, paca (*Cuniculus paca*), and agouti. The guinea pig is a smaller relative with the same adaptations. Such animals normally escape predators by running away, although both capybara and nutria will take to the water. The Old World porcupines are slow-moving terrestrial quadrupeds that are protected, as are the New World porcupines, by the quills, which are elongate, pointed hairs.

Giant rodents

Many rodents have become bipedal jumpers, enabling them to escape their enemies with long leaps. These forms include the kangaroo rats (*Dipodomys* and *Microdipodops*) of western North America, the jumping mice (*Zapus* and *Napaeozapus*) of eastern North America and eastern Asia, the jerboas (Dipodidae) and gerbils (*Gerbillus*) of North Africa and Southeast Asia, the saltatorial dormouse (*Selevinia*) of Kazakhstan, the chinchilla of the southern Andes, and the springhaas or Cape jumping hare (*Pedetes*) of South Africa. All of these are small, except *Pedetes*, which stands 30 centimetres (12 inches) tall. Most of the saltatorial rodents have very highly enlarged tympanic bullae—the bony covering of the middle ear—which is not true of other rodents. It is probable that this characteristic is an adaptation to life in a desert, where an amplification of the noise made by approaching predators may be of considerable importance. Certainly the large middle-ear cavity greatly increases the amplification of sounds. The fact that the bullae are particularly large in leaping forms suggests further that there may be some relationship between the size of the bulla and the balancing and stabilizing activities of the ears.

Although a number of rodents are at least partially aquatic, special adaptations are rare, being found only in the beavers. Beavers have large hind legs, with strong webs between the toes and an enlarged first digit, as long as the other toes, making very efficient paddles. Swimming is carried out primarily by the feet, but the broad flat tail may be used on occasion for sculling. A number of other rodents that are semiaquatic have webbed feet and soft, dense underfur but few other aquatic adaptations. These semiaquatic forms include muskrats, water voles,

capybaras, nutrias, South American fish-eating rats, and the water rats of Australia and New Guinea.

Seed-eating rodents

Food habits. As a whole rodents are herbivorous, although most of them will eat animal food on occasion. The diet includes a wide variety of plant foods, although seeds are the favourite item. Many are particularly fond of the seeds of the various grasses, both wild and domestic. These may be eaten on the spot, but large quantities are usually carried home in the cheek pouches that are common among rodents. Seeds carried home may be eaten in the safety of the burrow or stored for later use. Such storage is an important item to the plants concerned, as it places the seeds in a favourable location for sprouting, if the rodent either forgets about them or himself becomes food for a predator. Many rodents, such as squirrels, are fond of nuts and can open even the hardest black walnuts to get at the seed within. Acorns, seeds, fruits, berries, young leaves, buds and shoots, green leaves, tubers, and bulbs are eaten by a wide variety of rodents. Burrowing rodents tend to concentrate on the roots, tubers, and bulbs that they encounter in making their tunnels, although some burrowers forage on the surface as well. The larger caviomorphs, such as the capybara, paca, mara (*Dolichotis patagona*), and agouti (*Dasyprocta agouti*), are essentially grazing animals, eating all kinds of green vegetation, young stems, and fruits. Marmots (*Marmota*) have rather similar food habits. Old World porcupines are essentially omnivorous, including carrion in their food. New World porcupines eat leaves, twigs, buds, and bark. Beavers cut aspens, willows, and poplars, using leaves, buds, and bark for food; they also eat a variety of aquatic plants. Many desert-living rodents have a diet that, in the dry season, may be almost exclusively seeds, from which they are able to obtain enough water for survival, using the water produced by metabolism. African cane rats eat coarse grasses and shrubs, one of their favourite foods being sugarcane. A number of rodents, especially during hard winters, strip the bark from trees. Because of their large numbers, rodents can seriously damage the natural plant cover.

On the other hand, many rodents will, on occasion, eat animal food. Muskrats eat freshwater mussels and crayfish, as well as a wide variety of dead or dying water animals. Many rodents, will, at least occasionally, eat birds' eggs, nestlings, or insects. Several genera of South American cricetids live mostly on aquatic animals, of which fish make up the largest part. The grasshopper mice (*Onychomys*) of western United States and adjacent parts of Mexico and Canada are almost exclusively carnivores. Their food consists primarily of insects and earthworms, but may include birds and even other rodents that they kill. In the Arctic portion of their range, ground squirrels eat any carrion available, including their own dead relatives or even walrus or whale meat. They particularly like meat with a high fat content, presumably for the energy value.

Longevity. Rodents are generally considered to have a very short life span. This is certainly true in nature, where rodents are one of the primary food sources of carnivorous birds and mammals. Particularly among the small, mouselike rodents, the average life expectation at birth must be only a few weeks or months; relatively few individuals live much more than a year; and an animal two years old has reached a ripe old age. It is clear that this limitation is largely imposed on the animals by the activities of predators. Cricetids, for example, which normally live less than two years in the wild, have been kept up to five years in captivity, chipmunks and ground squirrels up to seven or eight years, gerbils and dormice over five years, guinea pigs about eight years, chinchillas and North American porcupines about 10 years, and woodchucks, pacas, and the Old World porcupine even longer.

Limits of life span

Predation on rodents. Because rodents are one of the most important items in their food supply, carnivorous birds (especially hawks and owls) and mammals provide a very strong selective force acting on small rodents. Many raptorial birds use their eyes for hunting and are able to detect any rodent slightly less well concealed than the average. It has been shown experimentally that owls selectively capture light-coloured mice over dark ones on a dark background and dark over light on a light background down to a light level of 10^{-7} of a footcandle. As a result of such selective pressure, rodents have evolved fur colours that closely match the environmental background where they live. For example, a late Pleistocene flow of dark lava in New Mexico is now inhabited by melanistic (dark) rats and mice, in strong contrast to the normally coloured rodents surrounding it and to the almost white rodents found in the nearby White Sands area.

Among mammalian carnivores, all but the very largest normally eat rodents, at least as an important part of their diet, and many will start teaching their young how to hunt at the expense of small rodents. The abundance of rodents, moreover, affects the numbers of their predators in at least some instances. The English ecologist Charles Elton has shown that there are striking parallels between cyclic abundance of lemmings and snowy owls and foxes in northern Labrador, the lemming maxima and minima preceding those of the predators by about six months to a year.

BEHAVIOUR

Gnawing. One of the most general habits of rodents is gnawing, much of which serves merely to wear down the incisors. These teeth grow continuously, at rates that have been found to range upward from two millimetres (0.08 inch) per week in the few species in which rates have been measured. Gnawing is performed by all rodents at frequent intervals. It involves the fore-and-aft movement of the lower jaw, the upper incisors holding a hard object and the lower incisors cutting against it. The same movements may be used with nothing held in the teeth, the lower incisors merely alternating between cutting against the rear side of the upper incisors and shifting forward so that the uppers cut against the rear of the lowers. Because the hard enamel is limited to the anterior side of the teeth, such use wears away the softer dentine at a faster rate, leaving the enamel to form a sharp chisel edge. Rodents prefer to use their incisors on hard objects, which provide part of the abrasion. These may be nuts, bark, tree trunks (as in beavers), often bones (which may also be gnawed for a supply of calcium), or even human possessions such as boards in houses and barns or even metal telephone cables.

Function of gnawing

Nesting and denning. *Food storage.* A large proportion of rodents build underground homes, with a central nest chamber, in which they sleep, raise their young, and, often, hibernate. Many others have similar nests in grass or trees. Special food storage areas often are associated with such living quarters; for burrowing forms, these food areas are special chambers off the main passageways. Ground squirrels, kangaroo rats, and other rodents bring grass seeds back to such chambers in their cheek pouches (on the inside of the mouth of ground squirrels; outside the mouth and fur lined in the Heteromyidae and Geomyidae), and will often store several times as many seeds as they will eat during the season when they rely on their stores. Excavation of one kangaroo rat den, from which a single rat weighing 149 grams (about five ounces) was removed, showed nine underground storage chambers, containing from one to nine litres (one to eight quarts) of seeds, with a total of almost 39 litres (35 quarts). Kangaroo rats, in addition, dig storage pits, about 2.5 centimetres (one inch) in diameter and the same in depth, near their burrows, which they fill with seeds. In one case, 875 such caches were located in an area of 5.1 square metres (55 square feet) adjacent to a single den. It has been estimated that seed collection in this manner may result in the loss of as much as a quarter of the grain crop in some parts of the world, and at times of rodent plagues, the destruction locally may approach totality. On the other hand, such underground stores are an important source of germinating seeds for wild grasses in steppe regions such as western North America and Central Asia.

The habit of squirrels of carrying acorns and nuts to hollow trees or barns, or digging holes in the ground in which the nuts are placed, is well known. The animal's memory of the location of these stores is poor, but if enough nuts or acorns are hidden, the animal will be able to find a sufficient number to keep him alive during the winter.

The North American pack rat or trade rat (*Neotoma cinerea*) is attracted by bright and shining objects, which it picks up to carry home to its nest, a jumble of sticks, twigs, grass, and assorted collectors items. A popular superstition is that this animal is a fair businessman, who, on seeing something he wants, always leaves a replacement that is, in his opinion at least, of equal value. The fact is that, while carrying one trophy, the rat may see another that is more attractive and so puts down the first to pick up the second, leading the human who has lost a possession to believe that the rat was carrying out a "business deal."

Constructions by beavers

Beaver dams and lodges. Among the best known activities of rodents are those of beavers, which go to great lengths to store food, cutting alder and other food trees into 0.5- to 2.5-metre (1.6- to 8-foot) lengths and floating the logs in their ponds or embedding one end of these sticks in the mud of the ponds formed by their dams. These sticks make an available food supply during the winter when the ponds are frozen. In order to provide an aquatic habitat, safe from their normal predators, beavers build dams that often run several hundred feet in length, and as much as two metres (6.6 feet) high on the downstream side. The largest dam reported, from near Three Forks, Montana, was 652 metres (2,140 feet) long, 4.3 metres (14 feet) high at the highest point, and seven metres (23 feet) thick at the base. The dams are made of twigs, branches, and logs from which the bark has been eaten, piled on the ground with alternating layers of gravel or mud. When finished, the upper surface is plastered with mud, usually dug from the bottom of the pond above the dam, to make it watertight. The pond behind the dam serves as the refuge and first defense of the beaver. Consequently, beavers work continually to maintain the dams, by repairing, raising, and lengthening them, a process that may extend over several generations. Abandoned beaver ponds gradually silt up, forming very characteristic meadows.

Beavers also build lodges in the ponds behind their dams or burrows in the banks. Lodges are built up in the same manner as dams, and they are enlarged along with the rising water level of the ponds as the dam is raised. For ventilation, however, the upper part of the lodge is much more loosely constructed than the dam. The floor is kept above the water level, and there may be two levels, the lower for feeding, the upper for sleeping. The entrance to the lodge is through a tunnel, the outer end of which is below water level. Bank lodges are burrows in the bank, with the inside arranged like that of lodges. Again, access is gained through a tunnel with the mouth below water level. Burrows may extend more than nine metres into the bank.

Beaver canals are less well known but highly remarkable. They are dug to permit the transport of birch or aspen logs for food supplies from the sources where they are cut to the ponds. The logs are floated in the water, where the beaver is much safer than on land. Such canals are dug whenever they can be made with little or no damming. They vary from 0.3 to 1.2 metres (one to four feet) in width, up to 0.6 metres (two feet) deep, and canals as long as 223 metres (732 feet) have been reported.

Beavers live on the bark of trees, that of aspen being their favourite, but birch, cottonwood, willow, and alder also are used. When these are in short supply other plants are eaten, but conifers are rarely cut except for building materials. In one night a single adult beaver can fell a seven- to 10-centimetre (three- to four-inch) poplar, cut it into sections one to three metres long, and drag the logs to the water. Normally, beavers do not cut up logs over 15 centimetres (six inches) in diameter, although they will fell trees considerably larger. The largest tree on record cut by beavers was 115 centimetres (46 inches) in diameter. The cutting of trees is apparently done at random, with all gnawing likely to be on one side, unless the tree has a large diameter, in which case it may be gnawed all the way around. Because trees normally fall downhill, hence toward a pond, this is probably the origin of the legend that beavers can make trees fall as they wish.

Types of dormancy

Hibernation. Many rodents use their nests or burrows for shelter during unfavourable seasons, especially winter. There is considerable variation, even among closely related animals, in the amount of activity that occurs at such times and how often animals wake and eat some of the stored food. In a considerable number, including chipmunks, pocket mice (*Perognathus*), some jerboas, and some field mice, there is extensive torpor in wintertime, the animals sleeping extensively, but waking two or three times a day to eat. Hamsters (*Cricetus* and *Mesocricetus*) are deep hibernators, going into a sound sleep from which they awaken only periodically to eat. The most pronounced type of hibernation involves the accumulation of extensive amounts of body fat during the late summer and early fall, and deep hibernation with few or no awakenings during the winter. This condition occurs in marmots, some ground squirrels, a large proportion of dormice (whose English name is derived from the French *dormir* meaning "to sleep"), the jerboa (*Allactaga*), and most or all zapodids (jumping mice and birch mice). Estivation, or summer sleep, is rare in rodents but occurs in woodchucks and some ground squirrels. No suggestions of hibernation occur in murids, caviomorphs, or phiomorphs, any other tropical rodents, or rodents with a recent tropical or subtropical ancestry.

Population movements. Several types of rodents, subject to periodic fluctuations in numbers, reduce the amount of overpopulation by migration. Generally, the migration is simply the movement of juveniles away from a home area that has become fully populated. Migration of such animals may be quite extensive, but, because it is usually an individual phenomenon, it is often not noticed. Such animals are subject to very high mortality from predators because they are moving in unaccustomed territory and without the shelter of a permanent home. Muskrats and beavers are examples that are more readily noted, because they move from one suitable stream to another and may travel as much as several miles across country looking for a suitable home. There are many reports of major migrations. In August 1946, gray and fox squirrels migrated out of an area in northwest Wisconsin, apparently due to a shortage of acorns. When they reached streams and rivers, they crossed them by swimming, many drowning in the wider rivers. In 1935 a mass movement of gray squirrels was noted from the area east of the Hudson River, to the west. Hundreds (one report says 2,000) of drowned squirrels were found along the west bank of the Hudson River.

Lemming migrations

The most famous migrations of rodents, however, are those of lemmings, especially in Scandinavia. There tend to be two migrations per year, one in spring and one in autumn. The exact causes of the movement are not known, but a change of habitat with season seems to be the most important single factor. It has been believed that the migrations are caused by overpopulation and a shortage of food, or by claustrophobia (a feeling of mental anguish from the crowded conditions), but these probably are not valid causes.

The lemming migrations are individual activities rather than unified movements, as is popularly supposed. Careful observations of migrations show that each individual acts alone, but that there may be groups of several individuals within a few minutes, followed by a gap of 10 minutes or more. In autumn, at least, the migrations normally occur at night. Individual lemmings generally move fairly rapidly in a generally constant direction, although they will occasionally stop to feed or groom. Rates of migration have been calculated as about one metre per second (2.25 miles per hour), but such speeds are not sustained, and it is probable that distances of eight–10 kilometres (five–six miles) per day are normal. The migrations tend to be oriented by roads or paths made by humans, trails made by reindeer, or other similar routes, although the general direction seems to be outward in all directions from the general source area and to be determined before the movement begins. Contrary to the older reports and popular belief, lemmings do not rush forward without hesitation into water when reaching a shoreline. They apparently try to avoid swimming, if possible, running up and down the shore looking for a narrow crossing or an area where they can cross on ice. Apparently, they enter water willingly only if they can see the silhouette of the far shore. This is in marked contrast to activities of their relative, the water

vole (*Arvicola*), which always heads for the water when threatened. When swimming lemmings use their hind legs almost exclusively but swim very high out of the water. Lemmings become exhausted and drown after swimming 15 to 25 minutes in water with waves about 15 centimetres (six inches) high. Observations along the Swedish-Finnish border show that the lemmings had no problem crossing a strait 200 metres (650 feet) wide on a calm night, but that considerable numbers drowned on a windy night. A lemming was observed swimming at approximately the middle of a lake two kilometres (1.2 miles) wide. Reports of lemmings swimming out into the North Sea and being found alive 16 kilometres (10 miles) or more from shore must be viewed skeptically.

Recent studies in Scandinavia indicate that the migrations are a normal part of the activity of the lemmings. They serve not only as a means of dispersal of the species but also to permit the animals to occupy different habitats at different seasons.

Rodents are often thought of as defenseless animals, but the incisors are very sharp and powerful, are activated by powerful jaw muscles, and can inflict a deep wound. Among themselves, rodents fight for territories, the possessor of a territory usually being able to drive interlopers away. They also fight very effectively in self-defense, as indicated by the popular expression, "fighting like a cornered rat." A full-grown wharf rat is capable of defending itself against a determined tomcat. Even animals as small as lemmings are able to discourage attack by weasels.

REPRODUCTION

Flexibility in breeding habits

The reproductive habits of rodents are exceedingly varied in nature and are capable of being even further modified in domesticated or partially domesticated forms. Many, especially the larger types, reproduce once a year. Others produce several litters during a single season. Some have only one or two young at a time; others, large numbers. Some are capable of reproduction at very early ages, others (particularly members of the Caviomorpha) not until after a considerable period of growth. Most are born naked and helpless, and are cared for in nests; a few are able to run and keep up with their mothers almost at once. Most rodents are polygamous; some mate for the duration of a single breeding season; and a few (beavers, for example) have permanent mates.

Beavers do not breed until the second January or February after birth, producing a litter of two or four young after about 12 weeks of gestation. The capybara has a litter that is, on the average, slightly larger, after 15 to 18 weeks gestation; the viscacha, a smaller animal, has two young in the spring about 22 weeks after breeding. Nutrias breed twice a year after reaching an age of one year, if the winter temperature does not fall below 16° C (60° F) for lengthy periods, and produce litters averaging about five young. The European porcupine (*Hystrix cristata*) breeds in the spring, with one to four young being born about 16 weeks later, and some of its tropical relatives (other members of the Hystricidae) produce two litters a year. The North American porcupine (*Erethizon dorsatum*) of the caviomorph family Erethizontidae, has a single young after 30 weeks gestation. Most of the smaller members of the order, however, have considerably higher reproductive rates. In many cases there may be more than one litter per year, with high numbers per litter, examples being shown in Table 2.

Table 2: Reproductive Rates of Certain Rodents

animals	litters/year	young/litter
North American gray squirrel (*Sciurus carolinensis*)	2	2–3
Eurasian gray squirrel (*S. vulgaris*)	2	5–7
Red squirrels (*Tamiasciurus*)	2	4–6
Pocket gophers (*Geomys*)	1–2	1–4
Pocket mice (*Perognathus*)	1–2	2–8
Kangaroo rats (*Dipodomys*)	1–3	2–4
Deer mice (*Peromyscus*)	up to 4	2–7
Hamsters (*Cricetus*)	several	6–12
Lemmings (*Lemmus*)	several	3–9
Muskrats (*Ondatra*)	2–5	5–7
Voles (*Microtus*)	up to 13	4–8

Source: E.P. Walker, *Mammals of the World* (1964) and S.A. Asdell, *Patterns of Mammalian Reproduction* (1964).

This rather high rate of breeding is intensified by the fact that, in many of the smaller rodents, sexual maturity is reached at an early age, normally earlier in the females than in the males. The females breed when less than a year old in many squirrels, some pocket gophers, and the pack rat. In most of the Cricetidae, however, the young appear to reach sexual maturity considerably earlier—harvest mice (*Reithrodontomys*) in five weeks; the hamster (*Cricetus*) in six weeks; and voles (*Microtus*) in six to seven weeks.

In the United States, wild populations of the house mouse reproduce throughout the year, with an average of 5.5 litters and 31 young per female per year in buildings, and 10.2 litters and 57 young per year on farms. In the laboratory mouse, the mean litter size has been reported as ranging from 4.5 to 7.4, depending on the strain. The second litter is the largest, after which there is a steady decrease. Litter size has been reported to have a range of two to 12, and as many as 19 healthy embryos have been removed just before term from a single female. There may be five or more litters per year. The gestation period is about 20 days, and the first mating usually occurs at seven to 10 weeks of age, though it has been reported that, in one strain of albino mice, the first estrus occurs, on the average, at 39 days and results in about 50 percent pregnancies. The breeding span of most mice in the laboratory is 12 to 18 months. Lactating females may become pregnant, but the gestation will be lengthened by one to two weeks.

Reproductive potential

Wild Norway rats breed throughout the year, taking advantage of the sheltered environment available from living in association with humans. The size of the litter is correlated with the size of the mother. In the laboratory female rats reach sexual maturity in 33 to 120 days. The number of young varies with the strain, two typical ones having litters averaging 6.5 and 8.9. Normally, a female's second or third litter is the largest, and the litter size decreases rapidly after the tenth. Over a number of generations of laboratory life in a colony of gray rats, however, the total number of young per female grew from an average of 23 to an average of 63.

The laboratory guinea pig has a gestation period of about 68 days, a very long period for such a small animal but characteristic of caviomorphs. There are usually three or four young per litter. The age of puberty varies from 55 to 70 days.

Although most rodents seem to increase their reproductive potential under domestication, this is not true of chinchillas. In the wild, they produce litters of one to six after about 15 weeks pregnancy; domesticated ones seem normally to have only one offspring at a time.

FORM AND FUNCTION

In most aspects rodents are relatively primitive, not highly specialized mammals. The skeleton is usually that of a quadrupedal, scampering mammal, not far from the basic placental stock. The digits are clawed and usually five in number, with little or no opposability of the first digit. The limbs are not far from the same length, although the hind legs are always somewhat longer. The animals are adapted to a broadly herbivorous diet. The main specialization of the digestive system is the possession of a large cecum (a blind pouch) at the junction of the large and small intestines.

Specializations for gnawing. As opposed to this basic primitiveness, the rodents have developed, as their basic innovation, a gnawing mechanism of an efficiency that is not approached by that of any other mammals. The glenoid fossa, the concavity where the lower jaw articulates with the skull, slopes downward, from rear to front, and there are no processes (as there are in all other mammals) at the anterior and posterior limits of the fossa that restrict the anteroposterior movement of the jaw. The jaw, therefore, is capable of functioning when pulled to the rear, separating the incisors from each other, and permitting chewing or grinding by the cheek teeth. The jaw can also be pulled forward and downward, separating the

cheek teeth and bringing the tips of the incisors together for gnawing.

Evolutionary shifts in jaw muscle attachments

These shifts in the position of the jaw, as well as the functioning of the jaw in either position, are brought about by a combination of the actions of the various jaw muscles, of which the temporal, pterygoid, and masseter are the most important. The forward and backward (anteroposterior) movements, including those of gnawing, were caused, primitively, by all three muscles, all of which have a slight anteroposterior component. But a shift of the anterior muscle, the masseter, began to occur during the Eocene Epoch (about 50,000,000 years ago). Originally, in a condition called protrogomorphous, the masseter ran from the zygomatic arch (cheekbone) to the lower jaw. Parts of the muscle, retaining the original points of insertion on the lower jaw, shifted their origins forward onto the snout, doubling the length of the muscle and greatly changing its direction of pull. In some rodents it was the lateral portion of the masseter that shifted forward onto the face, compressing the infraorbital foramen (an opening in the bone), through which pass nerves and blood vessels, between the muscle and the snout (the sciuromorphous condition); in others it was the deeper portion of the masseter that shifted forward, through the infraorbital foramen (presumably following an initial enlargement of the foramen), onto the face, resulting in further enlargement of the foramen until it may now be larger than the eye socket (the hystricomorphous condition); and in still others, a combination of the two shifts has occurred (the myomorphous condition). Although these changes are of importance in determining rodent taxonomic relationships, they are probably not as controlling as was once thought, as each structural condition may have originated more than once.

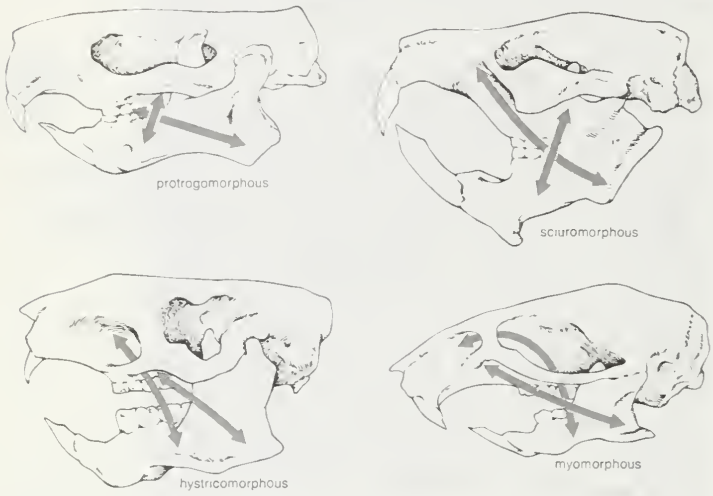

Figure 31: Skulls of the four basic types of rodents. Arrows show positions of branches of the masseter muscle.

Continuous growth of incisors

But the main structural change from the primitive mammalian condition has occurred in the incisors. In all known rodents, beginning with the very earliest, the incisors are reduced to a single pair in each of the upper and lower jaws. These teeth grow throughout life, the enamel cap being restricted to the anterior 30 to 60 percent of the perimeter of the tooth. The rate of incisor growth has been measured in several rodents, and varies from about two to three millimetres per week (0.08–0.12 inch) in nonburrowing forms to five millimetres (0.2) per week in pocket gophers, in which the incisors are used for digging as well as for gnawing. In hibernating rodents, the incisors continue to grow, but at a greatly reduced rate: If the incisors do not meet, due to deformity or breakage, the teeth will continue to grow indefinitely. Since the lower teeth are arcs of large circles, the lower incisors simply curve forward and upward, becoming completely nonfunctional. But the upper incisors are large arcs of much smaller circles. With growth, they may spiral outward, like the spirals on a handle-bar moustache, or they may grow around and upward through the throat between the lower jaws, growing through the snout and eventually locking the jaws closed. Either condition is fatal, but rodents have survived in nature for a long time with such malformed incisors.

Because of the continual growth of their incisors, rodents have an unusually heavy need for calcium, which, together with a need for abrasion of the incisors, explains the frequency with which rodents gnaw bones.

Adaptations for specialized locomotion. Many rodents have shifted their locomotion from the characteristic scampering type. In burrowing rodents, the limbs are short and massive, and the hands, particularly, are widened and strengthened with heavy claws. Many, but not all, burrowing rodents use their incisors to help in digging. In such cases, a fold of skin is likely to close the mouth behind the incisors, and the radius of curvature of both upper and lower incisors is increased, so that they extend forward from the mouth, cutting the soil an appreciable distance in front of the animal. Eyes and ears are generally reduced in size in these forms.

There is little difference, structurally, between the terrestrial scampering rodents and the arboreal scamperers, such as squirrels. The claws of the latter are sharper, but locomotion is basically the same. A few rodents, such as the New World porcupine, actually climb (as would a human) rather than running up and down the bark, as does a squirrel. Only one rodent, the tree porcupine (*Coendou*) of Central America and northern South America, has a truly prehensile tail (although several rodents have semiprehensile tails that they can wrap around branches for extra support). A number of gliding rodents, "flying squirrels" of one sort or another, some of which are not closely related to the true squirrels (Sciuridae), are supported in the air by a fur-covered membrane (patagium) extending between the fore and hind limbs and usually between the hind limbs and the tail.

A rather common development among rodents has been the reduction of the forelimbs and an increase in the size of the hind limbs and tail for locomotion by means of a series of kangaroo-like leaps, which in several forms can exceed 4.5 metres (15 feet).

Adaptations for water conservation. With their wide geographic distribution, rodents have invaded desert regions in all parts of the world. Many of these have developed the ability to function on limited supplies of water. This has been achieved in several ways. Some are nocturnal, remaining asleep during the heat of the day in burrows deep enough to reach ground moisture, thus reducing evaporation. Others seek out succulent desert plants for food. But it has been shown that a number of desert rodents (kangaroo rats and jerboas, for example) have the ability to live exclusively on seeds, with no external water source, and to obtain all of their needed water from their metabolism. Such forms also produce a greatly reduced quantity of extremely concentrated urine and a small amount of feces. Two species of spiny mouse (*Acomys*) were investigated in Israel. Both inhabit the same desert areas, but one is diurnal and the other is nocturnal. Both produce urine the urea content of which is extremely high. Neither species can survive on a diet of barley without water to drink, although gerbils and jerboas from the same area showed no ill effects after four weeks without water. The diurnal spiny mice, however, were able to survive and grow with no water except seawater, whereas the nocturnal ones could not tolerate such a salt concentration.

EVOLUTION AND PALEONTOLOGY

Rodents are relatively poorly represented in collections of fossils, in spite of their great abundance at the present time. They have often been overlooked because of their small size, but modern intensive exploration for fossils usually results in a much more abundant representation of small mammals, especially rodents.

Paleocene. The earliest known rodents come from the late Paleocene (about 57,000,000 years ago) of North America, by which time they had already acquired all of the diagnostic features of the order. The ancestral family, the Paramyidae, was also present in Europe, where it first appeared in the earliest Eocene. There was very rapid diversification of the order during the Eocene, initially involving the Paramyidae, but with other families soon

Paramyidae, the earliest rodents

appearing. Most of the Eocene rodents were protrogomorphous, the masseter muscle restricted to its primitive origin on the cheekbone. By the middle Eocene of Europe, rodents with advanced types of masseters were present, and others occurred in the late Eocene of North America. The skeleton of the paramyids was basically that of a generalized scampering animal, approximating a rat in its method of locomotion. Before the end of the Eocene it is probable that both leaping and burrowing variations had arisen, although there is some uncertainty on this point.

Oligocene. A major gap in the knowledge of rodent evolution occurs at the Eocene-Oligocene boundary (about 38,000,000 years ago). A number of modern families with advanced types of jaw muscles appeared at about the same time in North America, Europe, or Asia, including the Cricetidae, Heteromyidae, Geomyidae, Castoridae, and Ctenodactylidae, with no good indications at present as to their geographic or ancestral sources. (The Ctenodactylidae are known from the Eocene of Kazakhstan, however.) At about the same time, rodent groups appeared suddenly in South America and Africa (Caviomorpha and Phiomorpha, respectively). Both groups are hystricomorphous and hystricognathous and have often been considered to have been related, though others consider them to have acquired their similarities independently.

Miocene. The majority of the living families of rodents had appeared by the Oligocene, and most of the remaining ones occur in the Miocene (around 26,000,000 years ago), so that the later part of the evolution of the rodents was largely a diversification of the various groups. The ancestors of a wide variety of specialized modern forms can be recognized from teeth, but most of them are not known from skeletons, and the evolutionary status of the modern locomotor conditions is not well known. Highly evolved burrowing rodents were certainly present in the Oligocene in Mongolia, however, and less specialized ones occurred in North America. Ancestral kangaroo rats had attained a leaping ability by the Miocene of North America. Gliding and burrowing forms are known from the Miocene of Africa. In South America, the differentiation of the descendants of the invaders present in the early Oligocene proceeded rapidly, and the Miocene forms occupied nearly all potential rodent niches on that continent.

Richard Keane

Figure 32. Reconstruction of *Epigaulus*, a primitive Pliocene rodent.

Appearance of Muridae

Later evolution of rodents. The latest rodents to differentiate apparently were the members of the family Muridae. This group appears suddenly in early Pliocene deposits of Europe, probably having invaded that continent from Asia, the southeastern part of which, together with the adjacent East Indies, is now considered the evolutionary centre of the family. The Muridae expanded rapidly all over the Old World. An isolated incisor is known from the Pliocene (approximately 4,000,000 years ago) of New Guinea, where considerable local evolution has occurred. The murids reached Australia late in the Cenozoic Era (they are unknown there before the Pleistocene), and underwent a rapid evolution, developing arboreal, burrowing, and leaping forms, paralleling the evolution of the entire order in the rest of the world.

When North and South America were united in the beginning of the Pleistocene (about 2,500,000 years ago), there was a major invasion of South America by cricetids, which expanded rapidly and became highly diverse in that area.

An interesting aspect of rodent evolution are the very rapid diversifications (evolutionary explosions) that occurred whenever highly specialized members of the order reached areas that had been previously uninhabited by gnawing mammals (South America and Africa in the Oligocene, New Guinea in the Pliocene, Australia in the Pleistocene). These, apparently, resulted in a rapid spread into most of the major available ecologic niches in a matter of, at most, 2,000,000 or 3,000,000 years. The differentiation of the South American cricetines since the beginning of the Pleistocene has not been quite as fast, though still explosive, presumably because there already were numerous rodents on that continent. The initial diversification of the rodents during the Eocene seems to have taken place at a considerably slower rate, probably because they had not yet become as thoroughly adapted for gnawing as was the case later.

Because of their small size and great abundance, rodent fossils are becoming progressively more important as guide fossils that enable accurate separation of successive geologic horizons.

CLASSIFICATION

Distinguishing taxonomic features. Many features have been used to determine the relationships of the subgroups of the rodents. The most generally used are the differentiations of the jaw muscles or the modifications of the skull and jaws resulting from muscular changes. The masseter muscle may have its primitive position, arising from the cheekbone (protrogomorphous); its lateral division may have shifted forward onto the snout, compressing the infraorbital foramen against the snout (sciuromorphous); the medial division may have moved forward through the infraorbital foramen, onto the snout, greatly enlarging the foramen (hystricomorphous); or both branches of the masseter may have shifted (myomorphous). In most rodents the angular process at the rear of the lower jaw extends downward from the ventral side of the alveolus of the incisor (sciurognathous); in some, all of which are also hystricomorphous, the angle arises from the side of the alveolus (hystricognathous). Other features that have been given important weight in delimiting the major subgroups include: crown patterns of the cheek teeth (premolars and molars); histologic structure of incisor enamel, which may have one layer (uniserial), a few (pauciserial), or many (multiserial); structure of the penis or of the baculum (os penis); structure of the male genital tract, including particularly the presence or absence of an outgrowth, the sacculus urethralis; fusion or lack thereof of two of the ear ossicles, the malleus and incus; and the pattern of development of the extra-embryonic fetal membranes.

ANNOTATED CLASSIFICATION

The classification presented here is based upon that of American paleontologist A.E. Wood. The rodents are one of the outstanding examples of a group in which closely similar structures have evolved numerous times independently, a phenomenon known as parallelism, with the result that there is very strong disagreement among taxonomists working with the group as to how the order should be subdivided.

Groups indicated by a dagger (†) are known only from fossil remains. Dental formulas indicate the number of pairs of teeth present in the upper jaw (above the line) and lower jaw (below), the figures representing, respectively, pairs of incisors, canines, premolars, and molars. When a partial formula is given the type of tooth is indicated by I, C, P, or M.

ORDER RODENTIA

Gnawing mammals with ever-growing incisors, reduced to a single pair in both upper and lower jaws and with the enamel limited to the anterior face of the incisors, so that wear maintains a sharp chisel edge; glenoid fossa slanted, with neither preglenoid nor postglenoid process, masseter the principal jaw muscle; dental formula reduced, never exceeding $\frac{1.0.2.3}{1.0.1.3} = 22$. About 350 living genera and 2,400 living species; over 400 extinct genera have been described.

Suborder Sciuromorpha

Masseter primitively either limited to zygoma, or rarely with only a slight forward displacement, but in the squirrels shifted forward onto face (sciuromorphous). Always sciurognathous. No sacculus urethralis. Malleus and incus bones of ear separate. Incisor enamel pauciserial or uniserial. Paleocene to Recent.

†*Family Paramyidae*

Paleocene to early Miocene; Northern Hemisphere. Cheek teeth cuspidate, clearly derived from basic mammalian tribosphenic type. Tympanic bullae became co-ossified with the skull several times independently, within the family. Incisor enamel pauciserial, with one possible exception. Presumably ancestral to the rest of the order. One subfamily incipiently hystricognathous. From size of a mouse to as large as a beaver. Locomotion, when known, scampering, with possible incipient leaping in one form.

†*Family Sciuravidae*

Eocene of North America; one genus from Eocene of Central Asia. Cheek teeth formed of 4 transverse crests rather than of separate cusps; locomotion probably scampering; mouse-size to rat-size. Incisor enamel pauciserial. Perhaps ancestral to several mouse- or ratlike groups.

†*Family Ischyromyidae*

Late Eocene to Oligocene of North America. Masseter muscle has begun to move forward onto the snout in some forms, in primitive position in others. Cheek teeth 4-crested. Incisor enamel uniserial. Locomotion scampering. Size of a gray squirrel or somewhat larger.

†*Family Cylindrodontidae*

Middle Eocene to Oligocene of North America. Oligocene of Central Asia. Burrowing rodents with high-crowned to ever-growing cheek teeth, based on a pattern of 4 transverse crests. The most specialized forms used the incisors for digging, as shown by forward extension of these teeth. Incisor enamel uniserial. Size from that of a chipmunk to that of a marmot. Presumably derived from North American Sciuravidae.

†*Family Protoptychidae*

Late Eocene of North America. Skull with highly inflated auditory bullae, suggesting, by analogy with other rodents, that these were leaping animals. Cheek teeth high crowned, with pattern of 4 crests. Size of a gray squirrel.

Family Aplodontidae (mountain beaver, or sewellel, and fossil relatives)

Late Eocene to Recent of North America. Oligocene and Miocene of Europe, Pliocene of Asia. Single living species restricted to wet areas from British Columbia south to San Francisco Bay. Extreme hypsodont cheek teeth, based on cuspidate rather than crested pattern. Incisor enamel uniserial. Burrowers. Head and body length of living species (*Aplodontia rufa*) 300 to 460 mm (11.8–18.1 in.), with a short tail; weight 900 to 1,800 g (2–4 lb).

†*Family Mylagaulidae*

Miocene to Pliocene of North America. Strongly hypsodont cheek teeth, with greatly enlarged premolars, whose continual growth forced 1 or more of the anterior molars out of the jaws. Incisor enamel uniserial. Some individuals had paired horns on the snout. Whether these are taxonomic or sexual characters has not yet been demonstrated. Powerful burrowers. About the same size as *Aplodontia*.

Family Sciuridae (squirrels, chipmunks, and marmots)

Oligocene to Recent of Northern Hemisphere, Miocene to Recent of Africa, Recent of South America. Highly developed sciuromorphous pattern, with masseter muscle extending forward along the side of the snout and compressing the infraorbital foramen. Postorbital process of frontal separates the eye from the temporal muscle. Cheek teeth typically very similar to those of the Paramyidae, but some forms have rather complicated tooth patterns. Incisor enamel uniserial. About 70 living genera.

Suborder Myomorpha

Lateral branch of masseter muscle usually displaced forward alongside of snout, forcing infraorbital foramen against side of snout; in most forms, deep masseter penetrates a variable distance through upper part of infraorbital foramen. Sciurognathous. Incisor enamel uniserial. Locomotion scampering, jumping, arboreal scampering, or fossorial. A few forms are partially adapted to an aquatic life. Malleus and incus never fused. No sacculus urethralis. Cheek teeth usually reduced in number, with only a single fossil genus known that retains the primitive rodent dental formula; except for the Geomyoidea, the premolars are either lost or greatly reduced; the last molars are occasionally lost as well. Most members of the group are small, from the size of a mouse to that of a rat (head and body length ranges from 50 to 300 mm (2–11.8 in.), except in the Rhizomyidae, which may be somewhat larger).

Family Cricetidae (field mice, deer mice, voles, lemmings, muskrats)

Early Oligocene to Recent of Europe and North America, middle Oligocene to Recent of Asia, late Pliocene to Recent of South America, Pleistocene of Madagascar, Recent of Africa. Deep masseter expanded through upper part of infraorbital foramen to face; no premolars, molars $\frac{3}{3}$; cheek-tooth pattern based on cusps arranged into 5 transverse crests in both upper and lower teeth; teeth low crowned to very high crowned. Scampering, fossorial, arboreal scampering, jumping, or partly aquatic.

Family Muridae (Old World rats and mice)

Early Pliocene to Recent of Europe and Asia, late Pliocene to Recent of East Indies, Pleistocene to Recent of Africa and Australia. Introduced throughout the world by man. Deep masseter as in Cricetidae; cheek teeth normally the 3 molars, but one subfamily, the Hydromurinae of Australia and New Guinea, has lost the third molars, reducing the cheek teeth to $M\frac{2}{2}$; tooth pattern based on rounded cusps, arranged in transverse rows, but derivable by modification of a pattern like that of primitive cricetids; low to medium high crowned teeth. Scampering, arboreal scampering, occasionally fossorial or semiaquatic.

Family Heteromyidae (pocket mice, kangaroo rats and mice)

Oligocene to Recent of North America, Recent of northern South America. These and the next two families are sciuromorphous, with no penetration of the infraorbital foramen by the masseter, and seem to be closely related. Fur-lined cheek pouches, opening beside the mouth and reaching back to the shoulders, are used for the transportation of food to underground storage areas near the nests. Central stock of family scampering; specialized ones leap with their hind legs. Generally small, mouselike; length of head and body from 55 to 180 mm (2.2–7.1 in.). Cheek teeth, which include $P\frac{1}{1}$ $M\frac{3}{3}$, are low crowned to very high crowned. Pattern of teeth based on 2 transverse rows of 3 cusps each. Derivable from late Eocene members of the Eomyidae.

Family Geomyidae (pocket gophers)

Early Miocene to Recent of North America. Similar to heteromyids in regard to jaw muscles, dental formula, and tooth pattern, and in possession of fur-lined cheek pouches. Highly adapted burrowing animals. Cheek teeth have already become high crowned in the Miocene, and those of the living forms grow throughout the animal's life, with the enamel reduced to a plate on the anterior side of the upper teeth and the posterior side of the lowers.

†*Family Eomyidae*

Late Eocene to late Pliocene of North America; late Eocene to Pleistocene of Europe. Sciuromorphous jaw muscles; cranial anatomy and jaw structure very similar to heteromyids. Cheek teeth usually low crowned, with pattern of 5 crests, rather similar to that of the cricetids, although some members of the family developed teeth suggesting that they might be ancestral to heteromyids. Cheek teeth usually $P\frac{1}{1}$ $M\frac{3}{3}$, but one genus had $P\frac{2}{1}$. Skeleton and habits unknown.

Family Zapodidae (birch and jumping mice)

Late Oligocene to Recent of Eurasia, early Miocene to Recent of North America. A late Eocene genus from California is often (perhaps incorrectly) placed here. The Old World birch mice are arboreal scampering forms, as were probably all the earlier fossil members of the family. The jumping mice are as saltatorial as the kangaroo rats. Infraorbital foramen of medium size, with the deep masseter passing through it but with the superficial masseter remaining on the zygomatic arch. Cheek teeth $P\frac{1}{0}$ $M\frac{3}{3}$, with pattern very similar to that of cricetids, with which the fossils have frequently been confused.

Family Dipodidae (jerboas)

Late Oligocene to Recent of Asia, late Miocene to Recent of Europe, Pleistocene to Recent of North Africa. Masseter muscle like that of zapodids but with larger deep division. Highly saltatorial rodents of the steppes and deserts of the Old World, with extremely inflated auditory bullae. Cheek teeth $P\frac{1-}{0}$ $M\frac{3}{3}$, high crowned in all living and most fossil forms. Tooth pattern suggestive of that of zapodids, from which the family is probably descended. General tendency to elongate the hind foot and to fuse the 3 median metatarsals to form a cannon bone, as part of the leaping adaptation.

Family Spalacidae (mole rats)

Early Pliocene to Recent of Europe, Pleistocene to Recent of Western Asia and North Africa. Highly specialized burrowing rodents with short, powerful legs and no external tail. Eyelids permanently closed. Masseter muscle a short distance forward

on face. Cheek teeth reduced to $M\frac{3}{3}$, (or possibly $P\frac{1}{1}$ $M\frac{2}{2}$). Ancestry unknown.

Family Rhizomyidae (African mole rats, bamboo rats)

Oligocene of Europe, early Miocene to Recent of Asia, and Pleistocene to Recent of Africa. Myomorphous, with considerable forward extension of the masseter. Burrowing animals with powerful legs and short tails, superficially resembling pocket gophers (Geomyidad). Cheek teeth high crowned to ever-growing, consisting of $P\frac{1-0}{1-0}$ $M\frac{3}{3}$. The European Oligocene *Rhizospalax* has features suggesting that this family and the Spalacidae are related. Otherwise, relationships unknown.

Suborder Caviomorpha

Deep branch to masseter has shifted its origin forward onto the face, passing through the very large infraorbital foramen. Angle of jaw hystricognathous. Malleus and incus fused; usually a sacculus urethalis in male genital tract. Incisor enamel multiserial. Cheek teeth usually $P\frac{1}{1}$ $M\frac{3}{3}$, but occasionally the milk premolar is retained throughout life, the formula being $dP\frac{1}{1}$, $M\frac{3}{3}$. Early Oligocene to Recent of South America, Pleistocene to Recent of North America and West Indies.

Family Octodontidae (octodonts, degus)

Early Oligocene to Recent of South America, Pleistocene to Recent of the West Indies. Small for caviomorphs, generally somewhat ratlike in appearance. Scampering to fossorial in habits. Occur from sea level to elevations of more than 3,000 m (10,000 ft) in the southern half of South America. The teeth range from low crowned to ever-growing, the enamel of the grinding surface arranged either in the shape of a kidney or figure 8. The burrowing forms use the incisors in digging. The genus *Platypittamys* from the early Oligocene of Patagonia is very close to being a common ancestor of all the Caviomorpha.

Family Echimyidae (spiny rats)

Oligocene to Recent of South America. Pleistocene to Recent of West Indies and Central America. Ratlike in appearance. Usually with spiny fur, although there are a few exceptions. Cheek teeth rooted, with a pattern formed by transverse folds of enamel. In all but the earliest known members of the family, the milk or deciduous premolars are retained throughout life, and permanent premolars never make an appearance. Inhabit moist forested regions; climbing or scampering; one genus is burrowing.

Family Ctenomyidae (tuco-tucos)

Pliocene to Recent of South America. The single living genus inhabits all of the southern half of South America, from sea level to elevations over 4,000 m (13,000 ft). They are fossorial and presumably derived from octodontids. Body form and size are very similar to those of the North American pocket gophers, with powerful digging muscles in the forelimbs and long, powerful claws.

Family Abrocomidae (chinchilla rats or abrocomes)

The common name comes from the soft underfur and ratlike appearance. Pliocene to Recent of South America. The living species inhabit mountainous areas of Peru, Bolivia, Argentina, and Chile. Presumably evolved from octodontids. The cheek teeth grow throughout life.

Family Chinchillidae (chinchillas and viscachas)

Early Oligocene to Recent of South America. One living genus (*Lagostomus*) lives in lowlands of Argentina; the other two (*Lagidium* and *Chinchilla*) live at elevations of about 800 to 6,500 m in the southern half of the Andes. The fur of *Chinchilla* is very soft and dense—that of the other genera less so. All gregarious, but especially the lowland viscachas (*Lagostomus*), which occupy colonies resembling those of prairie dogs. The lowland viscachas are large, head and body length being 470 to 660 mm (18.5–26 in.); the mountain genera are 230 to 320 mm (9–12.6 in.; *Lagidium*) and 225 to 380 mm (8.9–15 in.; *Chinchilla*). Cheek teeth ever-growing, but details of pattern lost early in life.

Family Capromyidae (hutias, coypus)

Middle Pliocene to Recent of South America, Pleistocene to Recent of West Indies, introduced in southern United States and parts of Europe. Differ from the Chinchillidae, from which they are probably derived, in having high-crowned to ever-growing cheek teeth, but with the details of the pattern persistent. The hutias of the West Indies resemble large rats. The coypus of South America are considerably larger, looking rather like a large muskrat. The fur is excellent, and the flesh is widely eaten in South America.

Family Dasyproctidae (pacas and agoutis)

Early Oligocene to Recent of South America, Pleistocene to Recent of West Indies, Recent of Central America. Large rodents (head and body length 320 to 800 mm [12.6–31.5 in.]), with weight up to 10 kg (22 lb). Limbs modified for cursorial locomotion, with the lateral toes, especially on the hind foot, reduced in size. Flesh is very palatable. Pacas in moist forested areas from Mexico to southern Brazil; agoutis in the same regions (plus the Lesser Antilles), but not restricted to forested areas.

Family Dinomyidae (pacaranas)

Early Miocene to Recent of South America; Pleistocene of West Indies. There is only a single living genus inhabiting the lower elevations of the northern half of the Andes. The animal is among the largest of living rodents. A considerable number of fossil forms, once thought to represent a separate family (Heptaxodontidae) probably belong here.

†*Family Elasmodontomyidae*

Pleistocene to Recent of Puerto Rico and northern Lesser Antilles. These forms are all extinct, but survived until about the time the area was colonized by the Spaniards. Medium-sized ground-living rodents, with ever-growing cheek teeth formed of a series of enamel plates inclined at about 45° to the long axis of the jaws.

†*Family Eocardiidae*

Early Oligocene to middle Miocene of South America. Cheek teeth medium to high crowned. Size about that of a guinea pig.

Family Caviidae (guinea pigs, cavies, and maras)

Late Miocene to Recent of South America. Cheek teeth ever-growing, with a simplified crown pattern of alternating V's. Digits reduced to 4 on the front and 3 on the hind foot. Cavies with short legs, ears and tails; maras superficially resembling hares.

Family Hydrochoeridae (capybaras)

Early Pliocene to Recent of South America, Pleistocene to Recent of Central America, Pleistocene of West Indies and southern United States. Most members of this family are extinct, there being but a single living genus, with 1 species in eastern Panama and the other in South America east of the Andes and north of the Rio Paraná. Forest dwellers, capable of escape by running, but tend to retreat to water when closely pursued. Derived from Caviidae and have the same reduction of digits. Largest living rodents, head and body length reaching 1.2 m (3.9 ft); they may weigh over 45 kg (100 lb).

Family Erethizontidae (New World porcupines)

Early Oligocene to Recent of South America, Pleistocene to Recent of North America, recent of Central America. Large, slow-moving, heavy-bodied rodents, with some hairs modified into sharp, barbed spines that are easily detached when they make contact with an enemy. Cheek teeth rooted, with a simple pattern of reentrant folds, essentially unchanged since the Oligocene. One South American genus has a prehensile tail.

Suborder Phiomorpha

A group of families of African rodents the ancestry of which can be traced back to the early Oligocene of Egypt. Most of them are hystricomorphous and hystricognathous, and they are often considered very closely related to the Caviomorpha. Multiserial incisor enamel; malleus and incus fused and sacculus urethralis present in living forms. Cheek teeth $\frac{4}{4}$, consisting (in all but a few of the earliest types) of the last deciduous premolar, retained throughout life, and $M\frac{3}{3}$.

†*Family Phiomyidae*

Oligocene to Miocene of Africa. These rodents reached Africa when it was isolated from the rest of the world and differentiated to become highly diverse, including scampering, burrowing, and perhaps arboreal and leaping forms. In the Miocene other rodents reached Africa, and only a few lines of phiomyids were able to survive the resulting competition. Several Oligocene genera retained permanent premolars, although in 1, at least, they apparently never were functional.

Family Petromuridae (rock rats or dassie rats)

Pleistocene to Recent of southern South Africa. Ratlike in body form, the single species inhabits rocky hills, living in narrow crevices in rocks.

Family Thryonomyidae (cane rats)

Miocene to Recent of Africa and early Pliocene of India. Body form and habitat generally similar to a muskrat, inhabiting marshes and the borders of streams and lakes. There is only a single living genus, spread over Africa south of the Sahara. Head and body 350 to 610 mm.

Family Bathyergidae (blesmols or African mole rats)

Miocene to Recent of Africa. The most completely fossorial of all rodents, with short, powerful limbs and heavy claws. The incisors are highly procumbent, and in some forms are used in burrowing. In some genera the growing base of the upper incisors has shifted backward to a level behind the rear of the upper cheek teeth. Only slight penetration of in-

fraorbital foramen by masseter (probably secondary reduction); angle hystricognathous but peculiar. One genus (*Heterocephalus*) has the pelage reduced to scattered short hairs. External ears are greatly reduced; eyes are reduced and the eyelids usually kept closed. The number of cheek teeth reaches $\frac{6}{6}$; it is by no means clear which teeth are involved. These animals spend essentially all their lives in their burrows; some are colonial.

Families of uncertain relationships

The remaining 10 families of rodents are of completely uncertain relationships, and are best treated as individual families.

Family Hystricidae (Old World porcupines)

Pliocene to Recent of Asia, Africa, and Europe, Pleistocene to Recent of East Indies. Spined forms, resembling the New World porcupines in appearance, but less arboreal in habits; quills without barbs. The ease with which even a slight touch loosens the quills, leaving them inserted in the attacker, is the origin of the belief that these animals are capable of shooting their quills like arrows, as reported, for example, by Marco Polo. Hystricognathous and hystricomorphous; malleus and incus fused; incisor enamel multiserial; sacculus urethalis present; cheek teeth consist of $P\frac{1}{1}$, $M\frac{3}{3}$, all exhibiting a crown pattern broken up into numerous small cuspules. The origin and relationships of the group are not clear, but they may have originated in southern Asia.

Family Castoridae (beavers)

Early Oligocene to Recent of Europe and North America, late Oligocene to Recent of Asia. Sciuromorphous and sciurognathous rodents, with cheek teeth ($P\frac{(2-1)}{0}$, $M\frac{3}{3}$) progressively becoming high crowned and ever-growing. Restricted at present to a single genus (*Castor*), formerly widespread in Eurasia and North America, but greatly reduced as a result of very intensive trapping for the very fine, soft fur. Aquatic animals, with webbed feet and broad, flattened tail. Numerous fossils from the Tertiary do not seem to have been aquatic but rather to have been fossorial. In western Nebraska an early Miocene beaver seems to have constructed spiral burrows ("Devils' corkscrews").

†*Family Eutypomyidae*

Rodents from the Oligocene of North America sometimes (but probably erroneously) thought to have been related to the beavers, but with very complexly folded enamel on the cheek teeth, and with a peculiar foot structure of uncertain function (very slender inner digits and heavy outer ones).

Family Anomaluridae (scaly-tailed "squirrels")

Miocene to Recent of Africa. Sciurognathous but hystricomorphous rodents; arboreal, and most living forms with a membrane extending from front to hind legs to tail, used in gliding from one tree to another. A long cartilaginous support, derived from the ulna in the region of the elbow, supports the anterior end of the membrane. Head and body length about 60 to 430 mm (2.4–16.9 in.).

Family Ctenodactylidae (gundis)

Oligocene of Mongolia, Miocene of India, and Miocene to Recent of Africa. Hystricomorphous and sciurognathous rodents; malleus and incus fused; perhaps a sacculus urethalis; incisor enamel multiserial. Quite diverse in Oligocene of Mongolia, but the fossils do not suggest close relationship to any possible ancestors. Scamperers, with body form similar to that of a guinea pig; 4 toes on each foot. Head and body length 160 to 240 mm (6.3–9.4 in.).

Family Pedetidae (springhaas or Cape jumping hare)

Miocene to Recent of Africa. Hystricomorphous and sciurognathous; malleus and incus not fused; incisor enamel multiserial. The single living genus lives in eastern and southern Africa. The Cape jumping hare is a large rodent, with elongate hind limbs, jumping like a kangaroo. The cheek teeth ($P\frac{1}{1}$, $M\frac{3}{3}$) are ever-growing, with the pattern preserved only in completely unworn teeth. Head and body length about 350 to 430 mm (13.8–16.9 in.).

Family Gliridae (dormice)

Middle Eocene to Recent of Europe, Recent of Asia, Miocene to Recent of northern Africa. Sciuromorphous and sciurognathous; uniserial incisor enamel. Small arboreal rodents, similar in appearance to the smaller squirrels. Generally have partial hibernation. It has recently been demonstrated that they can be traced back to an ancestry among small European paramyids of early to middle Eocene; as a result, although they are similar to sciurids in being sciuromorphous, they are clearly of independent origin. Head and body length about 60 to 190 mm (2.4–7.5 in.).

Family Seleveniidae (jumping dormice)

Probably related to dormice; a single genus recently discovered in the deserts of Central Asia. Elongate hind legs and a long tail. Head and body length 72 to 96 mm (2.8–3.8 in.).

†*Family Pseudosciuridae*

European, middle Eocene to Oligocene. Hystricomorphous and sciurognathous; incisor enamel pauciserial. Cheek teeth low crowned. They can be derived from European early Eocene paramyids, and gave rise to the Theridomyidae. The gradual development of the hystricomorphous condition can be traced in this group.

†*Family Theridomyidae*

Abundant European late Eocene and Oligocene rodents, with low-crowned to ever-growing cheek teeth. Incisor enamel pauciserial or uniserial. They have had a central position in many theories of the origin and relationships of the various hystricomorphous groups (Caviomorpha, Phiomorpha, Hystricidae, Anomaluridae, Ctenodactylidae, and Pedetidae), but there is no evidence to show that they were actually related to any of these.

Critical appraisal. The rodents are one of the most clearly demarcated of all mammalian orders. No animals are known, either living or fossil, where there is question as to whether or not they belong to this order. Within the order, however, there is great disagreement as to the interrelationships of various families or groups of families. There is no question that the Caviomorpha, as listed above, are related, and there seems to be little question that the Phiomorpha are a natural group. There is disagreement as to whether the two suborders should be united with each other, or with the Hystricidae. If the three are united, the combination should be called the suborder Hystricomorpha (the oldest name for such a group). The Anomaluridae, Ctenodactylidae, Pedetidae, Pseudosciuridae, and Theridomyidae are included in the Hystricomorpha by some authors. The relationships of all five families are very uncertain (except that pseudosciurids clearly gave rise to theridomyids). Much uncertainty exists as to whether the families here included in the Myomorpha are a natural unit. There is considerable diversity within the group. Many authors unite the Muridae and Cricetidae into a single family; still others separate the microtines from the cricetids as a third family. The two families are recognized here largely as a matter of convenience—about 100 genera each of murids and cricetids are known; combining them makes an unwieldy family including over half the order. The microtines were quite obviously derived in late Pliocene times from cricetids; if they are recognized as a distinct family, it is the only family of either animals or plants known to have originated so recently.

Uncertain relationships

Currently, attempts are still being made to find satisfactory bases on which to subdivide the order. The incompleteness of knowledge of fossil rodents is a major handicap that will certainly be overcome in the future. The classification presented here is an attempt to give what seems to be a reasonable interpretation of the present knowledge of the subject. (A.E.W.)

Carnivora (cats, dogs, bears, skunks, seals, walruses)

The order Carnivora includes 10 families of living mammals: Canidae (dogs, wolves, jackals, and foxes), Ursidae (bears), Procyonidae (raccoons), Mustelidae (skunks, mink, weasels, badgers, and otters), Viverridae (civets and mongooses), Hyaenidae (hyenas), Felidae (cats), Otariidae (eared seals), Odobenidae (walrus), and Phocidae (earless seals). The term carnivore is frequently applied by mammalogists to members of this order and is employed in that sense in the present article. In a more general sense, a carnivore is any animal (or even, occasionally, a plant) that eats the flesh of other animals, as opposed to a "herbivore," which eats plants. Although the Carnivora are basically meat eaters, a substantial number, especially among bears and procyonids, feed extensively on vegetable material.

GENERAL FEATURES

Importance of carnivora. There is probably no other group of animals more familiar to man than mammals belonging to the order Carnivora. The more popular do-

mesticated pets of man, the dog and the cat, are both derived from wild members of this order. The majority of luxurious natural furs (ermine, mink, sable, otter) worn by women of fashion, as well as the furs of utility used by primitive man, come from members of the Carnivora. Many of the animals that attract the largest crowds at circuses and zoos are members of this order. Most of the large, dangerous carnivores are the objects of hunters, who wish to obtain a trophy grizzly bear, polar bear, or tiger. The man stranded in the wild fears the wolf, dhole, bear, tiger, leopard, or jaguar, virtually the only predators capable of injuring him. The stockman is concerned about possible depredations upon his herd by nature's large predators.

The carnivores, the meat eaters, form the apex of the pyramid of life, the food pyramid, and thus are basic to the existence of a "balance of nature" in a world unmolested by man. In today's world, man's world, this precarious balance was first upset by the extermination of many carnivores. Formerly considered undesirable because of their predation on game animals, carnivores are now recognized as necessary elements in natural systems. Far from depressing game numbers, carnivores improve the stability of game populations by keeping numbers within the carrying capacity of the food supply. As a result, individual animals are better fed and less subject to disease. Many of these predators dig dens and provide burrows in which other forms of wildlife can take refuge. Those carnivores best known for their burrow building are the badgers and the skunks. Digging results in the mixing of soils and the reduction of the runoff of water during rains.

Intelligence and training

Carnivores rank high on the scale of intelligence among mammals. The large size of the brain, compared to that of the animal, is an indication of their superior mental powers. For this reason, these animals are among the easiest to train for entertainment purposes, as pets, or as hunting companions. Their highly developed sense of smell supplements the sharper vision of man. Dogs are the most common carnivores trained for hunting, but the cheetah, caracal, and ferret have also been used to some extent. In China the otter is trained to drive fish under a large net, which is then dropped and pulled in. Carnivores, dependent for survival upon their ability to prey upon living animals in a variety of situations, have evolved a relatively high degree of learning ability (see LEARNING, ANIMAL).

Carnivorous mammals tend to establish territories, areas defended against others of the same species; herbivorous ones, which eat vegetation, are less apt to do so. Territories are often exclusive, defended by the residents against other animals of their own kind. Such areas may sometimes be marked by secretions produced by anal or scent glands.

There is a wide range of social patterns among carnivores. Some (bears, raccoon, red and gray foxes, genets, most cats, and most mustelids) are strictly solitary, except during the breeding season. Some remain paired throughout the year (black-backed jackal and lesser panda) or occasionally hunt in pairs (gray fox, crab-eating fox, and kinkajou). Other carnivores, such as the wolf, African hunting dog, dhole, and coatimundi, normally hunt in packs or bands. Still others form sedentary colonies during the breeding season (sea lions, fur seals, and elephant seals), during a somewhat larger part of the year (sea otters), or all year round (meerkats).

Form and function. The smallest living member of the Carnivora is the least weasel (*Mustela nivalis*), which weighs about two ounces. The largest terrestrial form is the Alaskan grizzly (*Ursus arctos*), weighing up to 780 kilograms (1700 pounds). The largest aquatic form is the elephant seal (*Mirounga leonina*), which may weigh 3,640 kilograms (four tons). Most carnivores weigh between four and eight kilograms (nine and 18 pounds).

Most members of the order are terrestrial. Some, such as the sea otter, river otter, and polar bear, spend most of their lives in water. The pinnipeds, or seals, are more aquatic than other members of the order. Aquatic or semiaquatic forms tend to have body specializations such as a streamlined body and webbed feet for this mode of life.

Dentition

Carnivores, like other mammals, have a number of different kinds of teeth: incisors in front, followed by canines, premolars, and molars in the rear. Most carnivores, especially those that feed exclusively on meat, have carnassial, or shearing, teeth that function in slicing meat and cutting tough sinews. The carnassials are usually formed by the fourth upper premolar and the first lower molar, working one against the other with a scissorlike action. Cats, hyenas, and weasels, all highly carnivorous, have well-developed carnassials; while the bear and procyonids, which tend to be omnivorous (eating both plants and animals), and the seals, which eat fish or marine invertebrates, have little or no modification of these teeth for shearing. The teeth behind the carnassials tend to be lost or reduced in size in highly carnivorous species. Most members of the order have six prominent incisors on both the upper and lower jaw, two canines on each jaw, six to eight premolars, and four molars above and four to six molars below. Incisors are adapted for nipping off flesh. The outer most incisors are usually larger than the inner ones. The strong canines are usually large, pointed, and adapted to aid in the stabbing of prey. The premolars always have sharply pointed cusps, and in some forms (*e.g.*, seals) all the cheek teeth (premolars and molars) have this shape. Except for the carnassials, molars tend to be flat teeth utilized for crushing. Terrestrial carnivores that depend largely on meat, such as weasels, cats, and hyenas, tend to have fewer teeth (30–34), the flat molars having been lost. Omnivorous carnivores, such as raccoon and bear, have more teeth (40–42). Seals have fewer teeth than terrestrial carnivores. In addition, seals exhibit little stability in the numbers of teeth; for example, a walrus may have from 18 to 24 teeth.

Several features of the skull are characteristic of the order Carnivora. The articulating surfaces (condyles) on the lower jaw are transverse, their axis at right angles to that of the head, forming a half-cylindrical hinge that allows the jaw to move only in a vertical plane but with considerable strength. The clavicles (collarbones) are either reduced or absent entirely and, if present, are usually embedded in muscles without articulation with other bones. This allows for a greater flexibility in the shoulder area and prevents breakage of the clavicles when the animal springs on its prey.

The brain is large in relation to the weight of the body and contains complex convolutions characteristic of highly intelligent animals. The stomach is simple, and a blind pouch (cecum) attached to the intestine is usually reduced or absent. Since animal tissues are in general simpler to digest than plant tissues, the carnivore's dependence on a diet with a high proportion of meat has led to less-complex compartmentalization of the stomach and a decrease in the length and folding (surface area) of the intestine. The teats are located on the abdomen along two primitive lines (milk ridges), a characteristic of mammals that lie down when nursing.

Distribution and abundance. Carnivores are found worldwide. Terrestrial forms are absent from most oceanic islands, though the coastlines are usually visited by seals (pinnipeds). Except for the dingo (which probably was introduced by aboriginal man), Australia has no native terrestrial members of the Carnivora. Man has taken his pets, as well as a number of wild species, to most islands. For example, a large population of the red fox now inhabits Australia, having been introduced there by fox hunters.

Since carnivores are large and depend on meat, there must be fewer carnivores in the environment than those animals that form their diet. The maintenance of established territories limits the number of predators to the carrying capacity of prey populations. In general, carnivores have a population density of approximately 0.4 per square kilometre (one per square mile). By comparison, omnivorous mammals average about eight per square kilometre (20 per square mile), and herbivorous rodents attain densities of up to 40,000 per square kilometre (100,000 per square mile) at peak population. Existing at relatively low densities, carnivores are vulnerable to prey, population fluctuations, habitat disturbance, and predation by man. In some cases the mobility and adaptability of carnivores has enabled species to shift ecological roles and survive the changes brought about by human activities; in other instances less-flexible species have become extinct.

World carnivore population

The world population of aquatic carnivores (pinnipeds) has been estimated to be between 13,000,000 and 27,000,000 animals. Estimates of the total numbers of terrestrial carnivores have not been made. The yearly sale of furs indicates a harvest of at least 6,000,000 pelts of wild carnivores; this is equalled only by the number of mink raised and harvested on fur farms (approximately 8,000,000 annually in the mid-1960s). There are probably around 50,000,000 to 60,000,000 terrestrial members of the Carnivora present today. Some species (many cats, pandas, and bear, some seals) are becoming quite rare and near extinction.

SURVEY OF CARNIVORE FAMILIES

Dogs and allies (family Canidae). *Natural history.* Canids are basically meat eaters, although some vegetable matter is taken. The gray or timber wolf (*Canis lupus*), the African hunting dog (*Lycaon pictus*), and the dhole, or wild dog of India (*Cuon alpinus*), are strictly carnivorous. The various foxes and jackals, coyotes, and the raccoon dog eat whatever food is abundant—small mammals, birds, insects, crustaceans, mollusks, fruits, or berries. The canids that are strictly carnivorous tend to hunt in packs; those that are omnivorous tend to be solitary in their hunting habits. Since the carnivorous forms depend primarily on one or a few prey species, they usually follow the moving herds of caribou or antelope, on which they feed, or move into areas where the prey species are more numerous. African hunting dogs are extremely social, always hunting in packs so intricately organized that some researchers doubt that an individual dog could survive alone. The varied diet of the omnivore reduces the necessity for organized attack on the prey species and for extensive movement.

Canids have the ability to endure a continuous chase pattern with exceptional stamina but are not capable of great bursts of speed. Their senses of smell and hearing are highly developed. Smell is used largely to track prey, and hearing to warn of impending danger. Smell is also used in association with the demarcation of territory, which tends to be outlined by frequent urination at established scent posts. Sight is less well developed, but movement is noted quickly. Canids are highly intelligent, can be trained easily, and form a basis for such sayings of man as "sly as a fox." From a behavioural standpoint wild canids are cunning or crafty, even vicious or treacherous by human standards, but usually cowardly or furtive unless running in a pack.

Reproductive behaviour of canids

Canids give birth in a den in the ground, in a hollow log or tree, in a hidden brushy area, among boulders, or in a crevice of rock. The African hunting dog often dens in old diggings of the aardvark. Usually one litter of from four to six young is produced each year after a gestation period of from 51 to 80 days, depending on the species. The Arctic fox, *Alopex lagopus,* may produce two litters in a season. Most breeding takes place late in the winter, the young being born in middle or late spring. Canids living in the northern regions breed a month or so later than those in the southern regions. Carnivorous animals tend to produce young soon after the peak in the prey reproduction, a time of abundant food availability. Thus the timing of the breeding season and the duration of the gestation period must be coordinated with the season of available food in order that the young be produced when the most food is available for their rapid growth. The eyes of the young usually open in about two weeks, and they nurse for from four to six weeks. Canids of the smaller species can begin production of their own young when only one year old, but the larger forms, such as the wolf, reach sexual maturity at two or three years of age.

Canids are basically adapted to running and do so on their toes (a mode of walking or running called digitigrade). They live in a variety of habitats but generally tend to be animals of the open or grassland areas where their prey species are more abundant. Only the rare bush dog (*Speothos venaticus*) confines itself to forested areas. The red fox (*Vulpes vulpes*) tends to be an animal of the forest edge, and the gray fox (*Urocyon cinereoargenteus*) an animal inhabiting wooded areas. Thus, in North America, where both forms exist, these foxes live in slightly different niches. Although basically terrestrial in habits, the gray fox is not averse to climbing trees. The raccoon dog (*Nyctereutes procyonoides*) often lives in tree hollows if the entrance is close to the ground. The family Canidae is worldwide, being absent only from New Zealand, Antarctica, and most oceanic islands. The Arctic fox is found farther north than any other strictly terrestrial mammal. Every major habitat has some type of canid, from the Arctic tundra, through the desert and grassland, to the tropical forest.

Figure 33: Representative carnivores: Procyonidae, Ursidae, Canidae.
Drawing by R. Keane. Indian dhole based on Zoological Society of London photograph.

Canid communication

Canids communicate with a variety of sounds. The vocal repertoire, most highly developed in social species, includes howls, yelps, snarls, barks, and growls. These sounds are frequently associated with specialized visual signals involving movements of the ears and tail, raising of certain areas of the fur, and baring of the teeth. Within the social group or pack there is a complex dominance hierarchy,

involving age levels, pair bonds, physical condition, and sexual state. Vocal and visual signals serve to minimize aggressive interactions, such as quarrels over food, that might prove injurious to the group as a whole and to the individual members. In solitary species vocalizations serve to advertise the territory, to ward off aggressors, and to communicate with the mate and young.

Importance to man. The domestic dog (*Canis familiaris*) is undoubtedly the canid of the greatest importance economically. Numerous humans are actually employed in raising, selling, doctoring, grooming, training, or providing and manufacturing food for "man's best friend." Dogs probably were the first wild animals to be domesticated; they have been found associated with Neolithic sites dating back some 8,000 years.

Some varieties of canids are important to the fur trade. At one time, a mutant form of the red fox, called the "silver fox," formed a significant part of the fur-farming industry. The raccoon dog is still raised in some regions of Russia. The more important canids whose fur is utilized are the raccoon dog, red fox, gray fox, Arctic fox, and timber wolf. Coyotes, kit and swift foxes (*Vulpes macrotis* and *V. velox*), jackals (*Canis aureus, C. adustus, C. mesomelas*), the Corsac fox (*Vulpes corsac*), the hoary fox (*Vulpes cana*), the dhole, the South African silver fox (*Vulpes chama*), the Cape fox (*Octocyon megalotis*), the maned wolf (*Chrysocyon brachyurus*), the crab-eating fox (*Cerdocyon thous*), and South American foxes (*Dusicyon* species) are occasionally used by the fur trade. Other canids, especially the red fox, are hunted primarily for sport. Some hunters call or lure foxes by using an imitation of the sound of an injured rabbit to attract the attention of the fox.

Canids also are basically important as a natural control over rodent populations. Livestock is occasionally endangered when not properly protected from the forays of wild canids. Individual foxes learn where an easy meal is located—for example, where a farmer's chickens are not properly housed. In many cases all individuals of the species are condemned because of the damaging activity of a few. Proper selective control of those individuals actually doing the damage is the only sane conservation practice. Some species also form important natural reservoirs for disease-causing organisms, especially the rabies virus. Not many canids are utilized by man for food, but the American Indian once regarded dog meat as a delicacy to be eaten on special occasions. Dog meat is also consumed in eastern Asia.

Form and function. Canids have unspecialized incisor teeth and large fanglike canines used to kill prey by slashing. The premolars are narrow and sharp and the carnassials well developed; the molars form broad surfaces that can crush substantial bones. Most canids have the basic dental formula of terrestrial carnivores, with a total of 42 teeth.

Distinguishing physical features of canids

The possession of a long face or muzzle is characteristic of wild canids. All have a relatively long and obviously bushy tail. The ears are pointed, held erect, and often quite large in desert species. As well as functioning for sound detection, these large ears are believed to act as heat regulators, allowing a greater amount of heat to be dissipated in hot climates. Arctic foxes tend to have small ears, providing less loss of heat in a region where heat conservation is important to survival. Most canids have relatively long legs (especially long in the maned wolf, *Chrysocyon brachyurus,* of South America). The long legs and digitigrade gait are special adaptations for ease of running. Canids have four well-developed toes plus a dew claw (reduced hind toe) on the front foot (except in the African hunting dog, which lacks the dew claw) and four toes on the rear foot. Each toe is capped by a blunt, nonretractile claw (*i.e.,* with no sheath into which it can be withdrawn). The short claws are not adapted for use as a weapon but do aid the animal during the digging of a den or during pursuit of small prey animals in their burrows. Scent glands are often present at the base of the tail. Most canids have a uniform coloration, although there are some contrasting colours on the gray fox, a raccoonlike mask on the raccoon dog, a blotching of black, yellow, and white colours on the African hunting dog, and a lighter-coloured belly in most canids.

Bears (family Ursidae). *Natural history.* Members of the Ursidae, except for the carnivorous polar bear (*Ursus maritimus*), are omnivorous, consuming many items that seem small for an animal the size of a bear. Ants, bees, seeds of trees, roots of the skunk cabbage, nuts, berries, insect larvae such as grubs, and even the dainty dog-toothed violet are eaten. Many bears relish honey, and the sun bear (*Helarctos malayanus*) is sometimes called the "honey bear" because of its preference for this food. Meat items taken by bears include rodents, fish, deer, pigs, and lambs. Grizzlies and Alaskan brown bears (North American subspecies of the widespread *Ursus arctos*) are known for their skillful fishing abilities during the spawning runs of salmon. The polar bear feeds almost exclusively on seals and is the most carnivorous of all bears, but little vegetation grows within its range, so the carnivorous habit is dictated by the Arctic environment. The sloth bear (*Melursus ursinus*) delights especially in raiding and destroying termite nests, sucking up termites and larvae with its funnellike lips. Bamboo shoots form the major food of the giant panda (*Ailuropoda melanoleuca*), which has a special bone formation of the forefoot that functions as a sixth digit, opposable to the other five and thus useful in handling bamboo.

Moving slowly about, bears seem to be sluggish and oblivious to much that is going on around them, but once they are disturbed their reactions may be violent and highly unpredictable. Although clumsy in appearance, a grizzly can move surprisingly fast, even through dense cover that would seriously impede a man or a horse. Their senses of sight and hearing are poorly developed, and most hunting is done by the sense of smell. Thus the smell of bacon kept in camp is an invitation to a bear in search of food. Bears, like many of their canid relatives, are solitary, except during the mating season.

Bears tend to congregate during the mating season and then pair off and mate in seclusion. Males play no role in raising the young, leaving the female soon after mating. The gestation period may vary, the fertilized egg remaining dormant in the uterus (delayed implantation), insuring the birth of young when food is abundant. Ursids breed only once a year. With a breeding season usually in late spring or early summer and delayed implantation, most young are born in January or February when the female is in the winter den. Newborn grizzlies weigh about one pound and are about nine inches long from the tip of the nose to the tip of the short tail. The Himalayan brown bear (a race of *U. arctos*) have their young later (in April and May) than the North American populations, but the polar bear has the greatest variation of any bear population in the dates when young are born (January to April). Twins are most common in bears, but up to five young may be produced. The cubs nurse for about two months and stay with the female until the next breeding (about a year and a half after birth). Most young, however, can get along on their own when about six months old. Bears reach breeding condition at three and one-half to four years of age, males usually a few months later than females. Litters are produced every second year after the initial litter.

Winter sleep of bears

Most bears eat large amounts of food before entering a den for a period of deep sleep during the winter. The polar bear digs a den in the snow. Grizzlies build large mounds of dirt in front of their dens. Bears are not true hibernators, since they lack the physiological characteristics (lower heart rate, body temperatures, breathing rate, and blood pressure) exhibited by those animals that do hibernate. A true hibernator is slow to be awakened from its deep sleep, and those who believe bears hibernate need only kick a sleeping bear to become convinced to the contrary. Bears usually are quiet, but they do growl at times when feeding or when being challenged by another bear.

Ursids do not roam over great distances even though they are rather large carnivores. Black bears (*Ursus americanus*) tend to stay within an area of about 36 square kilometres (14 square miles), grizzlies within an area 16 kilometres (10 miles) in diameter, or about 200 square kilometres (80 square miles). A grizzly marks the boundary of its

territory each spring by rubbing trees, scratching bark, or even biting large pieces from the trunks of trees. All bears, except the grizzly, Eurasian brown, and probably the polar bear, climb trees. Bears inhabit forested areas and areas that have a minimum of disturbance by man. At one time the grizzly was an animal of the plains and was one of the mammals reported by Lewis and Clark in their journey through eastern Montana in 1804. Polar bears have been noted in the open sea 65 kilometres (40 miles) from the nearest shore and on ice 320 kilometres (200 miles) from the nearest land.

Ursids are largely animals of north temperate regions, being found farther north than any other mammal (only the Arctic fox is found as far north on land). Most of the southern continents, Central and South America, Africa, and Australia, lack bears. The bear that formerly occurred in the Atlas Mountains of Morocco (*Ursus crowtheri*) became extinct in the early 19th century. The spectacled bear (*Tremarctos ornatus*) of the Andes is the southernmost form.

Importance to man. If taken when young, the grizzly can be tamed quite easily and is not uncommon in circus acts. Unfortunately, man has come to picture the bear as being quite tame and harmless, with the result that the bear is viewed without the respect that this potentially dangerous creature deserves. The grizzly is the most dangerous of the bears to man, of the most interest economically because of the damage that it can do to livestock, and of the most interest to the big-game hunter as a prized trophy. Some ursids, such as the Asiatic black bear (*Selenarctos thibetanus*), destroy fruits. At times the North American black bear does considerable damage to fruit crops and to corn fields when the corn is in the milk stage, pulling the stalks into a pile from as far as the bear can reach.

Use of bear pelts

The pelts of bears have been used for a number of purposes. Perhaps most popular has been the bearskin rug. Skins also have been used for lap rugs or sledge rugs, hats for the English Guard regiments, trimmings of coats, and for muffs. Skins of the rare giant panda commanded a high price in the early 1900s, but this animal apparently is close to extinction today. Black bears are prized as a food source in China, as is the flesh of the polar bear in the far north. The liver of the polar bear, however, is highly poisonous, due to high levels of vitamin A. The teeth and claws of bears have been favourite ornaments with the Indians and Eskimos for years, and the fat furnishes the "bear grease" of commerce.

Form and function. The teeth of the omnivorous bears are unspecialized. The first three premolars are usually either missing or extremely small. The carnassials are poorly developed, and the molars have broad, flat crowns. Except for variability as to the presence of premolars, the ursid dental formula is that of the Carnivora generally. The sloth bear lacks one pair of upper incisors. The jaw of the bear is controlled at the hinge by a powerful set of muscles.

Bears have an elongate skull that is especially heavy in the back portion. These plantigrade animals (plantigrades walk on the sole and heel of the foot) are powerful in build and have relatively short, massive legs with five toes on each foot. The toes end in enlarged, nonretractile claws that are especially well developed in the sloth bear and to some extent in the grizzly. The claws on the front feet are usually better developed than those on the rear and are especially adapted for digging out marmots or other small rodents. Bears, however, seldom use the claws to construct burrows. They generally have naked soles, but those of the polar bear are covered with hair, enabling the animal to walk on ice with a firm footing. In swimming, the polar bear uses only its front limbs, an aquatic adaptation found in no other four-legged mammal. Bears lack a clavicle but have a baculum (penis bone). Their lips, which are not attached to the gums, are protrusible and mobile. Ursids have a short (7 to 13 centimetres; 2.8 to 5.1 inches), stubby tail and are the largest living terrestrial members of the Carnivora. The Alaskan grizzly may weigh as much as 780 kilograms (1,700 pounds), and the smallest bear, the sun bear, weighs approximately 27 kilograms (60 pounds). In most species the two sexes are about the same size, but the male tends to be larger in the grizzly and polar bear. Bears of the genus *Ursus* tend to be of a uniform colour, ranging from white to brown, blue gray, and black. Unlike the majority of carnivores, ursids are often black or mostly black. The North American black bear occurs in a number of colour variants or phases; in addition to the typical black phase, there is a tan-brown phase (called the cinnamon bear) and a bluish-black phase (called the glacier bear). The spectacled bear and the several specialized Asian bears are black with white or tan markings. The giant panda is strikingly black and white, and the remaining genera largely black, with areas of white or orange on the chest, neck, or face. The fur is coarse, long, and shaggy in most northern forms.

Bear claws

Raccoons and allies (family Procyonidae). *Natural history.* The family Procyonidae includes raccoons, coatis or coatimundis, olingos, and the ringtailed cat, kinkajou, and lesser panda. Procyonids, like bears, are omnivorous, eating numerous types of insects, crayfish, crabs, fishes, amphibians, reptiles, birds, small mammals, and a variety of fruits, nuts, roots, and young plants. A characteristic of most omnivorous animals is that they take whatever foods are available, varying their food habits with the season, the locality, and the abundance or population levels of the food items from one year to the next. The ringtailed cat (*Bassariscus astutus*) tends to be more carnivorous than the raccoon (*Procyon lotor*). The lesser panda (*Ailurus fulgens*) is the most vegetarian of the group.

The various senses of procyonids do not seem to be especially well developed, but the raccoons and lesser panda appear to be above average in intelligence and are often described as being cunning. Raccoons are well known for their insatiable curiosity and ability to use their "hands" in performing feats such as opening doors and getting into mischief when kept as pets. This curiosity of raccoons is well known by trappers, who have used bright objects placed on the treadle of a trap to attract them. The sense of touch probably is of the greatest importance to the raccoon in its food-gathering activities. Most procyonids, except perhaps the coatis (*Nasua* species), are more active in the twilight and evening hours than in the daylight. Procyonids tend to be solitary, although families often move and feed as a group. Coatis travel in bands, some individuals moving through the trees as others follow on the ground. Olingos (*Bassaricyon* species) also move about in small bands. All procyonids are arboreal and move around in trees with agility. On the ground, the raccoon resembles a small bear as it ambles along.

Procyonid breeding habits

Procyonids breed in late winter or early spring. During copulation, the female raccoon makes sharp rattling cries. After a gestation period of about two months (for the raccoons 54 to 66 days, for lesser panda 90 days), two to six young are produced. One litter a year is usual. Young raccoons "twitter" like young birds when disturbed in the nest, and the young of other procyonids also produce high-pitched calls. Most adult procyonids produce a variety of snarls, growls, whines, screams, and barks. Most of these calls have little carrying power. Young raccoons are dependent on the female for the first 10 weeks but may nurse until approximately 20 weeks of age (ringtails to about four months) and may stay in the family group into winter. Being mainly arboreal, young procyonids are born in tree dens. Raccoons use old buildings or dens in the ground if tree dens are scarce. Ringtails use crevices in rocks.

Except for the lesser panda, which is found in the southeastern Himalayas of Asia at elevations from 1,980 to 3,650 metres (6,500 to 12,000 feet), procyonids are found naturally only in the New World. They are largely mammals of the lower elevations of temperate and tropical regions, in areas well supplied with water and trees. Raccoons have been introduced successfully into many parts of Europe (Germany, White Russia, the Ukraine) and Asia (Lake Balkhash, Siberia).

Importance to man. The raccoon is the only procyonid of major economic significance. Raccoon hunting has been a sport of substantial importance in the United States, and in some parts of the United States many people own dogs trained to hunt raccoons. The coatimundi also is hunted with dogs and its flesh is also eaten. Meat of the raccoon is

Figure 34: Representative carnivores: Mustelidae.
Drawing by R. Keane, striped skunk based on E.P. Walker, *Mammals of the World*

in more demand as food than that of any other carnivore. The meat is roasted, fried, stewed, barbecued, fricasseed, and made into patties. The "coonskin" cap has become part of American legend. The fur of the raccoon is one of the staple items of the fur trade in the United States today, as it has been over many of the past 100 years. Also used are the furs of the ringtailed cat, kinkajou (*Potos flavus*), and the lesser panda.

Raccoons at times do damage to fields of corn and to abandoned buildings, which they frequently inhabit when natural dens are scarce. In certain regions, raccoons become a problem to nesting waterfowl, especially wood ducks and goldeneye, which, like the raccoons, raise their young in hollow trees.

Most procyonids make interesting pets. Raccoons, kinkajous, and coatis are frequently sold as house pets, but their inquisitive nature and climbing ability make them troublesome if allowed to run loose indoors.

Form and function. The unspecialized teeth of procyonids are adapted for an omnivorous diet. The elongate canines are oblong in cross section, and the premolars are small, narrow, and pointed. As in bears, the carnassials are poorly developed and the molars are broad. Procyonids have the basic dental formula of the Carnivora, except that there is one less lower molar.

Procyonids are plantigrade or semiplantigrade, with legs of moderate length and five flexible toes with nonretractile or (in the ringtail cat and lesser panda) semiretractile claws. The tail is well developed (20 to 70 centimetres [7.9 to 27.6 inches] long), bushy, and in all forms except the kinkajou ringed by light and dark bands. In the kinkajou, it is prehensile, gripping a branch like a fifth limb. The anal scent glands of the kinkajou and lesser panda produce a musky odour when the animal becomes excited. The snout is extremely flexible in the coati and somewhat movable in other procyonids. The members of this family are medium in size, ranging from 0.8 to 22 kilograms (1.75 to 48.4 pounds) in weight (the record weight of a raccoon is 30.2 kilograms [66 pounds, 6 ounces]). There is no difference in size between males and females. In coloration the procyonids range from gray or brown to the rich, reddish brown of the lesser panda.

Mustelids (family Mustelidae). *Natural history.* The family Mustelidae contains a variety of animals unmatched by any other family in the Carnivora except the civets (Viverridae). The family includes the weasels, ferrets, mink, marten, fisher, skunks, wolverine, otters, badgers, and a number of less well-known animals, a total of about 70 species in 25 genera. The weasels, mink, and polecats (*Mustela* species) are fierce predators, feeding exclusively on small mammals and birds, hunting and trailing their prey with a keen sense of smell. At times, bird eggs, salamanders, snakes, and insects are taken. The smallest mustelid, the least weasel (*M. nivalis*), consumes a third to half its body weight per day, killing the prey by biting at the base of the skull. Weasels often store food in underground caches. The Asiatic polecat (*M. eversmanni*) and the North American black-footed ferret (*M. nigripes*) feed almost exclusively on the animals whose colonies they inhabit, the polecat on marmots and ground squirrels, the ferret on prairie dogs. Both of these animals occasionally feed on insects. Mink (*M. vison* and *M. lutreola*) feed largely on aquatic animals (muskrats, crayfish, mollusks, and fish) as well as on organisms inhabiting the banks of bodies of water.

Feeding habits of mustelids

The fisher (*Martes pennanti*) feeds mainly on mammals, but a few nuts, birds and eggs, fish, and seeds are taken. This animal is noted for its ability to kill and eat porcupines. Small terrestrial mammals make up over 90 percent of the food of the American marten (*M. americana*). The Eurasian pine marten (*M. martes*) and the stone or beech marten (*M. foina*) feed largely on small mammals but in the autumn may turn to wild berries and fruit. The yellow-throated marten (*M. flavigula*) of Asia is one of the largest martens and feeds on the young of larger mammals such as musk deer, wild boars, roe deer, spotted deer, and raccoon dogs, as well as on squirrels, rabbits, and the smaller rodents. These large mustelids also take a variety of other food items: mollusks, grasshoppers, spawning fish, birds and their eggs, cedar nuts, grapes, and berries.

Badgers are quite variable in their diet. About 50 percent of the diet of the American badger (*Taxidea taxus*) is composed of ground squirrels, which are captured in their burrows. Badgers can dig with remarkable speed and can overtake the rodent when the latter has taken refuge in a blind tunnel. The remainder of their food is made up of small rodents, rabbits, birds and their eggs, snakes, turtle eggs, and insects. Insects, in fact, form a staple food of the young badger. The Eurasian badger (*Meles meles*) and the ferret badgers (*Melogale* species) are more omnivorous than the American badger and prefer insects (especially bees) and their larvae (grubs). Earthworms, mollusks, crustaceans, frogs, lizards, birds, eggs, as well as vegetable matter, such as berries, nuts, grains, fruits, bulbs, and green vegetation, are also taken. Ratels or honey badgers (*Mellivora capensis*) eat small mammals, lizards and snakes, insects, fruit, and especially honey. An interesting association exists between the African honey guide (a piciform bird) and the honey badger. When the bird finds honey it gives a special call, which attracts the badger. The latter breaks open the hive with its long, sharp claws, eats the honey, and leaves the wax and bee larvae for the bird. If the bird does not succeed initially in attracting a honey badger, it seeks one out and, using the "honey" call, which the badger recognizes, leads it to the bee tree.

Skunks (*Mephitis, Spilogale, Conepatus*) are omnivorous mustelids, with small mammals forming an important part of the diet. Skunks may be becoming scarce in some parts of North America due to poisons gradually accumulated through extensive feeding on insects poisoned in agricultural control programs.

Otters feed largely on the invertebrates and vertebrates (especially fish) found in their aquatic environment. The oriental small-clawed otter (*Aonyx cinerea*) and the clawless otter (*Aonyx capensis*) feed to a greater extent on invertebrates (clams, snails, crabs) than does the river otter (*Lutra* species). *Lutra canadensis* at times takes large numbers of crayfish. The African small-clawed otter (*Aonyx* species) is believed to feed on small mammals, the eggs of birds, and amphibians more than on fish. The sea otter (*Enhydra lutris*) is perhaps known best for its habit of breaking open sea urchins and clams on a rock held on its chest while it floats on its back. Seaweed, cuttlefish, and small fishes also are eaten.

Sharp senses of mustelids

Smell apparently is the most important sense to mustelids hunting on land. Black-footed ferrets have been noted to stop repeatedly and sniff the air while hunting. Hearing is also well developed and seems to be utilized as a means of detecting danger. Sight is less developed and, in the ferret at least, of little importance beyond about 90 metres (300 feet). Of most importance to otters, living in an aquatic environment, is an acute sense of touch, through their very sensitive whiskers, which they use as an aid to guide them through the water. Most mustelids are silent, seldom making more than a squeak, whistle, or bark. Many will snarl or growl when annoyed. The giant otter (*Pteronura brasiliensis*) of South America is perhaps the most vocal, with its high-pitched whistle. Yellow-throated martens give a harsh cry when excited and often chuckle in a low tone.

Almost all mustelids are active both day and night, although most of their activity is nocturnal. Only the Old World badgers (*Meles meles*), ferret badgers (*Melogale* species), spotted skunks (*Spilogale* species), and hog-nosed skunks (*Conepatus* species) seem to be almost strictly nocturnal. The giant otter and sea otter seem to be more diurnal than other mustelids.

Except when travelling with young in a family group, most adult mustelids are solitary in habits. Sea otters seem to be more or less gregarious, as are Old World badgers. Badgers build a labyrinth of underground passages that some call "badger cities" because of the extent of the burrows and number of badgers that inhabit them. Female skunks (*Mephitis* species) often den together in large groups during the winter. Grisons (*Galictis* species) and yellow-throated martens often travel in groups of five or six. Tayras (*Eira barbara*) and ratels tend to travel in pairs.

Since a great variation exists in the habits of mustelids, a great diversity would be expected in the habitats in which they live. Most mustelids, however, are terrestrial, living in forested or brushy areas. Many species can survive in a variety of habitats, from forest to desert. Some, like the marten and fisher, are strongly arboreal. Others, like the otter, are largely aquatic. The New World skunks and the North African spotted weasel (*Poecilictis libyca*) tend to inhabit areas farmed by man. The ferrets, American badger, and Eurasian polecats live mainly in grassland or semi-arid areas. Wolverines live in the more northern areas of taiga and forested tundras.

The locomotion of mustelids also varies. Most small mustelids scamper across the ground, making intermittent bounds as they move along. The larger forms sometimes lumber slowly. During their travels, mustelids tend to stop, sit up on their haunches, and look over the area. Some are extremely agile in trees; others are excellent swimmers.

Delayed implantation is perhaps more characteristic of the mustelids than any other group of the Carnivora. Members of the genus *Mustela* have gestation periods (determined from the date of fertilization) ranging from as much as 220–337 days (long-tailed weasel, *M. longicauda*) to as little as 36–42 days (ferrets). In the genus *Martes* the period is highly variable, between 220 and 297 days. The gestation period of badgers (*Taxidea, Mellivora, Meles*) ranges from six to eight months and that of otter from eight months to a little more than a year. Skunks (*Mephitis* species) do not have delayed implantation and apparently have the least variation in the period of gestation (62 to 72 days). Mink (*Mustela vison*) usually produce young in 45 to 50 days, with extremes from 38 to 76 days. On mink ranches, the later in the year that mink are bred, the shorter the gestation period.

Mustelid reproduction

The breeding season usually is in the late winter or early spring (mink, skunks, polecats, otters) or in the summer (weasels, marten, wolverine, sables, European and American badgers). Some mustelids breed at almost any time of the year (least weasel, river and sea otters). Those with exceptionally long gestation periods breed soon after a litter is born or in the following year. Some forms have two litters a year (striped skunk, least weasel, ratel), but in most only one litter is produced. Average litter size varies from one young in the sea otter to between eight and 12 young (up to 18) in the Asiatic polecat. Most mustelids have between three and five young in a litter. The young of mustelids are born in ground dens, in rock crevices, under the roots of trees, under haystacks or buildings, or in hollow trees (the pine and American martens). The young of most species are weaned when between six and 10 weeks of age, but young river otters nurse for about four months. Wolverine young are allowed to remain with the female for two years before establishing their own territories. In most species, however, the family disperses near the end of the summer or early fall. Mustelids are found worldwide, except for most oceanic islands, Australia, and Madagascar. Introductions have been made on some of the larger islands, such as New Zealand. Mustelids, like bears, generally are more abundant in the more northern continents.

Importance to man. Of all mammalian families, the Mustelidae contains the greatest variety of valuable mammals utilized by the fur trade. Fur coats that command the highest prices are usually those made from these luxuriant furbearers, especially mink, ermine (short-tailed weasel), and sable (a name applied by the fur trade to several species of *Martes*, especially the Eurasian *M. zibellina* but also the American *M. americana*). Excellent skins are produced by the marten, fisher, skunk, and otter. In fact, the durability of all furs, including those from other mammalian orders, is based on the river otter, which has been given the top rank of 100. Pelts of the ermine and sea otter have been the furs of royalty for hundreds of years. More than $100,000,000 worth of ranch mink skins alone are produced yearly, and some breeds (like the Kojah mink) brought $2,700 per skin in the late 1960s. During the 18th and 19th centuries a collar made from the sea otter was regarded by some as the highest of status symbols, equivalent to owning a Rolls Royce or private yacht today. In 1968, at the first sale of sea-otter skins in 55 years, the better-quality skins brought $2,300 apiece.

The pelt of the wolverine is prized highly by the Eskimos and others in Arctic areas because, when used for the lining of a parka, it can be cleared of frost from breath by a sweep of the hand. Moisture does not freeze to wolverine hair as it does to other furs. Badger hair has been utilized in the past to manufacture shaving brushes. Hair from the tails of many species is in high demand for paint brushes. Among the Chinese, for example, the tail of the kolinsky or China mink (*Mustela sibirica*) is used for making delicate paint and artists' brushes and is in more demand than is the rest of the pelt. The tails are removed from the skins and sold by the pound. Hairs from the tail of the sable also make excellent brushes, because the taper of the individual hairs causes the brush to form a sharp point when wet.

Importance in the food chain

Being largely carnivorous, the mustelids form an important link in the biological food chain. Rodents are kept at a reasonable level by this natural control. The spotted skunk, ferret badger, long-tailed weasel, Patagonian weasel, zorille (*Ictonyx striatus*), and sometimes the striped skunk (*Mephitis mephitis*) have been encouraged to live in or near the habitations of man because of their ability to keep the rodent and pest insect populations under control. Systematic destruction of these valuable predators can be a costly mistake to farmers.

Being carnivorous, mustelids sometimes become pests, especially around poultry—particularly when the poultry farmer is lax in his sanitation. Weasels, marbled polecats, and striped skunks are the common offenders. Considerable exaggeration of the prowess and deliberate maliciousness of the wolverine exists in literature. The behaviour of this animal has led many trappers to regard it as a

true "demon of the north." A wolverine travels a trapline because it learns that a ready source of food is being held captive. In many cases the wolverine will follow the trapline back to the trapper's cabin and ransack the area in its search for food. The largest of the mustelids (around 11.5 kilograms, or 25 pounds), this animal can do extensive damage.

Those mustelids that are proficient diggers (*e.g.*, badgers) sometimes become a hazard to horses (and riders), which stumble when stepping into a burrow. Other mustelids, such as the North American skunk, tend to be one of the more common wild mammals that serve as a reservoir for rabies. Meat of the Malayan stink badger (*Mydaus javanensis*), and sometimes the skunk (*Mephitis mephitis*), is eaten in some areas of the world. The obnoxious scent glands of mustelids discourage man from eating most of these animals, however. On the other hand, the scent from these glands was used in the past as a base for perfumes. Grisons and the ferret (*Mustela putorius*) have been trained by man to enter the burrows of other animals and drive them out; the grison to flush chinchillas, and the ferret, rabbits and rats. In China Oriental clawed otter and river otter are trained to catch fish or to chase them under nets which are then dropped, securing the catch. In some areas the bones or various parts of the tayra, African striped weasel, Malayan stink badger, hog-nosed skunks, and the African small-clawed otter are believed to possess medicinal value.

Form and function. Being highly carnivorous, mustelids have well-developed carnassials and a reduced number of premolar and molar teeth, the total number of teeth being between 30 and 38 (average, 34). With such a reduction in tooth number, the facial area of these animals is shortened. In the wolverine and American badger the bone of the lower jaw has a projection, the postglenoid process, that curves over the jaw articulation (glenoid fossa), resulting in a condition in which the mandible can be locked in place.

Mustelids are either digitigrade or plantigrade, and they have five toes on each foot. Most mustelids have short legs and many tend to have an elongate, slender body. They are quiet, agile, and graceful in their movements. There is a great variation in the tails of mustelids: flattened and elongate in the otter; stubby in the stink badgers; short in some of the weasels and badgers, long and thin in other weasels; long and bushy in marten; and especially elongate, with long hairs, in the skunks. The ears are small and rounded. Colours are usually brown or black. Some weasels change colour, becoming white in the winter, thus protecting the animal or, perhaps more probably, hiding it from its prey and making capture easier. Such white weasels are called ermine in the fur trade. Most mustelids have well-developed anal scent glands. The skunks, zorille, and the marbled polecat (*Vormela peregusna*), and to some extent the stink badger and ratel, can forcibly eject the vile-smelling material as a spray or fluid. All mustelids that possess powerful, controllable scent glands (except the stink badger) are marked in obvious contrasting colours, usually black and white. Such a striking colour combination may serve as a warning to potential predators, minimizing the likelihood that the animal will be attacked. After a single encounter with an adult mustelid, a predator avoids all animals so marked, including the less formidable young of the mustelid.

Repellent scent of mustelids

The smallest member of the Carnivora, the least weasel, belongs to the family Mustelidae and weighs 30 to 70 grams (one to 2.5 ounces). The largest mustelid is the sea otter, which may weigh 41 kilograms (90 pounds). In most mustelids the males are larger than the females.

Civets and allies (family Viverridae). *Natural history.* Viverrids are more numerous than the mustelids in terms of living genera (about 36) and species (about 75).

They are largely omnivorous in food habits, eating a variety of small mammals, birds, reptiles, eggs of birds and reptiles, amphibians, fishes, crustaceans, insects and their grubs, and earthworms, as well as vegetation such as fruits, nuts, bulbs or roots, and other plant material. A few, such as the palm civets (*Nandinia, Arctogalidia, Paradoxurus, Macrogalidia*), tend to be mostly vegetarian but at times take small mammals, birds, and insects. The binturong (*Arctictis binturong*), the largest member of the family, feeds mainly on fruit, although carrion is sometimes eaten. Although the suricates or slender-tailed meerkats (*Suricata suricatta*) tend toward an omnivorous diet, bulbous roots constitute most of their food. Approximately half of the genera of viverrids are composed of species that tend to be more carnivorous than herbivorous; the remaining genera are truly omnivorous. Some species tend to feed on one type of food: the ruddy mongoose (*Herpestes smithi*) on large snails, the Indian mongoose (*H. edwardsi*) on carrion remaining from the feasts of the large predators, the water mongoose (*Atilax paludinosus*) on crocodile eggs, the striped-necked mongoose (*H. vitticollis*) and the Congo water civet (*Osbornictis piscivora*) on fish. The banded palm civet (*Hemigalus derbyanus*) and Owston's civet are sometimes known to eat significant amounts of earthworms.

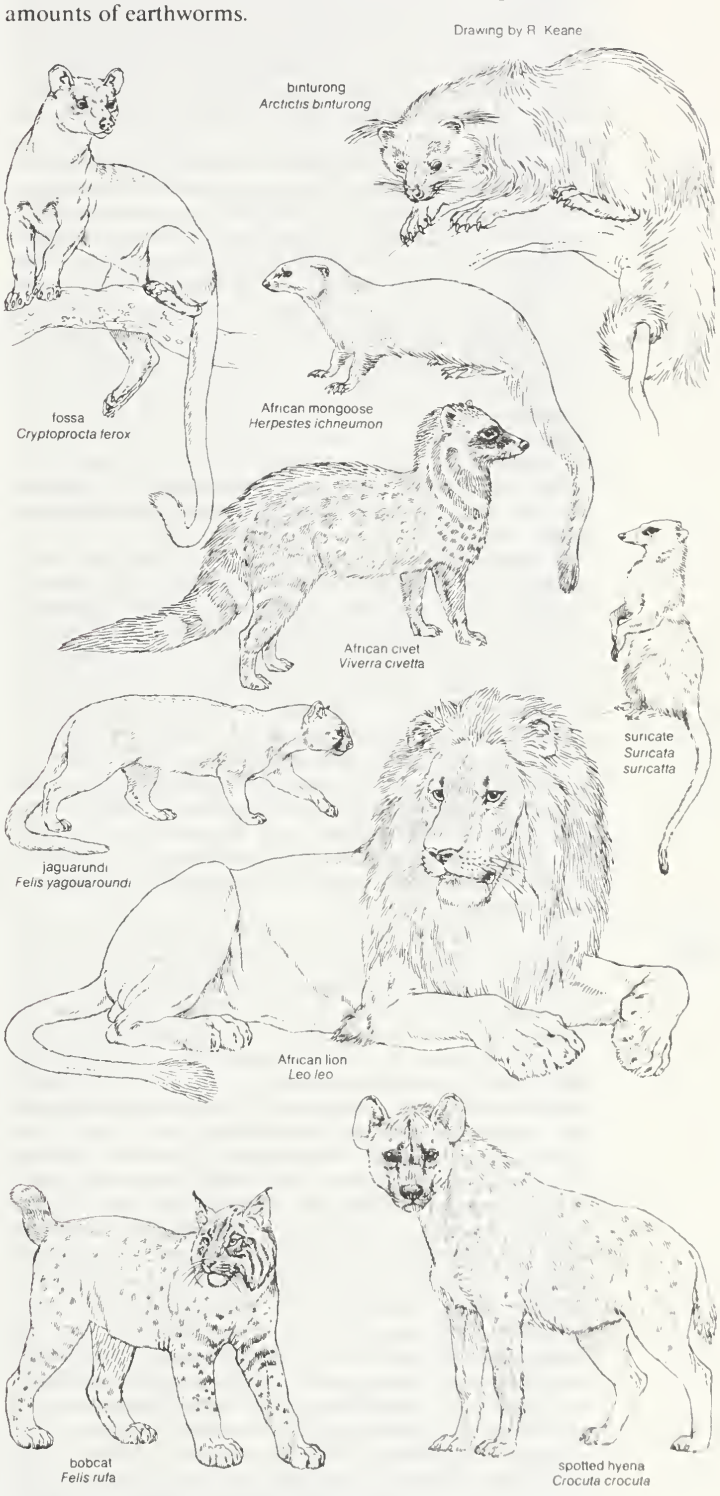

Figure 35: Representative carnivores: Viverridae, Felidae, Hyaenidae.

A number of viverrids (*Herpestes, Atilax, Mungos, Helogale*) are noted for their peculiar habit of opening eggs, as well as other food items with hard shells (crabs, mollusks, nuts). The animal stands on its hindlegs and hits the egg against the ground. Sometimes it carries the egg to a rock and, standing with its back to the rock, throws the egg between its legs and against the rock until the shell is broken. (Early reports of this behaviour met with skepticism but have been verified by other observers.) The Madagascar narrow-striped mongoose (*Mungotictis lineatus*) exhibits the same behaviour but lies on its side and uses all four feet to toss the egg.

Viverrids as snake-killers

Viverrids are perhaps best known for their ability to kill some kinds of poisonous snakes, especially cobras, which are slow in striking and apparently unable to strike when at close quarters. The mongoose can dart within the outer striking range of the snake and grab and break the lower jaw. The mongoose is much less successful against a snake that has a very rapid strike and return to the pre-strike defensive position, such as a rattlesnake. The white-tailed mongoose (*Ichneumia albicauda*) has the unusual habit of feeding on the tree hyrax, which it follows and kills in the tops of trees.

Viverrids are highly variable in hunting and social behaviour. Some species are solitary; others hunt in groups, ranging from a single pair to a family group or a wandering band of more than 20 individuals. Two species, the meerkats (*Suricata suricatta* and *Cynictis penicillata*), live in colonies. Colonial organization is unusual for animals that are largely carnivorous but is found also in the European badger. An interesting relationship exists between the type of association and the time of day that viverrids are active. The viverrids that travel singly or hunt in pairs comprise the majority of species, and all are nocturnal. All those viverrids that hunt in bands or live in colonies are diurnal. The only exceptions are the mongooses of the genus *Herpestes*, which may hunt singly or in bands and may be either nocturnal or diurnal depending on the species involved.

The senses for seeing, hearing, and smelling are well developed in viverrids. Predatory birds apparently are recognized almost instantly and at considerable distances. Viverrids, like mustelids, tend to be silent, but such sounds as purring, grunting, chirping, low-pitched coughing, growling, hissing, whining, twittering, and barking have been described. More elaborate or complex "language" usually is found in gregarious forms. Specific warning or danger cries, signifying the approach of either a ground or aerial predator, are known in the social meerkats. The noisiest viverrid, however, is the nocturnal, arboreal binturong, which growls, hisses, and, at times, howls loudly. Also extremely noisy are the cusimanses (*Crossarchus* species), which travel in large groups grunting, chattering, and twittering.

Viverrid habitats

Most viverrids are terrestrial, but at least 10 genera have forms that inhabit trees to a considerable extent. Mostly arboreal are the African palm civet (*Nandinia binotata*), the small-toothed palm civet (*Arctogalidia trivirgata*), the musang (*Paradoxurus* species), the masked palm civet (*Paguma larvata*), the binturong, the fossa (*Cryptoprocta ferox*), and the slender mongoose (*Herpestes sanguineus*). The linsangs (*Prionodon* species), although spending some time on the ground, are good climbers and live in the hollows of trees. Palm civets (subfamily Paradoxurinae), a few other civets, and genets also spend considerable time in trees. Mongooses, however, seldom climb and are unable to move about easily in trees. This inability is evident when they descend from trees. An efficient well-adapted climber comes down a tree head first. Of the mongooses, only the slender mongoose, and perhaps the Indian gray mongoose, have been observed descending head first. All other mongooses back down. Although most viverrids can swim if need be, three genera have semi-aquatic members: the Congo water civet, the African civet (*Viverra civetta*), and at least three species of mongooses of the genus *Herpestes (H. brachyurus, H. urva,* and *H. vitticollis).* The otter civet (*Cynogale bennetti*) has slightly webbed feet and is aquatic. An even more aquatic viverrid, or at least a more agile one, is the water mongoose, which dives and swims like an otter, although, unlike the otter, its feet are not webbed.

Some mongooses exhibit curious antics to attract their prey. For example, the white-tailed mongoose may dance outside chicken pens and bite off the heads of chickens that curiously stick their heads through the netting. The banded mongoose is said to stand upright and fall over on its side, using such antics to attract curious guinea fowl so that they approach close enough for capture. An interesting habit found in the meerkat plays a role in heat regulation. The belly of this animal has little hair, much less than the back. In the winter or during cold weather, the meerkat basks in the sun, standing on its hind feet with the ventral surface directed toward the heat source. When the temperatures are high, the animal seeks out cool surfaces, on which it lies on its stomach. It may even dig out an area to expose the cool subsurface layers of earth before lying down.

The fossa walks on the soles of its feet and thus is plantigrade or semiplantigrade, but most other viverrids walk on their toes (digitigrade).

Information concerning reproduction in viverrids is sketchy. In most species studied there are two litters a year (usually one in spring and one in fall), although breeding can occur throughout the year. The gestation period is usually between 49 and 64 days, but in various mongooses of the genus *Herpestes* it ranges from 32 to 49 days. Most litters consist of three or four young, but the black-legged mongooses (*Bdeogale* species) may have only a single young. Most female viverrids have two pairs of abdominal nipples, thus perhaps restricting the litter size to four, but some females of the genus *Herpestes* have three pairs. The young are born in burrows, in a nest of grass on the ground, or in hollow trees.

Viverrids are found in the Old World tropics and subtropics, throughout Africa, southern Asia, Madagascar, and southeastern Europe. Only the genet (*Genetta genetta*) occurs naturally in Europe. Although restricted to southern France and Spain today, it was at one time found as far north and east as Belgium and Germany. Various mongooses (*Herpestes* species) have been introduced into the West Indies, Hawaii, and New Zealand, as well as Italy and certain areas of the Balkan Peninsula. Viverrids are most abundant in Southeast Asia (India and the Malay Peninsula). In habits and habitat they fill the niches of the mustelids and procyonids found more abundantly in the northern regions or in the New World. Viverrids are the only members of the Carnivora to reach Madagascar, where they have flourished and undergone adaptive radiation. About a sixth of the known genera of viverrids are restricted in distribution to this large island.

Importance to man. Probably of most significance economically is the musk, called civet, produced by the anal gland in members of the viverrid group known as "civet cats." Civet is a yellowish substance with the consistency of butter and is of great importance as a base for perfumes. It is produced by the anal scent glands and stored in a sac near the genital region. The Oriental and African civets (*Viverra* species) and the lesser Oriental civet, or rasse (*Viverricula indica*), are kept in captivity so that this musky secretion can be collected several times weekly. The secretion is obtained by scraping the sac with a wooden spatula. As much as four grams of civet can be obtained in one week. Long, narrow cages are used to prevent the animal from turning and biting while the secretion is being collected.

Viverrids as the source of musk

This musk has been in great demand for many years and has commanded high prices. Civet is used as a base for perfume extracts, and in India the product of the lesser Oriental civet has been used to flavour tobacco. In some areas, parts from viverrids (the binturong and the linsang, *Poiana richardsoni*) are believed to have various medicinal values.

The only civets of value to the fur trade are certain members of the subfamily Viverrinae. Of these, the large Indian, or "Chinese," civet (*Viverra zibetha*) is the only one to be utilized for fur to any great extent. Fur of the small Indian civet and the genet is used for trimming clothing. Some members of tribes in Madagascar use the tails of

civets for ornamentation. The meat of both the large and small Indian civets has been described as delicious.

The genet, white-tailed mongoose, and fossa often become pests in areas where poultry is raised. Most viverrids are efficient rat catchers, and some, such as the binturong, suricate, cusimanse, and certain mongooses, are domesticated because of their affectionate nature and their ability to eliminate mice, rats, and cockroaches from the residence of the owner. In some areas, Greece and southern Italy for example, genets have been kept as house pets, and this animal may have been the "cat" of the ancient Greeks. In other areas, the binturong is tamed to follow its master like a dog.

Form and function. Viverrids have from 36 to 42 teeth. The canines are slender and elongate and the carnassials well developed.

Viverrids have short legs with five toes on each foot, except for the meerkats; *Suricata* has four toes on each foot and *Cynictis* four on the hindfoot. The pollex ("thumb") and hallux ("big toe") are functionless and do not touch the ground. Each toe is capped with semiretractile claws that are more retractile in digitigrade species than in those that are semiplantigrade. Most viverrids have a long, slim body and a long, bushy tail. Except for some marsupials, the binturong is the only Old World mammal with a prehensile tail. The elongate head ends in a pointed, foxlike muzzle. Coloration in the civets can be quite variable in pattern, from uniform to spotted, blotched, or striped, and ranges from black and gray through various shades of brown to rufous and yellow. The stripes may run longitudinally (*Mungotictis, Galidictis*) or vertically (*Mungos, Chrotogale, Hemigalus*). Some forms of civets (especially *Bdeogale, Ichneumia*) have black legs.

Viverrids range in size from the dwarf mongoose (*Helogale parvula*) with a weight of about 500 grams (about one pound) and a total length of 300 millimetres (12 inches) to the binturong with a weight of up to 14,000 grams (about 30 pounds) and a length of 1,800 millimetres (72 inches).

Hyenas (family Hyaenidae). *Natural history.* Hyenas form a relatively homogeneous family that includes two basic types: the true hyenas (two species of *Hyaena* and one of *Crocuta*) and the aardwolf (*Proteles cristatus*).

Feeding habits of hyenas

Hyenas are noted for their scavenger feeding and bone-crushing habits, although they do hunt live animals. Their food consists largely of the remains of artiodactyls, such as the antelope, left by the large cats. Vultures and jackals often feed on such kills after the cats and before the hyenas move in. The spotted hyena (*Crocuta crocuta*) eats large amounts of bone and skin, seeming to prefer them to meat. These, of course, are the remains after the predator has had its fill. Spotted hyenas hunt in aggressive packs and at times attack and kill larger animals, even as large as a young rhino. If the animal attacked puts up a fight, the hyenas stop the attack and move away. In addition to carrion, brown hyenas (*Hyaena brunnea*) feed on small mammals, young or newborn larger mammals, reptiles, eggs, insects, fruits, and berries. In coastal areas they may feed on dead crabs, whales, and other sea life washed up on shore. The brown hyena is less apt to attack living animals than is the spotted hyena. The striped hyena (*Hyaena hyaena*) has food habits similar to those of the brown hyena. The aardwolf feeds almost exclusively on termites but eats a few other insects, such as beetles. A large quantity of soil and grass is usually eaten accidentally while feeding at termite mounds.

Since carrion produces a distinctive odour, hyenas depend on the sense of smell to a great degree. Most of their food probably is located by this sense alone, sight and hearing being less important. Sight is poorly developed in hyenas.

The well-known howl of the "laughing hyena" is the call of the spotted hyena. The other species are not as noisy.

In areas undisturbed by man, hyenas hunt during the day. Members of this family inhabit open areas of plains and brushland but at times may be found in open forested areas. Hyenas form packs and are tireless trotters and runners, at times wandering great distances.

Spotted hyenas breed during the dry months, from April to July; the aardwolf breeds from October to November. The gestation period is approximately three months (95 to 110 days in the spotted hyena). Hyenas usually have three or four young. Dens may be located in abandoned burrows, caves, dense brushy areas, or among rocks. Some hyenas use the burrows of the aardvark for nesting spots, as does the African hunting dog.

The Hyaenidae have a distribution similar to, but more restricted than, that of the viverrids. They are found throughout Africa and from southern Asia east to eastern India.

Importance to man. The scavenger habits of most of the members of the Hyaenidae make them of considerable benefit to the ecosystem as a whole and often directly to man. They perform the service of eliminating the remnants left by the large predators and thus fit into a niche unused by most mammals. In some parts of Africa, hyenas are allowed to roam the villages, cleaning up garbage. In some areas people place their dead out in the open to be removed by these inexpensive "natural undertakers."

Hyenas at times will attack and kill livestock and sometimes people, usually sleeping persons or young children. Being cowardly, they seldom fight if the individual puts up any type of defense. When hungry, they may raid camps and carry off various items made of leather. In attacking large livestock or antelope, they usually approach from the rear and kill their prey by tearing open the abdomen.

Form and function. Hyenas have a total of 34 teeth, fewer than the generalized number found in other carnivores. The aardwolf has fewer upper and lower premolars and molars, resulting in from 28 to 32 teeth. The incisors are unspecialized in all members of the Hyaenidae, with the third incisor being the largest. The canines are well-developed, sharp, and elongate. Premolars of hyenas have well-developed crowns, useful in bone crushing, and tend to be conical. In the aardwolf the premolars are small, widely spaced, and, along with the small molars, tend to be vestigial. The lack of development of the cheek teeth is related to its insect-food diet, which does not require a powerful dentition. The molars of the hyenas are large and powerful, aiding in bone crushing, as do the jaws, the most powerful found in any mammal of comparable size. The head tends to be massive, with a broad muzzle, not long-nosed as in the canids or short-faced as in the cats. Anal glands are present in most forms and are well developed in the aardwolf, which can eject an obnoxious fluid when threatened.

All hyenas have a characteristic stance. The front legs are longer than the hindlegs, causing the back to slope conspicuously from a high point at the shoulders to a low point at the hindquarters. Hyenas walk on their toes and run well. There are four toes on each foot, capped by blunt, nonretractile claws. *Proteles* has five toes on the front foot. Most members of the family have a well-developed mane on the neck, which may extend down the midline of the back. This mane often is more noticeable in the young hyenas, although well developed in all age classes of the aardwolf. All have large, rounded ears. These animals are grayish or brownish in colour, marked with spots (*Crocuta*), stripes (*Proteles, Hyaena hyaena*), or uniform with bars on the legs (*Hyaena brunnea*). The tail is medium in size, bushy at the base, and pointed at the end.

Cats (family Felidae). *Natural history.* Almost all cats are strictly carnivorous and feed on small mammals and birds or on the larger herbivorous artiodactyls like deer and various types of antelope. The fishing cat (*Felis viverrina*) feeds largely on fishes and clams or snails and thus fits into a slightly different niche from that of most cats. The flatheaded cat (*Felis planiceps*) is the only felid known to feed to any extent on vegetation, with fruit and items like sweet potatoes being preferred when available. The large cats sometimes drag the kill into a tree or place it under a bush after the initial gorging. Cats live on a feast-or-famine routine, gorging themselves when a kill is made and then fasting several days between kills.

Cats have good senses of sight and hearing. Long, sensitive whiskers on the face aid the cat during the stalking of the prey by brushing against any obstacle in a path and enabling the cat to avoid making excessive noise as it stalks its prey. The easiest, most open path can be fol-

Hunting method of cats

lowed through vegetation, even at night. Smell apparently is not as well developed as in some other carnivores, such as the dogs. Cats are nocturnal in habits. The cheetah is an exception to this rule, hunting predominantly by day. Their large eyes are especially adapted for seeing at night, when the amount of light is low. The cat stalks its prey to a point as close as allowed by available cover, then closes the final distance by a leap or a short dash. A chase may ensue, with the predator relying on superior speed and reflexes to overtake the dodging prey, which often has greater endurance. Although the endurance of most felids is sufficient for a chase of only a few hundred metres at most, the cheetah may pursue its prey for much greater distances, up to about 5,500 metres (3.4 miles). If overtaken, the prey is thrown down and dispatched with a deep bite, usually in the neck. Almost all hunting by these animals is done alone and quietly. The major exception to the solitary habit is the lion (*Leo leo*), in which the group, or pride, may number as many as 30 individuals. Cheetahs sometimes are found travelling in small groups but stalk and chase their prey individually.

The gestation period of most smaller cats is approximately two months (50 to 68 days), and that of the large cats is three or three and a half months (88 to 113 days). Two or three kittens make up the usual litter. The jaguar (*Leo onca*) tends to have only one kitten. The domestic cat (*Felis catus*) sometimes has more than six kittens. Female cats may have from four to eight nipples. The breeding season usually is in the late winter or early spring. In smaller species those females that have early litters may produce a second litter in late summer or early fall. Some cats are capable of breeding at any time during the year (lion, tiger, and leopard). The size of the animal does not seem to determine the litter size, number of litters, or the time of the breeding season. In the larger cats, however, the age of initial breeding is greater; the females may be three or four years of age and males as much as five or six years old. Smaller cats may breed when less than a year old. Most litters are born in places seldom disturbed by man, such as in a rocky cavern, under a fallen tree, or in a dense thicket. The serval (*Felis serval*) uses an old porcupine or aardvark burrow. In most species the male does not aid in the care and raising of the young, and in fact, the female may have to guard against his attacks on the kittens. The male jaguar and ocelot (*Felis pardalis*) do help in raising the young.

Vocalizations of cats

Cats are noted for their purring when apparently content and for their snarling, howling, or spitting when in conflict with another member of their kind. The larger forms, especially the lion, often roar, growl, or shriek. Usually, however, cats are silent. Many cats have "clawing trees," upon which they leave the marks of their claws as they stand and drag their front feet downward with the claws extended. House cats are well known for this habit, and an owner may supply an artificial tree to save damage to furniture. Whether such behaviour is for the purpose of cleaning or sharpening the claws is debatable, but the behaviour is innate; kittens raised in isolation soon begin to claw objects. Other characteristics of cats are the constant movement of the tail when stalking, the habit of washing the face, and the habit of digging a hole in which to bury the fecal material and urine.

Almost every area on earth has some type of native cat. Australia is the only continental area that has no native felids, though the family also is absent from Madagascar and a number of oceanic islands. Cats are found in most habitats, from the forest to the desert, although they are typically animals of wooded environments. Many are in danger of extinction because of their incompatability with the activities of man or because of their combined value to zoos and the fur trade.

Importance to man. The cat, like the dog, was originally taken into the home of man as a pet. Unlike the dog, the cat has not been trained to hunt or to serve as a guardian. Cats may perform the function of "mouse catcher" in those areas where mice become a problem, but most urban house cats do not have the opportunity to perform this unless garbage and trash are allowed to accumulate. On farms, where storage of grain is common and rodents become numerous, cats help to hold their numbers in check.

The fur of cats is sometimes in great demand, especially when high fashion calls for "fun furs," those with contrasting colours involving spots or stripes of the type found on the pelts of many cats. The demand is such that numerous kinds of cats are in danger of becoming extinct. In some regions of the world, catskins have been in great demand for many years. In parts of Africa the royal furs are usually those of a cat, as those in Eurasia are from the ermine or the sea otter. Chiefs and other high dignitaries of some native tribes use the pelt of the serval as a sleeveless cloak thrown over the shoulders.

Man-eaters

The larger cats are strong, fierce, and extremely dangerous when hungry. Should one of these animals learn that the flesh of man is edible, it must be eliminated. In many, if not most, cases the "man-eater" is an old cat no longer able to kill native wild prey. Although tigers and leopards are most famous for man-eating activities, lions and jaguars also may become dangerous. The American lion or puma (*Felis concolor*) tends to avoid contact with man and most records of its attacking man, except when cornered, are questionable. Similarly, if a large cat learns that a ready meal is available in the form of fenced or domesticated livestock, the rancher will have problems until the predator is eliminated. As in the case of the man-eater, the problem is caused by one animal and not all the individuals should be condemned.

Cats are intelligent and can be trained. Many kinds of cats can be tamed as pets, but some, especially the larger species, really can never be trusted when they become older or when they are sexually active. Most wild animals, to be trustworthy, must be fed by bottle before their eyes open, in which case the cat apparently will regard the human as its actual mother. The domestic cat, when liberated in the wild or allowed to roam in the field, may become a more serious and damaging predator on wildlife than the native predators in the region.

Form and function. Cats have a reduced number of premolar and molar teeth; the typical dental formula includes only 30 teeth. The incisors are small and chisel-like and the canines long and pointed. The premolars are sharp, and occasionally an upper premolar may be lacking. The lower molar is elongate and sharp, the upper molar rudimentary. Because of the reduction in the number and size of the cheek teeth, a space remains between the canines and premolars in all cats except the cheetah. Felids form the most carnivorous group in the order, and the highly developed carnassial teeth reflect this specialized food habit. There is little if any specialization in the teeth for grinding or chewing. The strong masseter (chewing) muscles of the jaw restrict the amount of lateral movement and primarily permit vertical movements of the jaw, for holding the prey in a viselike grip and for slicing off pieces of meat with the carnassials. Thus meat is cut off and swallowed in relatively unchewed chunks that are broken down by strong enzymes and acids in the digestive tract. Cats use the rasplike tongue to remove the flesh from the bone.

Because of the reduction in the number of teeth, cats have a short face and a rounded, compact head. The ears tend to be short or, in some forms, tufted with hair. Most forms, except the lynxes (*Felis lynx*, *Felis rufa*), have an elongate tail that comprises about a third of the total length. The agility of a cat is evident in its anatomy. The clavicle, or collarbone, is much reduced in size. It does not connect with other bones but is buried in the muscles of the shoulder region. This type of construction allows the animal to spring on its prey without danger of a supporting or connecting structure, like the clavicle, being broken. The hindlegs are well developed, with powerful muscles that propel the animal in its spring toward or onto the prey animal. In addition to the power of the hindlegs, the animal uses strong back muscles to straighten the spinal column and provide extra force in springing and running. Most of the skin covering the body of the cat is loose, allowing for even more freedom of movement as well as providing some protection during a fight.

Anatomical basis of feline agility

The legs of the jaguarundi (*Felis yagouaroundi*) are rather

short, and those of the cheetah elongate. All cats, except the cheetah, have retractile claws. Such claws can be drawn back into a sheath when the animal is walking, rendering the footsteps noiseless and keeping the claws sharp; or they can be extended as an aid in pulling down and holding the prey when the animal is attacking or in protecting the cat when attacked. The sharp, strongly curved claws are also utilized when the cat climbs trees. There are five toes on the front foot and four on the rear. The first toe and its pad on the front foot are raised so that only four toes register in a track.

Cats are usually some tone of brown in colour. Some, like the American mountain lion and jaguarundi, are uniform in coloration, but most are marked with spots, stripes, or rosettes. The young of the mountain lion are spotted, which may indicate a spotted ancestor. Characteristic of all cats is a dark stripe extending laterally from the external corner of the eye. This stripe tends to exaggerate the expression on the animal's face toward one of meanness but probably serves to conceal the face by breaking the roundness of the eyes. Many of the colour patterns are repeated again and again in the different species of cats, from the largest to the smallest. Several species have black or nearly black colour phases mixed into normally coloured populations. The only cat with a well-developed mane or long hair on the back and chest, or both, is the male African lion, which is also the only terrestrial member of the order Carnivora that shows obvious sexual dimorphism. In many felids the male is larger than the female, but this sexual difference is not easy to distinguish, because the difference in size is slight.

Walrus and seals (families Otariidae, Odobenidae, and Phocidae). *Natural history.* Members of the families Otariidae (eared seals), Odobenidae (walrus), and Phocidae (earless seals), commonly called pinnipeds, are strictly carnivorous and mostly marine. A few venture up freshwater rivers, and two forms (*Pusa* species) are landlocked on inland lakes. Pinnipeds are amphibious, being aquatic as to food habits but terrestrial for mating, bearing young, and resting. The diet of pinnipeds consists mainly of fishes, cuttlefishes, octopuses, and crustaceans. Most of the fishes fed upon by seals are those which school. A few pinnipeds are specialized for feeding on krill (macroscopic pelagic plankton, primarily small shrimplike euphausians). Seals known to feed largely on krill are the ringed seal (*Pusa hispida*), harp seal (*Pagophilus groenlandicus*), and crabeater seal (*Lobodon carcinophagus*); all take fishes as well. The crabeater seal is misnamed, as it is not known to feed on crabs. Some seals, such as the leopard seal (*Hydrurga leptonyx*), are quite predatory, feeding on penguins, other birds that land on water, and other seals. The Australian sea lion (*Neophoca cinerea*) feeds largely on penguins. Such predators take advantage of the surface light at night and probably feed by visual discrimination from below. The bearded seal (*Erignathus barbatus*) and walrus (*Odobenus rosmarus*) are bottom feeders, consuming largely sessile organisms such as mollusks. The walrus in addition occasionally feeds on small whales, narwhals, and seals.

Pinniped feeding

Generally, pinnipeds are adapted for excellent hearing, especially underwater. Some studies have even suggested the use of echolocation (reflected pulses of sound) in their movements and food-seeking activities, though conclusive evidence for this is lacking. Pinnipeds have a fair sense of smell on land, good enough to enable mothers to recognize their pups. Seals probably have an excellent sense of touch in the whiskers, which aids in locating their prey or warns the animal of a possible collision with a submerged object. Young walrus have such well-developed whiskers that these appear as a brushlike mustache. The walrus and bearded seal utilize these whiskers to filtre food organisms found on the bottom and as a tactile organ. Phocid seals have patches of elongate hairs above the inside corners of the eyes.

Pinnipeds may be solitary at certain times of the year, as is the Ross seal (*Ommatophoca*), which lives alone in winter. Most, however, are usually gregarious, much more so than terrestrial carnivores. During the breeding season more than a million individuals may congregate on an island. Each male sets up a territory and gathers as many females as he can. The territory is maintained by frequent loud vocalization, a threat stance with neck outstretched, rushing at an approaching rival, and possibly through the use of olfactory odours thought to be produced in the mouth. Although the term harem is usually used to describe the large number of females in the territory of a male, this concept is misleading, since the females can move from one group to another. The groups are a result of the females staying clear of the males as the latter patrol their territories. Once the territory is established, the male remains to protect it, going as long as two months without eating (sea lions and fur seals). Eared seals (the otarids) and walrus tend to gather harems, while the earless seals (the phocids) are mostly monogamous (one male, one female) in their breeding activities. The gathering of harems forces the mating activity to be terrestrial rather than aquatic. In many, if not most, of the northern species of seals the breeding season is restricted in many ways by the environment. In most areas only four months exist with a climate favourable for the production of young.

Territoriality in pinnipeds

Pinnipeds have a comparatively long gestation period, ranging from eight months in the leopard seal to 12 months in fur seals and sea lions. Breeding frequently takes place soon after the birth of the young (five days in the fur seal) or, as in the leopard seal, four months after the young are born. In most instances, copulation is on land, but some phocids mate in the water. The majority of pinnipeds exhibit delayed implantation in embryonic development. Delayed implantation allows births to occur at about the same time each year. The young are born either on land or on

Drawing by R. Keane Hawaiian monk seal based on San Diego Zoological Garden photograph

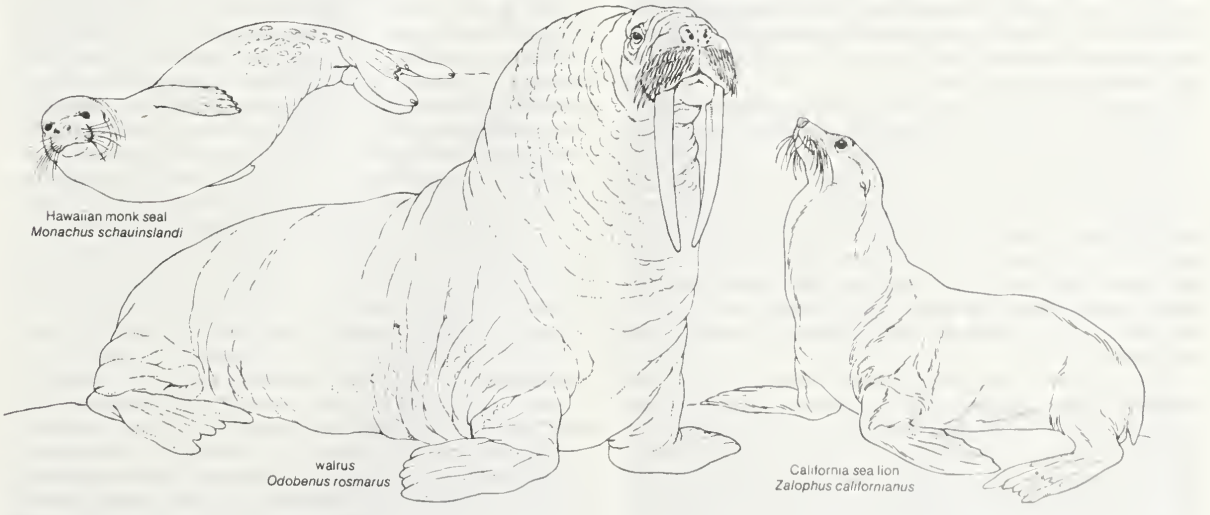

Figure 36: Representative carnivores: pinnipeds.

ice. Usually there is but one young born, although most females have two pairs of mammary glands (some phocids have one pair). The mother goes out to sea to feed soon after the young is born. Since she must search to find her young when she returns, there has probably been a selection against the production of more than one young, at least in highly gregarious forms, for the time spent searching for the second pup would be at the expense of the first. It is evolutionarily better to produce one vigorous offspring than two weak ones. Nursing usually takes place on land. At birth the newborn pup can travel on land and swim, although young otarids are several weeks old before they develop enough blubber to keep them floating and insulated against the cold water. The young of the earless seals nurse for only three to six weeks, and the females remain near the young throughout this period. Pinniped milk is low in water content and high in fat. Such high fat content results in the rapid growth of the young, but perhaps of more importance is the low water content, of benefit to the mother in a habitat where water conservation is so important.

Female pinnipeds are sexually mature when two to eight years of age, usually at the age of three or four years. Males, at least in the polygamous species (those which gather a "harem"), may not be allowed to mate for several years after reaching sexual maturity. In these species the younger males are driven by the old males to a bachelor group located outside of the breeding group and restricted to a given area. After the breeding season, pinnipeds are largely pelagic (open-sea dwellers), travelling long distances either singly or in small groups.

A number of animals prey on seals: large sharks, killer whales, polar bears, and other seals, such as the leopard seal and walrus. Seals, especially the young, spend a good deal of time playing. They resemble the river otter in this regard.

Seal barking

Pinnipeds produce a number of different types of sounds. Barking by male seals may be related to social dominance and territorial defense, as the polygamous species are extremely vocal and the monogamous forms extremely quiet. The "barking" of the circus seal (the California sea lion, *Zalophus californianus*) is familiar to most people. The study of underwater communication in seals is difficult and in its infancy, but a variety of sounds have been recorded. These sounds may play a role in navigation, social behaviour, and foraging. Seals also roar or bellow, honk, chirp, bleat, grunt, or cough.

These aquatic, carnivorous animals are found throughout most of the coastal regions of the world. They are especially abundant in the cold polar waters. The walrus and phocids are well distributed throughout the northern coastal and ice-front areas. The otarids do not extend as far north, southern Alaska and Kamchatka being the most northern points, and are absent from the mid-Atlantic and North Atlantic Ocean areas. Pinnipeds are absent from the region of the Indian Ocean, southern Asia and northern Australia, the coastal regions of Central America and northern South America, and most of the coastline of central Africa. A few seals are landlocked on the Caspian Sea (*Pusa caspica*) and Lake Baikal (*Pusa sibirica*), where they subsist mainly on fish.

Importance to man. The seal is of significant importance to the survival of the Eskimos and other inhabitants of the north, who use almost every part of the animal: the meat is eaten; bones used for implements; tendons for sewing; hides for leather to make footwear, boats, shelters, bags, clothing, and ornaments; and the oil and fat for fuel, lubrication, and tanning. The ivory tusks of the walrus are carved into statues and knife handles. Seals also are taken commercially for their oil, for meat that can be used for food or fertilizer and for their hides that are used as leather.

A few seals are of importance to the fur trade. Of special interest are the true fur seals, *Callorhinus ursinus* in the northern regions of the Pacific Ocean and *Arctocephalus* species in the southern regions off the coasts of South America, Africa, and Australia. Most of the species utilized by the fur trade are members of the family Otariidae, which have dense underfur. The young of members of the Odobenidae and Phocidae have an insulating coat of short, dense, wool-like hair at birth. Skins of these young animals are of some interest to the fur trade but are used mostly for novelties. Adult phocids have skins with stiff hair; the underfur is reduced to the point that the hide appears naked. However, some of the extremely striking phocids were in demand for furs in the late 1960s.

California sea lions are trained to entertain at circuses and zoos. Some seals become pests to commercial fisheries and may gather during salmon or herring runs, sometimes being killed in large numbers by fishermen.

Form and function. Basically, the difference in the tooth pattern of pinnipeds, in comparison to the dentition of terrestrial carnivores, reflects an adaptation toward grasping and tearing rather than chewing. Thus there is less variation in the form of the different teeth (commonly said to be homodont, or "similar teeth"), and there tends to be a reduction in the number of teeth. There are, generally, two or three pairs of upper incisors and one or two pairs of lowers. There is a pair of conical canines that form elongate tusks in the walrus. The premolars and molars are conical and so similar that they are difficult to differentiate and are usually referred to as postcanines. There are no carnassial teeth. Usually there are ten postcanine teeth each in the upper and lower jaws, but the exact number can vary so greatly, even within one species, that the total number of teeth may range from 26 to 38. In the walrus the tooth number is reduced even further, the usual number being two upper incisors, no lower incisors, four canines, and 12 postcanines, a total of only 18 teeth. This number is variable, with some individuals having as many as 24 teeth. Weddell's seals have canines and incisors adapted for cutting holes in the ice so that areas are available for breathing when the water freezes over. The upper incisors extend forward and contact the ice before the canines.

Adaptations for aquatic life

Pinnipeds have a number of aquatic adaptations that separate them from the terrestrial carnivores. The body is streamlined, allowing the animal to pass through the water with the least amount of friction. External ears are reduced or absent, also aiding in making the pattern of the body more streamlined. Adaptive features of the skull include an overlapping of the bones, a feature even more exaggerated in the whales, and a flattening of the head, an advantage during diving. The neck is thickened by increased musculature but is more flexible (at least in the eared seals) than in the terrestrial carnivores, allowing the animal to capture its prey in the water with greater ease. In most pinnipeds the face is short, with the cranial part of the skull longer than the facial region. The eyes are large, located forward, close together, and imbedded in a cushion of fat. The iris of the eye is contracted when out of water, dilated and almost circular when diving. This type of eye can accommodate rapidly when the animal moves from dim to bright light. The ears and nostrils can be closed while diving. The pelvic girdle is more nearly parallel to the vertebral column than in terrestrial forms. Such a change in the location of the pelvis enables the hindlimbs to be held in more of a trailing position and to be more efficient in propulsion through the water. The limbs are enclosed within the body skin to or beyond the elbows and knees. This enclosure also streamlines and results in a more efficient passage through the water. The extremities of the limbs are flattened to form paddles used to steer or propel the animal through its environment. Each paddle contains five toes, extending from bones in the palm and sole (metapodials), elongated to increase the surface area of the paddles. The first digit on both forefeet and hindfeet is more elongate than the other four. The tail is short and rudimentary, a condition approached by the sea otter but quite unlike the paddlelike tail of the freshwater otter. Mammary teats and external reproductive organs are so constructed that they can be withdrawn beneath the skin to aid in preserving the smooth outline of the body. The skin, adapted to a water environment, is tough and thick and contains a thick layer of subcutaneous fat or blubber. The blubber provides a source of energy that can be used during lactation or at times of fasting. Such fasting is characteristic of pinnipeds. This layer also provides the animal

with more buoyancy, so that sinking in the water is less apt to occur. In addition, the blubber insulates the body so that the body temperature remains nearly constant. A pinniped living in cold water may be exposed to a surface temperature of about 0° C (32° F) and yet have a body temperature of 37° C (98.6° F), requiring an efficient system of heat production and insulation. In warm waters, and especially in warm air, the animal cannot get rid of excess body heat rapidly enough to prevent overheating. The flippers, so useful for swimming, can be used on land as radiators to get rid of excess body heat. One of the most obvious behavioural features of a colony of seals on land is the waving or extension of the naked flippers.

Physiological adaptations for diving

There are a number of physiological adaptations to life in the sea. Being air breathers, seals must be able to carry as much oxygen as possible with them in diving and to conserve what they do take. This adjustment is obtained by the increased volume of blood (very large for an animal their size) and the decreased rate in the use of oxygen by the body (decreased metabolism). The heart rate decreases in the elephant seal from about 85 beats per minute when the animal is on the surface to approximately 12 per minute during a dive. This drop in heart beat rate conserves oxygen in terms of the amount being carried in the blood. There cannot, however, be a decrease in the amount of oxygen being carried to some parts of the body. The heart and brain, for example, must have a constant and sufficient supply, or the cells in these organs will be damaged. This problem is alleviated by closing down the small arteries in the tail and flippers, while the larger arteries to the head and brain remain unchanged. The muscles function without free oxygen during submergence; the energy is obtained by partly breaking down the blood sugars and without expending the limited supply of oxygen. Most dives last less than 15 minutes, and upon return to the surface there is a greater exchange of oxygen and carbon dioxide than is found in terrestrial mammals. The amount of tidal air in one respiratory cycle may be as much as 90 percent, compared to 20 percent in man. Most dives are deep vertical dives rather than extensive horizontal dives because of the problems of orientation toward the breathing hole in the ice when horizontal directions are taken. Since there is no exchange of gases with the environment while submerged, seals have the additional problem of an accumulation of carbon dioxide. They seem to be less sensitive than terrestrial animals to increased amounts of this gas. The body temperature is lowered, a result of the decreased rate of metabolism. Seals are also adapted to withstand the great pressures during their dives. Weddell's seal (*Leptonychotes weddelli*), for example, dives as deep as 335 metres (1,100 feet), more than four times the distance that man can go in a diving suit. The longest known dive by a Weddell's seal lasted 43 minutes and 20 seconds (to 350 metres [1,150 feet]), with one elderly bull reaching a depth of 600 metres (2,000 feet) but remaining down a shorter time. Exactly how these animals can accomplish such feats is unknown. The anatomy of the seal reveals part of the answer. Many structures in the body are built to yield to such pressures, not to resist them. Some of these adaptations are smaller lungs; elimination of most air from the lungs before the dive; a thorax that permits the lungs to collapse; incomplete rings of cartilage in trachea, permitting complete collapse; driving air out of the middle ear by partly filling the ear cavity with blood; and redistribution of blood in general. The phocids are more efficient divers than the otarids, and, of the phocids, those living in the Antarctic dive the deepest.

The clavicle, or collarbone, is absent, allowing more flexibility in the shoulder. The kidneys, unlike those of most mammals, are composed of numerous lobes resembling a bunch of grapes, a condition also found in the terrestrial bear and otter.

Members of the families Otariidae and Odobenidae can walk on their limbs when on land. Phocids must move by undulations of the body as the limbs cannot be turned in a position to support the body. This does not mean that the phocids are helpless on land; the crabeater seal, a phocid, is probably the fastest moving seal on land, being difficult for even a running man to catch.

EVOLUTION AND PALEONTOLOGY

Opinion is divided as to whether the order Carnivora arose from the ancient creodonts or had a separate and independent origin from the order Insectivora. Most paleontologists now favour the latter view. The Cretaceous insectivore *Procerberus* seems to be morphologically close to the most primitive carnivores (miacids), the creodonts, and the primitive hoofed mammals (ungulates). *Procerberus* was an unspecialized rat-sized predator. The order seems to be a separate and distinct line that includes the modern Fissipedia (terrestrial forms) as well as Pinnipedia (marine and aquatic forms), while also including the more ancient and extinct family Miacidae.

The extinct Miacids

Although not much is known about them, the miacids were probably arboreal forest dwellers of the tropics. Animals from this type of habitat are rarely preserved as fossils, which accounts for our incomplete knowledge of the group. These primitive carnivores may have resembled our modern weasels, with elongate bodies, short limbs, and long tails. Miacids possessed several creodont features, such as an unossified tympanic bulla (a large bubble of bone or cartilage surrounding the internal ear) and lack of fusion of the carpal (wrist) bones. Miacids differed from the creodonts in having a larger brain capacity, toe sections that were not grooved, and well-developed carnassial teeth. The carnassials, as in modern carnivores, involved the fourth upper premolar and first lower molar.

In the late Eocene and early Oligocene these primitive miacids underwent an adaptive radiation; *i.e.*, they produced diverse lines that seem to have been the beginnings of the present-day families of the Carnivora. The changes needed to convert a miacid into a modern terrestrial carnivore are minor: fusion of the separate bones of the carpus and ossification of the tympanic bulla. Carnivores that began to resemble the modern weasels, dogs, and civets were in evidence in the Oligocene, but these early carnivores were still quite similar to each other and had not differentiated to the extent of representing different families.

Two major lines within the Carnivora were distinct by the late Eocene. One, the Feloidea (or Aeluroidea), today contains cats, viverrids, and hyenas; the other, the Arctoidea (or Canoidea), contains the mustelids, dogs, bears, and raccoons. Some fossils are intermediate between the two lines, but most show definite relationships to one or the other.

Feloids had the tympanic bulla made up of an external (tympanic) and an internal (endotympanic) bone, each being a separate ossification. In many forms the claws were retractile. The transition between the miacids and viverrids (civets) was so gradual that some authorities have placed the miacids in the family Viverridae. Because of the similarities to the miacids, the viverrids are considered to form the basal stock of the feloid line. Hyenas appear to be a more recent line, having evolved from the viverrids in the early Miocene. *Ictitherium*, a mid-Miocene viverrid, had characteristics intermediate between the viverrids and hyenas, but apparently was more like the "true" hyenas. Other fossil viverrids also showed similarities to the hyenas. Although the cats seem to have evolved "suddenly," the resemblance of certain catlike viverrids (such as the Oligocene *Stenoplesictis* and the modern *Cryptoprocta* of Madagascar) to the recognized felids is regarded by some authorities as indicating the close relationship of the felids to the viverrids. In the late Eocene and early Oligocene, the felids were quite distinct, with a number of highly specialized cats already present. Of particular interest are the sabre-toothed cats such as *Hoplophoneus* and the false sabre-tooth *Dinictis*, which had large upper canines fitting into a flange on the lower jaw. The Pleistocene *Smilodon*, a more recent genus, is probably the best-known sabre-toothed cat. The genus *Felis* dates back to the early Pliocene, by which time its members had features similar to those of the modern cat.

Sabre-toothed cats

In contrast to the feloids, the arctoids almost never had retractile claws; the tympanic bulla was made up of the tympanic bone alone; and there was a canal below the bulla, through which the carotid artery passed, supplying blood to the brain. Some of the earlier miacids are difficult to separate from the mustelids, which were distinct

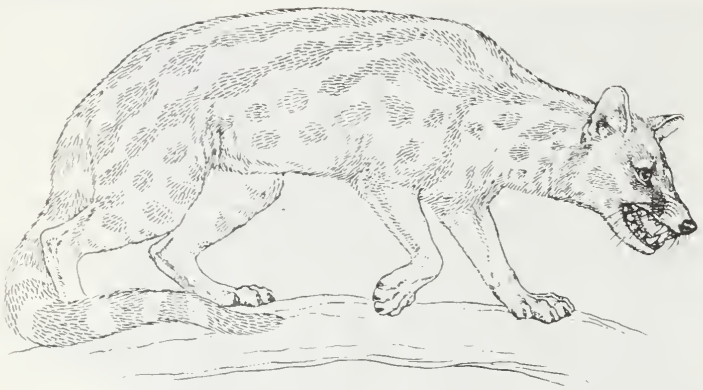

Figure 37: Oligocene carnivore, *Hesperocyon*, an ancestor of the dogs.

as early as the late Eocene. They probably were one of the first arctoid lines to differentiate. By the close of the Miocene, several general types of mustelids were evident: the weasels, badgers, skunks, and otters. Another ancient arctoid line included the dogs. Oligocene canids, represented by the genera *Cynodictis* and *Hesperocyon*, resembled elongate, short-legged weasels and civets. Both genera, although considered to be primitive dogs, were generalized enough to be ancestral to many carnivores. Genera that were more typically canid appeared in the early Oligocene. These were running animals, with four well-developed toes and reduced hindtoes (hallux and pollex), each ending in a blunt claw. More than 50 genera of doglike forms are known, but the main line of evolution seems to have passed through forms like *Temnocyon* (upper Oligocene) and *Cynodesmus* (lower Miocene) to the modern genera *Canis* (first seen in the lower Pliocene deposits), *Vulpes* (perhaps in the upper Miocene), and *Urocyon* (Pleistocene). Two lines of extinct canids are the hyena-like dogs and the bear dogs, neither of which has any relationship to the living hyenas or bears. Because of the close relationships of the bears, dogs, and raccoons, various taxonomists have disagreed on the placement of intermediate genera. For example, *Dinocyon*, *Hemicyon*, and *Cephalogale* were once considered to have been canids but are now placed with the bears and regarded as perhaps part of the ancestral lineage that diverged from the canid line in the late Oligocene or early Miocene. *Phlaocyon* and *Aletocyon* were once considered to be primitive procyonids because of their teeth, but the skull and ear structures are more reminiscent of the dogs. A recent

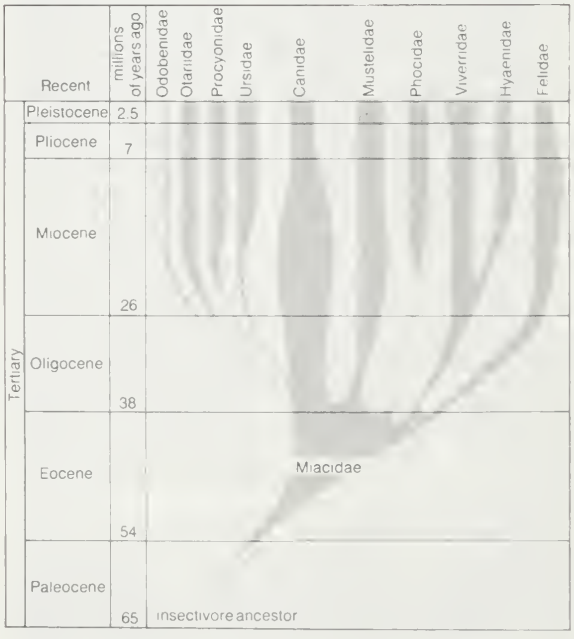

Figure 38: Phyletic dendrogram of Carnivora.

form, the giant panda (*Ailuropoda*), considered by some to be a bear and by others to be a procyonid, probably diverged from primitive ursid stock when the ancestor of the bear and raccoon lines still had features common to both. Procyonids (raccoons) are poorly represented in the fossil record, perhaps because of their arboreal habits. They appear to have diverged from the canid line in the late Oligocene.

The preponderance of carnivorous and carrion-eating fishes and mammals in the open sea, along with the buoyant characteristics of the bodies of the pinnipeds, results in the almost immediate destruction of any seal that dies. Thus, dead pinnipeds seldom settle intact and become buried (the first steps toward becoming a fossil) and are poorly represented in the fossil record. Relationships must instead be inferred through studies of recent forms. Although there is no fossil record of pinnipeds prior to the Miocene, it is probable that the ancestors of the pinnipeds evolved during the adaptive radiation of the miacids in the Eocene.

Evolution of pinnipeds

There are two rather distinct evolutionary lines in the animals called pinnipeds. One includes the two rather closely related families Otariidae and Odobenidae. This line may have become distinct in the early Miocene or late Oligocene, evolving from a form closely related to the canid ancestor of the bears. The other line led to the modern phocids, which are quite different from the otarid–odobenid group. Their affinity to any other group of the Carnivora has not been shown, although the mustelids have more frequently been suggested as related to the phocids than any other group. *Semantor*, an aquatic carnivore from the lower Pliocene, was once considered to belong to a separate pinniped family but is now considered a mustelid. The separation of the phocid and otarid–odobenid lines must have occurred at an extremely early date, if the two lines ever had a common pinniped ancestor. Some paleontologists postulate a separation in the early Miocene or late Oligocene. Possibly the two lines never evolved from a single aquatic group but had separate origins within the miacids, sometime in the late or even mid-Eocene. Or perhaps the otarids stemmed from an ancestral ursid type in the early Oligocene. Such an early separation, or lack of any real ancestral association, could have produced the dissimilarity of the two types of pinnipeds, as well as the difficulty in associating the phocids with any other family of the Carnivora.

CLASSIFICATION

Distinguishing taxonomic features. If one groups the seals with the terrestrial carnivores, the number of characteristics common to all members of the order Carnivora is small.

The characteristics used to separate the Carnivora from other mammalian orders and to define the subdivisions of the Carnivora are primarily structural. Of great importance are certain features of the skull (the type of jaw articulation and the shape of the paroccipital process), of the feet (the number of toes, lack of opposability of the hindtoe, type of claws, and fusion of the scaphoid and lunar bones), and of the teeth (both the overall tooth pattern and the shape of the individual tooth). The dentition is especially important in determining the relationships of fossil forms. Also useful in the taxonomy of modern carnivores are the convolutions (irregular ridges) around the lateral or sylvian fissure of the brain, the relative weights of the adrenal and thyroid glands, the type of uterus and placenta, and the position of the nipples.

Annotated classification. Although the terrestrial and marine carnivores are grouped together in the following classification, many authors separate them into two orders. In this article the split is indicated by erecting two suborders, the Fissipedia and Pinnipedia, based largely on the degree of specialization undergone by the members as they evolved and adapted to radically different environments. Basically the taxonomy presented combines the classifications by G.G. Simpson and A.S. Romer, North American paleontologists.

Numerical dental formulas are used below to indicate the number of each type of tooth in the right or left half

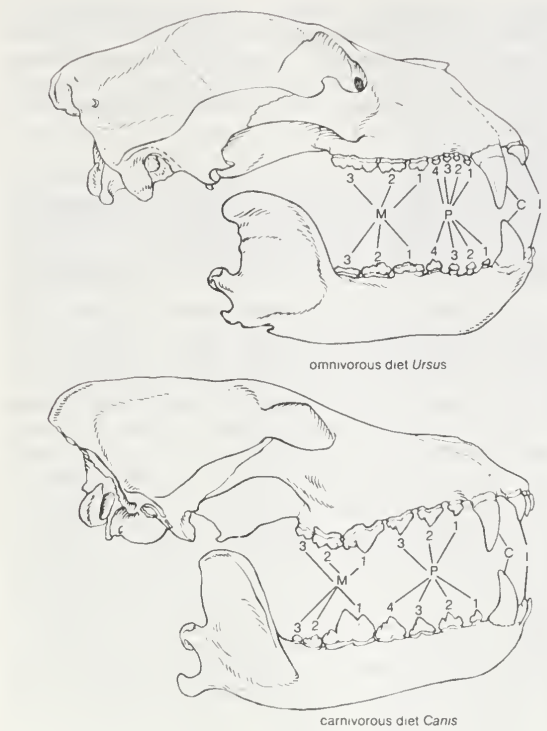

Figure 39: Tooth patterns in omnivorous and carnivorous members of Carnivora. Side view of lower mandible and cranium.

From Hall and Kelson, *The Mammals of North America* vol. II, copyright © 1959 The Ronald Press Company, New York

of the upper and lower jaws and the total number of teeth in the mouth. Four tooth types are indicated in the following manner:

$$\text{Upper jaw: } \frac{\text{incisors . canines . premolars . molars}}{\text{Lower jaw: incisors . canines . premolars . molars}} = \text{total number of teeth}$$

ORDER CARNIVORA

Medium- to large-sized terrestrial or aquatic meat eaters distributed worldwide; composed of 10 extant families, about 115 living genera, and 274 living species.

Suborder Fissipedia

Terrestrial (except otters and polar bear); usually 3 pairs of incisors above and below, adapted for biting off flesh; premolars vary in number from the usual 4 on each half of each jaw (4/4) to 4 above and 2 below (4/2); molars vary from 2/3 to 1/2; carnassial teeth well developed and formed by the 4th upper premolar and 1st lower molar; usual dental formula: $\frac{3 \cdot 1 \cdot 4 \cdot 2}{3 \cdot 1 \cdot 4 \cdot 3} = 42$ teeth; all-inclusive dental formula: $\frac{3 \cdot 1 \cdot (2\text{–}4) \cdot (1\text{–}4)}{(2\text{–}3) \cdot 1 \cdot (1\text{–}4) \cdot (1\text{–}5)} = 28\text{–}50$ teeth; facial part of skull usually elongate; tympanic bullae large; alisphenoid canal (a perforation in the skull for a branch of the carotid artery) usually present; lacrimal duct present; pelvis at distinct angle from vertebral column; femur (thigh bone) straight, moderately slender, with small head; fibula (minor lower bone of hindlimb) much smaller than tibia (shinbone); 1st metatarsal and bones of phalanges with epiphyses only at proximal ends; metapodials never elongate; vertebrae with interlocking processes; external ears (pinnae) well developed; intestine short (6 to 8 times length of body in dog); kidneys simple, not lobulate except in otters and young bears.

Superfamily Miacoidea

All extinct generalized carnivores with carnassial teeth. Middle Paleocene to upper Eocene. There is one family, Miacidae, about 13 genera.

Superfamily Feloidea (cats, civets, and hyenas)

Tympanic bullae divided, composed of external tympanic and internal endotympanic bones; paroccipital process in close contact with bullae; most have retractile or semiretractile claws; cecum small; baculum (bone of penis) present or absent; usually polyestrous; upper Eocene to Recent; 42 living genera and 115 species.

Family Viverridae (civets and mongooses). Upper Eocene to Recent. Distributed throughout most of the southern regions of the Old World (Asia, Europe, Malay Peninsula, most of Africa, Madagascar, and associated southern oceanic islands) but most abundant in the India–Malay region; introduced on New Zealand, Hawaii, and the West Indies. Small to medium sized (0.7 to 14 kg; 1.5 to 31 lb). Well-developed carnassials; upper carnassials usually lack an anterior lobe and the lower carnassials have a well-developed talonid process; middle incisor on each side located farther inward than the outer 2; incisors broad; 4 small premolars, with 1st minute or absent; molars 2/2 or in some cases 1/2 (*Prionodon*), 2/1 (*Salanoia*), or 1/1 (*Cryptoprocta*); molars large, especially the 1st; dental formula usually $\frac{3 \cdot 1 \cdot (3\text{–}4) \cdot 2}{3 \cdot 1 \cdot (3\text{–}4) \cdot 2} = 36\text{–}40$ teeth. Alisphenoid canal usually present (absent in *Eupleres* and most members of subfamily Galidiinae); entepicondylar foramen of humerus usually present; auditory bulla externally constricted and divided by septum. Baculum well developed. Intestinal cecum small, sometimes absent. Elongate body, short legs; digitigrade or semiplantigrade gait; 5 toes usually present, with semiretractile claws (retractile in *Cryptoprocta*); pollex and hallux located on side of foot above other toes. Ears small and rounded; tail usually long (12–90 cm; 4.7–35 in.) and bushy or tapering to a point from a bushy base. Scent glands often well developed, producing secretion called "civet." Usually uniform in coloration but some spotted or striped.

Subfamily Viverrinae (true civets, genets, and linsangs). Mainly African; approximately 7 living genera and 15 species.

Subfamily Paradoxurinae (palm civets). Mainly Asian, 6 living genera and 8 species.

Subfamily Hemigalinae (banded palm civets, web-footed civets). Asia or Madagascar, 5 living genera and 7 species.

Subfamily Galidiinae (striped and ring-tailed mongooses). Restricted to Madagascar, 4 living genera and 7 species.

Subfamily Herpestinae (true mongooses and meerkats). All African, 13 living genera and approximately 37 species.

Subfamily Cryptoproctinae (fossa). Monotypic. *Cryptoprocta ferox*, found only in Madagascar.

Subfamily Stenoplesictinae. Fossil. Upper Oligocene to middle Miocene of Europe.

Family Hyaenidae (hyenas and aardwolves). Middle Miocene to Recent. Found today throughout most of Africa and southern Asia (Turkey to eastern India). Medium-sized (10 to 80 kg; 22 to 175 lb) carrion feeders; teeth specialized for crushing bones; incisors unspecialized, outer (3rd) larger than other 2; canines powerful; premolars strong and conical; molars strong and large; carnassials well developed (hyenas); long, slender canines in aardwolf (*Proteles*) with small and widely spaced premolars, small molars, and no development of carnassials. Dental formula $\frac{3 \cdot 1 \cdot 4 \cdot 1}{3 \cdot 1 \cdot 3 \cdot 1} = 34$ teeth for hyenas; premolars 3/(2–1), molars 1/(1–2) = 28–32 for aardwolf. Alisphenoid canal absent; auditory bullae partially divided by a rudimentary septum in hyenas, divided in aardwolf; front legs longer than rear legs; digitigrade; 4 toes (5 on forefoot in aardwolf); claws blunt and nonretractile; entepicondylar foramen absent; baculum absent; more thoracic vertebrae (15) than any other feloid; tail of medium length (20 to 33 cm) and bushy. Preanal scent glands absent. Cecum 15 to 23 cm (6 to 9 in.) long. Short mane usually present. Ears large and rounded.

Subfamily Protelinae (aardwolf). African. 1 species. *Proteles cristatus*.

Subfamily Hyaeninae (hyenas). Africa and southwest Asia; 2 living genera, 3 species.

Subfamily Ictitheriinae. Fossil. Miocene–Pliocene. 1 Old World genus.

Family Felidae (cats). Upper Eocene to Recent. Now worldwide except for Antarctica, Australia, Madagascar, and some oceanic islands. Size medium to large (2.5 to 275 kg; 5.5 to 600 lb). Highly carnivorous; well-developed carnassials. Total number of teeth reduced from primitive carnivore condition; dental formula typically $\frac{3 \cdot 1 \cdot 3 \cdot 1}{3 \cdot 1 \cdot 2 \cdot 1} = 30$ teeth; alisphenoid canal absent; auditory bullae not constricted externally; posterior palatine foramina on maxillopalatine suture instead of on maxilla. Elongate body with relatively short legs; digitigrade; 5 toes on front, 4 on rear feet, capped with sharp, curved, retractile claws. Entepicondylar foramen present; baculum absent or vestigial; cecum small; tail short (lynx) to long (up to a third of total length). Preanal scent glands absent; tongue covered with horny papillae.

Subfamily Felinae (lynxes, typical cats, lions, tigers, leopards). Worldwide except Antarctica, Australia, Madagascar, and most oceanic islands. 2 living genera, 35 species.

Subfamily Acinonychinae (cheetah). Africa and southwest Asia. 1 species, *Acinonyx jubatus*.

Subfamilies Proailurinae, Nimravinae, Machairodontinae, Hyainailourinae. All fossil. About 39 genera.

Superfamily Canoidea (dogs, bears, raccoons, and weasels)

Tympanic bulla formed from tympanic bone only; not divided into 2 chambers; long canal beneath bulla; paroccipital process prominent and independent of bullae. Claws nonretrac-

tile. Cecum present or absent; baculum well developed; usually monestrous (1 litter of young per year). Eocene to Recent; 53 living genera and 133 species.

Family Canidae (dogs, foxes, jackals). Eocene to Recent. Now worldwide except Antarctica and most oceanic islands. Size medium (1.5 to 80 kg; 3.3 to 175 lb). Carnivorous or omnivorous; well-developed carnassials; dental formula typically $\frac{3 \cdot 1 \cdot 4 \cdot 2}{3 \cdot 1 \cdot 4 \cdot 3} = 42$; bush dog (*Speothos*) with (1–2)/2 molars (1 upper molar is sometimes minute or absent) = 38 to 40 teeth; Cape fox (*Otocyon*) with (3–4)/(4–5) molars = 46 to 50 teeth. Facial part of skull elongate; alisphenoid canal present; legs long and semirigid; digitigrade with 5 toes on front (1 dew claw) and 4 on rear foot; claws blunt and nearly straight. Entepicondylar foramen absent; baculum well developed and grooved. Cecum always present, short and simple or long and characteristically folded. Tail relatively long (up to about a third of total length) and bushy; scent glands often on dorsal part of base of tail. Ears pointed, erect, and large.

Subfamily Caninae (dogs, jackals, and foxes). Worldwide except Antarctica and most oceanic islands; dingo probably introduced on Australia in prehistoric times; wild dogs of New Guinea probably derived from domestic dogs. 11 living genera and approximately 37 species.

Subfamily Simocyoninae (dhole, hunting dog, bush dog). Asia, Africa south of the Sahara, and northern South America. 3 living monotypic genera: *Cuon alpinus, Lycaon pictus, Speothos venaticus.*

Subfamily Otocyoninae (big-eared fox). Eastern and southern Africa; monotypic, *Otocyon megalotis.*

Subfamilies Amphicynodontinae, Amphicyoninae, Borophaginae. Fossil only. Total genera about 34.

Family Ursidae (bear and giant panda). Middle Oligocene to Recent. Restricted to larger land masses of world, ice floes of Arctic, and in South America to Andes; bear of Atlas Mountains of northwest Africa now extinct. Size medium to large (27 to 780 kg; 60 to 1700 lb); usually omnivorous; carnassials poorly developed; dental formula variable, but typically $\frac{3 \cdot 1 \cdot 4 \cdot 2}{3 \cdot 1 \cdot 4 \cdot 3} = 42$ teeth. Skull elongate; alisphenoid canal present. Legs short, large, and powerful; plantigrade; 5 toes on each foot, capped by elongate, powerful, nonretractile claws. Entepicondylar foramen of humerus usually absent; lacrimal bone of skull, clavicle, and cecum absent; tail short, practically absent; ears small and rounded; lips mobile and free from gum. 6 genera and 8 living species.

Family Procyonidae (raccoons, coatis, lesser panda). Upper Eocene (probably) to Recent. Fossils through Pleistocene in Europe. Except for the lesser panda (*Ailurus*) of the southeastern Himalaya region of Asia, family is restricted to northern South America, Central America, and southern North America. Size medium (0.8 to 22 kg; 1.75 to 48.4 lb); omnivorous; carnassials poorly developed; dental formula usually $\frac{3 \cdot 1 \cdot 4 \cdot 2}{3 \cdot 1 \cdot 4 \cdot 2} = 40$, with some variation in number of premolars (kinkajou 3/3, lesser panda 3/4); alisphenoid canal absent except in *Ailurus;* legs of medium length; semiplantigrade to plantigrade; 5 flexible toes on each foot capped by nonretractile or semiretractile claws; entepicondylar foramen sometimes present; baculum well developed and, except for *Ailurus,* bilobed and hooked at distal end; cecum absent; clavicle vestigial; tail long (20 to 70 cm; 7.9 to 27.6 in.), often ringed, prehensile in *Potos;* ears small to medium in size and rounded. 7 living genera and approximately 14 species.

Family Mustelidae (weasels, badgers, skunks, otters). Eocene to Recent. Now worldwide except Madagascar, Australia, and most oceanic islands; introduced into New Zealand; more common in Northern Hemisphere. Size from smallest of carnivores (35 gm; 1.2 oz) to medium; mainly carnivorous; carnassials usually well developed; dental formula usually $\frac{3 \cdot 1 \cdot 3 \cdot 1}{3 \cdot 1 \cdot 3 \cdot 2} = 34$ teeth but may range from 30 to 38 teeth, with variation in incisors (3/2 in sea otter), molars (1/1 in ratel and African striped weasel), but especially premolars (2/3 in the African striped weasel, 4/2 in the river otter, 4/4 in American badger); alisphenoid canal absent; legs short in relation to elongate body; plantigrade to digitigrade; 5 toes on each foot, capped with nonretractile claws; entepicondylar foramen present or absent; tail usually long (up to 1/3 of total length); ears small and rounded; anal scent glands well developed.

Subfamily Mustelinae (weasels and Old World polecats). Subfamily with widest distribution and most kinds. There are 11 genera and 33 recent species.

Subfamily Mellivorinae (ratel or honey badger). African and southern Asia. There is 1 species, *Mellivora capensis.*

Subfamily Melinae (badgers). North America, Europe, Asia, with most forms found in Southeast Asia. There are 6 genera and 8 recent species.

Subfamily Mephitinae (skunks). New World only. There are 3 living genera and 11 species.

Subfamily Lutrinae (otters). Worldwide. There are 5 living genera and 19 species.

Subfamily Leptarctinae. Fossil. Miocene and Pliocene. New World. 3 genera.

Suborder Pinnipedia

Aquatic; teeth nearly homodont (uniform) and adapted for grasping and tearing, not chewing; 2 pairs of incisors below; postcanines (premolars and molars) similar, never more than 2-rooted, and usually 5 on each jaw (varies from 3 to 7); carnassials absent; usual dental formula $\frac{3 \cdot 1 \cdot 5\ \text{(postcanines)}}{2 \cdot 1 \cdot 5\ \text{(postcanines)}}$ = 34 teeth; all inclusive dental formula $\frac{1\text{–}3 \cdot 1 \cdot (3\text{–}7)}{0\text{–}2 \cdot 1 \cdot (3\text{–}6)}$ = 18–38 teeth; cranial part of skull longer in proportion to facial part than in most fissipeds; face profusely innervated by extremely large trigeminal nerve; brain more spherical and with greater development of convolutions than fissipeds. Tympanic bullae small in some; alisphenoid canal present or absent; lacrimal duct absent; basioccipital and sphenoid relatively large as compared with fissipeds; pelvis small and nearly parallel to vertebral column; femur broad, flattened, with globular head on short neck; fibula almost as large as tibia; metatarsals and all bones of phalanges with epiphyses at both ends of shaft; metapodials elongate; 5 well-developed digits on each limb; 1 digit on manus and 1st and 5th digits of pes usually longer than other digits; feet fully webbed; nails small to absent; baculum massive. Fusiform-shaped body; external ears (pinnae) reduced or absent; tail short or vestigial (5 to 20 cm [2 to 8 in.] long) with 8 to 15 caudal vertebrae. Intestine long; cecum short; kidneys lobulate. Thick layer of subcutaneous fat (blubber). One large, precocial young.

Family Otariidae (eared seals). Lower Miocene to Recent. Coastlines of Pacific, South Atlantic, and Indian oceans. Hindlimbs useful for support on land; nails well developed on middle 3 digits, rudimentary on outer ones. Small external pinnae of ears. 2 pairs of lower incisors; upper incisors of 1st pair notched transversely; usually 20 to 22 postcanine teeth; dental formula $\frac{3 \cdot 1 \cdot 4 \cdot (1\text{–}3)}{2 \cdot 1 \cdot 4 \cdot 1} = 34$ to 38 teeth. Males are 2 to 4 times as large as females (males 120 to 1,000 kg [265 to 2,200 lb]; females 60 to 270 kg [130 to 600 lb]); testes suspended in distinct external scrotum; small but distinct tail; obvious neck; skin whitish or light gray.

Subfamily Otariinae (sea lions). Coastal regions of northern and eastern Pacific Ocean, southern Australia and southwestern New Zealand; coastal regions off eastern coast of South America. There are 4 living genera and 5 species.

Subfamily Arctocephalinae (Pacific and southern fur seals). Southern coastal areas of all southern continents; north Pacific region. There are 2 living genera, 7 species.

Family Odobenidae (walrus). Upper Miocene to Recent. Circumpolar holarctic distribution, seldom south of about 58° north latitude. Hindlimbs useful for support on land. External pinnae absent; postorbital process absent; alisphenoid canal present. Lower incisors absent in adult; upper canines of both sexes form tusks; usually 12 postcanine teeth; dental formula $\frac{(1\text{–}2) \cdot 1 \cdot (3\text{–}4) \cdot 0}{0 \cdot 1 \cdot (3\text{–}4) \cdot 0} = 18\text{–}24$ teeth; males larger (up to 1,270 kg; 2,800 lb) than females (up to 860 kg; 1900 lb). Testes abdominal (internal). No free tail. Skin whitish or light gray. Monotypic, *Odobenus rosmarus.*

Family Phocidae (earless seals). Middle Miocene of Europe and North America; Pliocene of Asia; lower Pleistocene of Africa; Recent along northern and southern coastal areas, sporadic in tropical and southern regions. Hindlimbs useless on land (cannot be placed forward under body); nails equally well developed on all digits; external pinnae absent; postorbital process rudimentary or absent; alisphenoid canal absent; 2 to 4 lower incisors; usually 16 to 20 postcanine teeth; dental formula $\frac{(3\text{–}2) \cdot 1 \cdot 4 \cdot (0\text{–}2)}{(1\text{–}2) \cdot 1 \cdot 4 \cdot (0\text{–}2)} = 26$ to 36 teeth; males may be much larger than females (elephant seal, hooded seal), slightly larger (some members of subfamily Phocinae), equal in size (some Phocinae and some Monachinae), or females may be larger than males (some Monachinae); olfactory apparatus reduced; testes abdominal; stubby tail; no visible neck; skin brown or black.

Subfamily Phocinae (northern seals). Northern temperate to Arctic waters; 7 living genera and 9 species.

Subfamily Monachinae (southern seals). Tropical and Southern Hemisphere waters; 6 living genera and 9 species.

Critical appraisal. The taxonomy of the major categories of major groups placed in the Carnivora has been in a state of flux for at least 100 years, and these categories do not seem to be stabilizing, even today. Most

mammalogists at present regard the seals and terrestrial carnivores as belonging to different orders, the Pinnipedia and Carnivora. There are, in reality, only a few features common to the seals and their terrestrial relatives because of the extensive and numerous adaptations the aquatic forms have undergone to make them efficient carnivores of the sea. Mammalogists who have studied seals intensively now realize that there is no anatomical structure unmodified by the extensive aquatic adaptations; every organ and tissue examined has been found to be different in some way from its counterpart in terrestrial forms. In many, if not most, ways there is more difference between seals and terrestrial carnivores than between the bats and the insectivores, and few mammalogists would place the bats and insectivores in the same order. Other mammalogists, tending toward conservative taxonomy, feel the relationship of the terrestrial and aquatic carnivores can be best expressed by retaining them in two suborders, the Fissipedia and Pinnipedia, of the single order Carnivora. The conservative attitude is retained in this article.

Divergence of seals

Of the 10 living families recognized in the Carnivora, two have separated from their lines most recently and are most easily associated with other existing families: the Odobenidae with the Otariidae and the Hyaenidae with the Viverridae. The family Procyonidae has perhaps the greatest number of taxonomic problems. It appears to be a collection of primitive forms whose relationships are not yet clear. Most of the living genera have at one time been placed in distinct families or subfamilies (Nasuidae, Bassariscidae, Ailuridae, Bassaricyonidae, Procyoninae, Potosinae). In most other families there are also genera sufficiently different from other members of their family that they have been given separate families (the canids *Lycaon* and *Otocyon;* the giant panda *Ailuropoda;* the otters; the viverrid fossa *Cryproprocta;* and the aardwolf *Proteles*).

The arrangement of the 10 families into two distinct superfamilies, Canoidea and Feloidea (or Aeluroidea), appears to be a natural arrangement dating back to the works of W.H. Flower and H. Winge in the late 1800s. In the Canoidea, as revealed by studies in comparative anatomy and the fossil record, the families Canidae, Ursidae, and Procyonidae seem to be most closely related. Also placed in the Canoidea is the family Mustelidae, although some of the more primitive members show resemblances to the primitive viverrids as well as the canids. In the Feloidea, the families Viverridae and Hyaenidae seem most closely related, the Felidae being the most aberrant.

Those families that contain rather diverse lines have been divided into subfamilies; the number of subfamilies in each family indicating the amount of evolutionary divergence that has occurred. The groups that have probably been distinct the greatest length of time have the most subfamilies; the Viverridae with six and the Mustelidae with five. Within the viverrids some of the subfamilies are distinct, a few less distinct. Most distinct are the subfamilies Herpestinae and Cryptoproctinae. The Cryptoproctinae seems to be an ancient group with the genus *Cryptoprocta* retaining characteristics of the felids as well as the viverrids, so much so that some taxonomists have placed *Cryptoprocta* in the felids, although most mammalogists regard them to be more similar to the viverrids. The remaining four subfamilies have been combined and split in a number of ways. Usually retained, along with the two above subfamilies, are the subfamilies Viverrinae and Galidiinae. Each of the five mustelid subfamilies seems to be distinct from the others. Some authorities feel that the skunks and badgers may be close enough to place them in the same subfamily. Of the five subfamilies, the most diverse is the Mustelinae, with 11 distinct genera.

What much of the discussion above means, in terms of critical taxonomic appraisal, is that a system of classification is in some ways an artificial system set up for the convenience of man. Ideally, the system reflects real evolutionary relationships, but these must be inferred from a scanty fossil record and from comparisons of modern species. Since there are differences of opinion among specialists as to which taxonomic characters should be given the most weight, there are certain to be alternate classifications, the acceptability of which depends on new information continually being discovered. Just as the animals have evolved, so does the taxonomic system. (H.J.S.)

Cetacea (whales, dolphins, porpoises)

The order Cetacea consists of a group of primarily marine mammals occurring throughout the seas of the world and in certain tropical rivers and lakes. The name whale is often applied by scientists as a general name for the larger species; most of the smaller members of the order are called dolphins or porpoises. (The traditional grouping of these mammals in the single order Cetacea is not universally accepted. This disagreement is reflected in varying systems of classification [see below, *Annotated classification* and *Critical appraisal*]).

General features. The order Cetacea includes three distinct suborders: Archaeoceti, an extinct group of toothed whales; Odontoceti, the modern toothed whales; and Mysticeti, the baleen, or whalebone, whales. In addition to skull characteristics, the three groups are distinguishable by dentition: the archaeocetes were heterodont (*i.e.,* the anterior teeth were quite different in shape from the posterior ones), and milk teeth in the young were replaced by permanent teeth in the adult, as in most mammals; the odontocetes are mostly homodont (teeth of uniform shape), and most lack milk teeth; adult baleen whales lack teeth, and the animal feeds by straining minute organisms from the water by the baleen plates (see below). The odontocetes include about 70 species—the porpoises, dolphins, pilot whales, or "potheads," false killer whales, beaked whales, the sperm whale, and a few lesser known forms. They range in length from about 1.3 metres (4.3 feet) in the smaller porpoises to about 19 metres (62 feet) in the male sperm whale. The maximum length of the 10 species of baleen whales ranges from six metres (about 20 feet), in the case of the pygmy right whale (*Caperea marginata*), to about 33.6 metres (110 feet) in the largest recorded specimen of the blue whale (*Balaenoptera musculus*). A great range of adult weight is encompassed by the Cetacea, from about 45 kilograms (100 pounds) in some small porpoises to about 136,000 kilograms (150 tons) in the blue

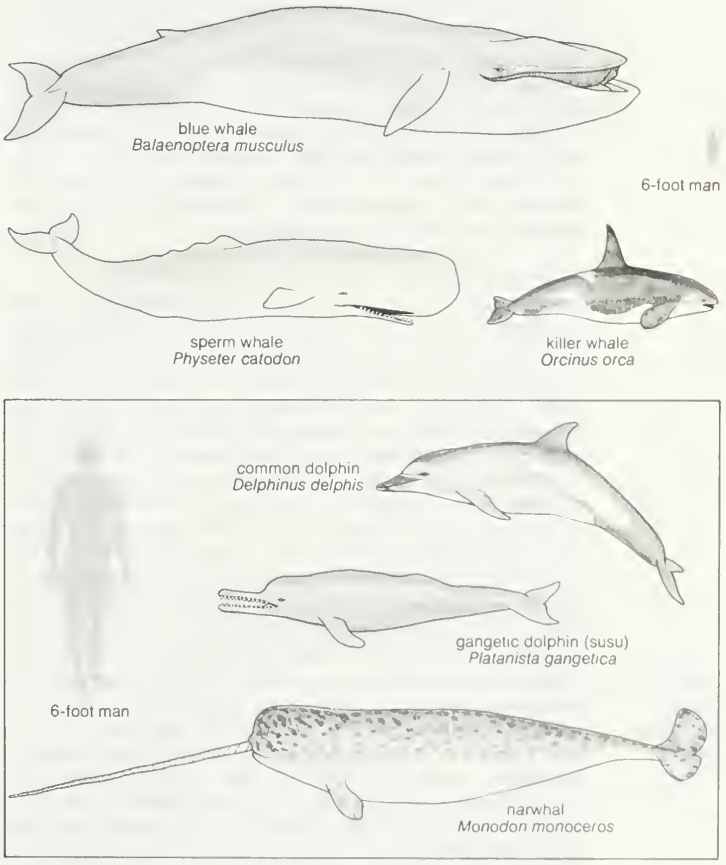

Figure 40: Body plans of representative cetaceans.

whale. The body of modern whales is fusiform (tapered); the tail, which ends in a horizontal blade (the flukes), is used for propulsion. The flukes are unsupported by bone. There is usually a dorsal fin on the back, also unsupported by bone. Breathing is accomplished rapidly at the water surface through paired (in mysticetes) or single (in odontocetes) blowholes, which are generally located on top of the head, some distance behind the tip of the snout. The exhalation produces the familiar spout, through the sudden condensation of water contained in the breath. Following inhalation, the animal holds its breath for variable periods, as it swims beneath the surface. Dives of smaller cetaceans last a few minutes, but those of some larger species may last an hour and perhaps longer.

Breathing through blowholes

The cetaceans are an ancient group, having split off from other mammals early in the history of the Mammalia. In spite of their many and profound adaptations for aquatic life, cetaceans are typical mammals, developing their young internally and giving birth at sea, nursing the young with milk, and possessing internal heat control mechanisms, or warm-bloodedness. Although hair is largely absent in most adult whales, the evidence from fetal or newborn animals indicates that the lack of hair is a secondary loss (*i.e.*, that hair was present in the ancestors of whales).

Importance to man. Many of the more abundant whales and porpoises are commercially important, their meat being used as food for animals and (especially in Japan) for humans and their oil for industrial lubrication and for conversion into soaps and fatty acids, which are used in cosmetics and detergents.

About two dozen countries have engaged in commercial whaling at one time or other, but by the early 1970s only Japan and the Soviet Union maintained whaling fleets in open ocean, the fleets of other countries having ceased operations as a result of declining markets for whale products and drastically reduced populations of the commercially valuable whales. Several other countries have continued to take whales from shore stations. Limitations on catches of the larger cetaceans, imposed by the International Whaling Commission (IWC), were too late to prevent the near extinction through overexploitation of the blue whale by the late 1950s. Populations of the fin whale (*Balaenoptera physalus*) have declined sharply under heavy fishing pressure. The decline in these species has led to increased pressure on the sei whale (*B. borealis*) and the sperm whale (*Physeter catodon*), by 1970. Effective regulation of commercial whaling in international waters to a level that would allow a sustained yield without depleting whale populations has been handicapped by the inability of the IWC to impose obligatory controls on its members. In 1971 the United States declared the commercially exploited whales to be endangered species and prohibited by law the importation of all whale products.

NATURAL HISTORY

Behaviour. *Social behaviour.* Most toothed whales spend their entire lives in tightly organized schools, which may range in numbers from a few animals to 1,000 or more individuals. Baleen whales are more often found singly, although small schools, or pods, occur on the breeding grounds, and whales may congregate in feeding areas in considerable numbers. Odontocete schools, at least, may be quite complex in structure, involving family groups, groups segregated by age and sex, and even schools composed of two or more species. Bottle-nosed dolphins (*Tursiops truncatus*), for example, are often found associated with schools of pilot whales (*Globicephala* species) in some areas and move with them, apparently because the food-finding capability of the large whale school is greater than that of the smaller dolphin group. Schools of toothed whales show a variety of swimming patterns, including movements as a rank or front, single file, or a more formless pattern. Within schools, subgroups usually swim, feed, and dive independently, except when the school is frightened or travelling rapidly; then members may pack together and leap and dive more uniformly. Groups of mothers with young are usually found together near the centre of a school.

Swimming patterns of toothed whales

Studies of captive odontocete schools, especially of bottle-nosed dolphins, have shown that mother–young relations may persist for several years, with the young returning to its mother in times of stress even when full grown. Other nonrelated females may also be part of such groups and may assist during birth and in defense against males. Adult males tend to segregate within the school, except during the breeding season; juvenile males may gather in small groups. Dominance hierarchies exist in which both males and females exert leadership, though dominance is strongest in large adult males. Aggression by the leader is used to establish such relationships and may take the form of biting, hitting the offender with the tail, clapping the jaws intimidatingly, or ramming with the snout. Juvenile males of many species are especially apt to be heavily scarred with tooth marks. Biting or raking with the teeth is also a marked part of sexual activity, and females are therefore apt to be scarred, especially in the genital area.

Play. Play, although common in odontocetes, is almost unknown in mysticetes. In porpoises, much play is sexual in nature, consisting of rubbing or prodding the genitals with the snout or fins and flippers, usually accompanied by sound production of a complicated character. Other forms of play consist of balancing floating objects, such as kelp, sticks, or feathers, on the fins and flukes, or holding objects in the mouth. Younger killer whales and sperm whales have been seen pushing small logs or planks; food items are also used. Fish may be thrown into the air or proffered to other fish lurking in crevices, apparently to lure them into the open. Underwater observations at sea have revealed porpoise groups swimming and diving together in complicated ballet-like movements, riding ocean swells or breaking surf, in precise formation swimming. In pilot whales, playlike swimming patterns have been observed, the animals resting vertically, head down, with a metre or so of their tails in the air, or swimming on their backs.

Epimeletic behaviour. Behaviour in which one animal assists another in trouble (epimeletic behaviour) is marked in whales, having been noted in both mysticetes and odontocetes. It consists of "standing by," in which school members refuse to leave a wounded animal or actually support a sick animal, sometimes one of a different species. An extreme form sometimes occurs in porpoises: a mother may support the body of her stillborn calf until it literally rots away. Most whales and porpoises appear to be solicitous of their young, and there are several reports of babies being shielded by the mother or taken on a pectoral flipper and rolled part way out of water.

Fright. Fright is typically shown by a bunching together of school members and rapid swimming, a reaction that has been used by fishermen to capture certain species. The school is frightened by noise production underwater—banging on pipes or metal bars or clacking two rocks together. The animals are run until their shortage of breath prevents deep dives and underwater evasion, and eventually they are herded ashore or into nets. Porpoises sometimes signal moderate levels of fright by slapping the water with the tail flukes.

Causes of fright

Feeding. Two general modes of feeding exist in cetaceans. Mysticetes are strainers who envelop large amounts of water, forcing it through horny fibrous mats of baleen (slatlike horny plates) that hang from the roof of the mouth and swallowing the food that remains on the inner surface of the baleen. The odontocetes actively pursue and capture swimming prey, especially fish and squid. Two types of feeding have been described in baleen whales: the skimming mode, in which the whale swims forward with the mouth slightly open, filtering a continuous column of water as it moves; and the gulping mode, in which the animal engulfs a mouthful of water and forces it out past the baleen before taking another mouthful.

Life history. *Reproduction.* Although all cetaceans are seasonal breeders, this period may be quite long. Adult male porpoises tend to accompany the females who are receptive. Impregnation occurs during the long period from spring to fall and, in both the large baleen whales and the porpoises, birth takes place about 11 to 12 months afterward. The sperm whale is an exception, gestation taking about 16 months. Growth is fairly rapid in all cetaceans,

and the birth size is large; a 1.6-metre (5.2-foot) harbour, or common, porpoise (*Phocoena phocoena*) is known to have given birth to a calf 0.6 metre (two feet) long, and a 30-metre (100-foot) blue whale was found to contain a full-term fetus 7.54 metres (24.7 feet) long.

Birth of whale calves takes place underwater; usually, the tail emerges first. The newborn porpoise is often pushed to the surface by its mother or by an attendant female for its first breath. After the umbilical cord snaps, close to the umbilicus, the baby begins to swim. The fins and flukes are folded and flaccid at birth but harden into proper position within a few hours. The young of both porpoises and larger whales accompany the mother very closely for the first few weeks, often positioning themselves at about the midbody of the parent and taking advantage of water flow, so that they are carried along with a minimum of effort.

Baleen whales apparently breed once every two years and nurse young from seven to more than ten months. The nursing span is more protrated in toothed whales: the young bottlenose dolphin may continue to nurse up to the age of 18 months and the young sperm whale for 12 to 13 months.

Mammary glands and milk

The paired mammary glands in all whales are hidden beneath the body blubber, the nipples being buried in a longitudinal fold located lateral to the genital aperture. Milk, which is secreted into the enlarged lacteal duct, is thought to be forced into the mouth of the baby by contractions of body muscles underlying the mammary gland. In baleen whales and most porpoises, the baby thrusts its snout into the mammary slit, taking the nipple in its tongue and receiving the milk; the tongue, when applied to the palate (roof of the mouth) forms a tube for receiving the milk. The baby sperm whale, which has a bulbous snout, takes the nipple sideways in its jaw. Whale milk is very high in fat content and almost lacking in milk sugar.

Migration. Most baleen whales undergo seasonal migrations, some as long as 5,000 kilometres (3,000 miles) each way, from feeding to calving grounds. With the exception of the sperm whale, odontocete migrations seem to be much more local in character and in some species apparently do not occur at all. There is a seasonal migration of sperm whales from calving grounds near the Equator toward the higher latitudes, but only adult males go beyond the temperate zones.

Summer concentrations of planktonic (free-floating) food, such as the euphausiid crustacea, or krill, are greatest in polar latitudes; hence, baleen whales congregate in these waters to feed. Movements toward the Equator occur in the austral (southern) or boreal (northern) fall and apparently terminate within about 30° of the Equator, usually far at sea, where birth of young takes place in the warm waters. The humpback whale (*Megaptera novaeangliae*) typically frequents island shores at this time, and mothers and young may be seen especially near subtropical islands. Long migrations are apparently made wholly or nearly completely without feeding, except on the summer grounds; the animals live off body fat reserves in the blubber coat. Some baleen whales feed closer to the Equator in such areas as the Persian Gulf and the Gulf of California; migrations in these populations, therefore, are probably of lesser extent. The migratory cycles of the gray whale (*Eschrichtius robustus*) and the humpback conform closely to an annual day length cycle, suggesting that a photoperiodic effect may be involved in the regulation of reproduction.

In the smaller toothed whales, some food-related seasonal movements occur in which porpoises and whales may congregate in certain areas in response to seasonal abundances of squid or fish. Other porpoise species are sedentary, and some continuously occupy discrete portions of a shoreline. Odontocetes apparently do not undergo prolonged periods of starvation and thus must have continuously available food supplies.

Locomotion. *Swimming and diving.* Swimming is accomplished by vertical undulatory movements of the tail, the thrust coming from both the horizontal flukes and the posterior part of the body. Typically, a swimming cetacean describes a roughly sinusoidal (undulatory) path as it swims, coming to the surface for a breath at the top of each curve and descending below the surface in between. Because breathing is accomplished through the paired or single blowhole on top of the head, the animal does not have to arch its neck to breathe and thus break the smooth path of travel. Only in the sperm whale is the blowhole anterior on the left side of the snout tip. The flukes are frequently thrown free of the water before steep dives, a habit uncommon in rorquals (*Balaenoptera*).

Small cetaceans normally do not dive for periods exceeding five to seven minutes, but the beaked whale (*Ziphius cavirostris*), the bottle-nosed whale (*Hyperoodon ampullatus*), and the sperm whale may stay below for very long periods; the sperm whale may routinely dive for an hour below the surface, and specimens that have become tangled in submarine cables indicate that it may reach depths of at least 1,100 metres (about 3,600 feet).

Vincent Serventy

Figure 41: Humpback whale surfacing, showing blowholes.

Length of dives

Speed. It has been reported that porpoises travel at speeds of at least 38 kilometres per hour (21 knots, or 24 miles per hour) and whales at 56 kilometres per hour (35 miles per hour). Tests on trained animals suggest that cetaceans possess unusually low drag because the boundary layers (water near the skin) remain partially laminar (smooth) at high speeds and do not become predominantly turbulent, as is the case around moving rigid bodies. Body shape is believed to play an important part in the low drag experienced by swimming whales.

Leaping and wave riding. Many whales and porpoises leap from the water from time to time, and some perform aerobatic manoeuvres. Sperm whales reportedly can jump clear of the water; humpback whales may mate as they leap in tandem from the water; and many porpoise species leap during fast swimming. Some species trained in captivity have vaulted as high as six metres (20 feet) above the water surface. One species group of the genus *Stenella* spins rapidly along its longitudinal axis as it leaps. Some of these leaps are thought to aid in shaking off suckerfish (*Remora*), but use in social contexts is also evident. The larger rorquals seem never to leap; the gray whale spy hops, or pitchpoles, often rising to about the level of its flippers and hanging for a moment, apparently viewing the aerial surroundings; or it may leap three-quarters of its length and fall back on its side.

Many species of smaller whales and porpoises come to the bows of vessels and may ride for many minutes without beating their tails, obtaining a thrust from the pressure wave in front of the ship's bow wave. Porpoises have also been observed riding the "bow wave" produced by a large mysticete when the latter was at the surface.

Sound production and communication. Acoustic behaviour, which is highly developed in all cetaceans, involves passive listening, social signalling, and echolocation. Although the acoustic sense and passive listening are developed in all cetaceans, only odontocetes have been shown to echolocate—*i.e.*, to use the echoes of their own

signals for discrimination and navigation. Two major sorts of sounds are produced by cetaceans: low-pitched signals predominantly in the human audible range, such as barks, whistles, screams, and moans; and brief clicks of high-intensity sound, some as high as 200 kilohertz, or about 13 times the upper frequency of humans. The former sounds seem to serve mostly in social communication; the latter serve largely in discrimination and navigation. Click production in porpoises allows highly refined discrimination; in experiments, porpoises can discriminate between objects of slightly differing sizes, detect the presence of fine wires, determine the locations of tiny objects, and discriminate among different kinds of metals. Clicks are projected from the porpoise forehead and upper jaw in a highly structured beam; the highest frequencies are strongest directly ahead of the animal. Low-frequency sounds are more omnidirectional, and their source in dolphins is thought to be in structures within the left nasal passage.

Types of communicative signals

Communicative signals are used in a variety of contexts. Humpback whales produce a variety of moans and calls in their breeding areas, porpoises emit distress cries, and specific signals are produced during birth. The finback whale produces a monotonously repeated, very low-pitched, narrow band sound (about 20 Hertz) that is thought to allow long distance communication between whales. Captive porpoises have mimicked human voice signals and artificial sounds, and a variety of sounds have been shaped by training techniques. No evidence exists, however, for a humanoid language in any cetacean.

Nonvocal signalling of emotional states, which occurs in porpoises and small whales, has not been studied in the larger whales. Such signals include showing the whites of eyes, which is a sign of rage, and various jaw claps and body postures, which carry social meaning.

FORM AND FUNCTION

General features. The general body form is fusiform, or spindle-shaped, with the head end variously modified into a more or less attenuated beak, rounded, bluff, or flattened. The tail always ends in a horizontal blade (the flukes), through which vertical movements of the tail produce forward thrust. The forelimbs are paddle- or sickle-shaped flippers that function in balance and steering. A dorsal fin is usually present. The flippers have all the recognizable elements of the mammalian forelimb skeleton. No external trace of the hindlimbs remains, but a greatly reduced pelvis is represented by a pair of slender, irregularly curved bones, remote from the backbone and embedded in the flesh in the vicinity of the reproductive opening. In some of the larger whales, bony or cartilaginous remnants of the hindlimb skeleton still persist as attachments to the pelvis.

The head varies in size from about one-tenth of the total length in some toothed whales, such as dolphins, to nearly one half in the sperm whale. No ear pinnae are to be distinguished adjacent to the inconspicuous opening of the external ear tube. Eyes and eyelids are present and usually functional, but vision is said to be reduced in some river dolphins.

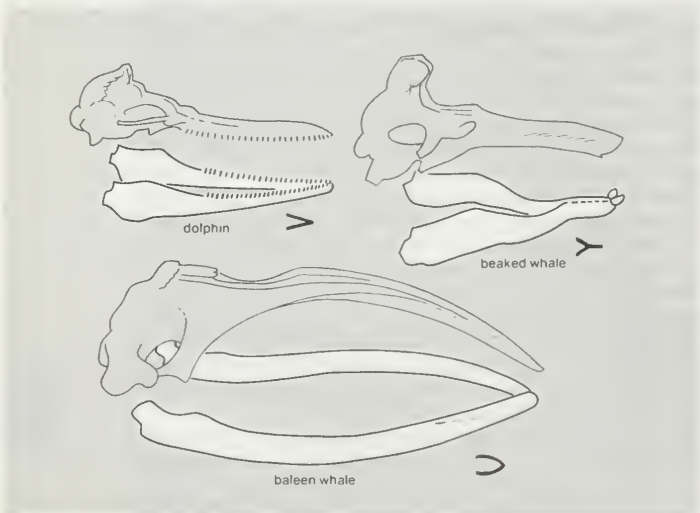

Figure 42: Three cetacean skulls. The small figures represent the general shape of the jaw as viewed from above.

The facial part of the skull is elongated into rostrum, or beak (Figure 42). The maxillary bones are spread laterally at their posterior ends and either override the frontal bones (in the toothed whales) or extend under the orbital processes of the frontal bones (in baleen whales). The telescoping of the skull and the laminated (layered) bony structure, together with the high, short, broad braincase, result in a skull form that is far removed from the usual mammalian pattern.

Feeding adaptations. The digestive tract and the dentition show several special features associated with feeding habits. Food enters the large gape and passes unchewed through the esophagus and into a specialized multichambered stomach. Specialization of the stomach is related to the simplification of dentition, which requires that the food, swallowed whole, undergo prolonged digestion. In the modern carnivorous cetaceans (the odontocetes), the teeth are simple, uniform in shape, peglike, and single rooted, frequently exceeding the primitive mammalian number (44). When the mouth is closed, the top teeth interdigitate with those of the lower jaw, rather than occluding, as do those of most land mammals. The teeth are used for seizing prey, which is not chewed before being swallowed. Among the dolphins, many species have reduced dentition. Risso's dolphin (*Grampus griseus*), which feeds predominantly on cuttlefish, has the teeth reduced to from two to six on each side of the lower jaw and none in the upper jaw. This reduction of teeth in association with a cuttlefish diet is even more evident in the bottle-nosed and beaked whales (Hyperoodontidae), whose slender jaws bear one pair (occasionally two pairs) of functional teeth in the mandible and none in the upper jaw, except in the Tasmanian beaked whale (*Tasmacetus shepherdi*), which has teeth in both jaws, totalling up to 90. The sperm whale, in which functional teeth are restricted to the lower jaw, eats large squid extensively, but fish are also taken.

Dentition

The baleen whales are plankton feeders, including in their diet small crustaceans such as krill (euphausians) and copepods (*Calanus*), and fishes such as herring, sardines, and capelin, which they strain from large amounts of water with the baleen plates. These are anchored to the roof of the mouth, somewhat spaced apart at right angles to the long axis of the head. Each plate is triangular, with its smallest side inserted in the jaw. The outer (labial) edge of the plate is smooth; the inner (lingual) side is frayed out into a fringe of bristles that collectively form a matted sieve or strainer. The strainer selectively removes the plankton from the water expelled from the whale's mouth. The plates are longest (to nearly four metres, or 13 feet) in right whales and shorter, broader, and stiffer in rorquals. Each half of the total baleen complement may comprise upward of 300 plates. Each plate is formed of parallel tubes of horn (keratin), with compacting horn between, which are enveloped, except at their fringed ends, in a covering layer. Between adjacent plates is a pad of softer horn. Baleen does not differ essentially from hair in chemical composition and, like the latter, has its origin in the skin.

The senses. *Smell.* The sense of smell is reduced or lacking in cetaceans. A reduced olfactory organ is, however, present in baleen whales; on the other hand, it is absent in odontocetes.

Sight. Underwater vision is excellent in porpoises (in species in which it has been tested), except for some river porpoises. The eyes of the Amazon River porpoise (*Inia geoffreyensis*) are reduced but apparently functional; those of the susu of the Ganges, Brahmaputra, and Indus rivers (*Platanista gangetica*) are rudimentary and vision is poor. Some evidence indicates that porpoise vision out of water is poor. The lens of the cetacean eye is modified for underwater vision: the sclerotic capsule of the eye is greatly thickened, and a variety of adaptations relating to pressure change and vision in water are present. There is no definite evidence for colour vision in cetaceans.

Hearing. Hearing is a major sense in all cetaceans.

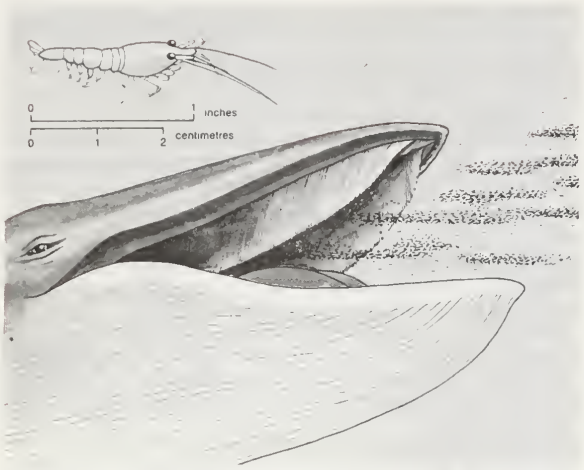

Figure 43: Fin whale swallowing krill, one of which is shown in the inset above.

In the bottle-nosed dolphin hearing capability extends through the human range (20 Hertz to 20 kilohertz) to about ten times the human upper limit (up to about 150 kilohertz). In odontocetes, the hearing of clicks is highly directional and is apparently mediated through the lower jaws and throat, rather than through the much reduced external ear canal. Three species of Japanese porpoises are approximately 10 times as capable as a human of discriminating pairs of clicks given in rapid succession.

Little is known about the sound reception of baleen whales other than evidence from whalers who know them to be extremely sensitive to boat noise.

Structure of the ear

The ear cartilages, of similar origin to those that support the pinna (external ear) in land mammals, have been sunk in the blubber over the external ear. In baleen whales, the external ear canal becomes a solid cord; it opens again near the eardrum and is filled with a solid waxy plug the laminations of which have been used for age determination, much in the manner of tree rings. In odontocetes, the tiny canal is generally open during its entire convoluted length. In one species, the Dall porpoise (*Phocoenoides dalli*), it is at least occasionally occluded at the surface. The middle ear ossicle bones differ widely from those found in terrestrial mammals, apparently in response to the conditions of hearing underwater. The middle ear bones and the inner ear (cochlea) are housed within a heavy, almost ivory-like, petrotympanic complex, which hangs nearly free from the skull and is surrounded by air sacs connecting with the respiratory tracts by way of the eustacian tube. These sacs are important in pressure equilibration during dives and in acoustic isolation of one ear from the other and of both ears from the animal's own sound signals. Masses of small blood vessels occupy much of the middle ear and are also instrumental in pressure equalization.

Taste. Marked food preferences have been noted in captive odontocete cetaceans. The presence of well-developed taste buds on the tongue point to a well-developed sense of taste.

Proprioception. The awareness of bodily position (proprioception) is as acute in cetaceans as in any other mammal. Their exquisitely refined capabilities in manoeuvering in the water provide other evidence of coordinative sense.

(K.S.N.)

PALEONTOLOGY AND EVOLUTION

It is generally agreed that whales originated in the early Paleocene or Upper Cretaceous (about 70,000,000 years ago) from some group of terrestrial meat-eating mammals. Some authorities believe that a likely parent group was the Mesonychidae, medium-sized, large-headed mammals of the order Creodonta, believed to be near the base stock of both the carnivores (Carnivora) and the ungulates (several orders of hoofed mammals). It has also been suggested that the whales evolved from a Paleocene member of the order Insectivora resembling the Eocene *Pantolestes*, a semiaquatic carnivorous animal about the size of the modern otter (*Lutra lutra*). An American paleontologist, L. Van Valen, has pointed out similarities between the mesonychids (as well as the closely related arctocyonids) and the earliest archaeocete whales, the protocetids. All that can be stated with certainty is that the ancestors of the protocetids must have evolved through an amphibious stage.

The earliest known whale fossil is a fragmentary shoulderblade from the lower Eocene of England (about 50,000,000 years ago). Remains of archaeocete whales of the family Protocetidae are found in middle Eocene formations. They were relatively small animals about the size of the modern porpoises (two to three metres long). The hindlimbs had already been lost, and the nostrils were midway between the terminal position found in most terrestrial vertebrates and the top of the head, where they are found in most advanced whales. The snout was elongated, but the skull bones were not telescoped as in modern forms; the teeth retained the differentiated (heterodont) condition found in terrestrial carnivores, the front teeth being tapered pegs and the cheek teeth serrated. At the time of their greatest development, in the late Eocene, some archaeocetes were large, the most striking being *Basilosaurus*, a slender animal that attained a length of some 20 metres (nearly 70 feet). One line of archaeocetes, the dorudontids, persisted into the early Miocene (about 20,000,000 years ago).

Paleontologists disagree as to whether the modern toothed whales (odontocetes) and baleen whales (mysticetes) arose from an early archaeocete relative or separately from different terrestrial ancestors. Recognizably odontocete remains are known from the upper Eocene, and even earlier odontocetes must have been contemporaries of the early archaeocetes. One early form, *Agorophius*, already showed some telescoping of the skull and the nostrils were above the eyes. The agorophiids appear to have had a relatively short history but were probably ancestral to the porpoise-like squalodonts, which appeared in the late Oligocene (about 28,000,000 years ago) and by the middle Miocene were the dominant toothed whales of the world's oceans. By the early Miocene most of the modern odontocete families were represented by some members. Fossils of sperm whales found in lower Miocene deposits have been assigned to the modern genus *Physeter*. These are among the oldest known representatives of the physeterid line, which produced a variety of other Miocene and later forms and must have existed as a well-differentiated group during the later part of the Oligocene.

Intermediate fossil forms

Two groups of fossil whales appear to be intermediate between the toothed and the baleen whales. In the Patriocetidae the nostrils were in an intermediate position between the snout and the forehead; the telescoping of the skull (in the symmetrical manner seen in later mysticetes) was only slightly evident. The other group, the Aetiocetidae, was placed in the Odontoceti on the basis of possession of teeth, but Van Valen has pointed out that *Aetiocetus* is mysticete in other respects and should be considered closer to the mysticete evolutionary stem.

The earliest fossils definitely assignable to the Mysticeti are the middle Oligocene cetotheres, a group that became quite abundant in the subsequent Miocene. Of the three modern families of baleen whales, two (Balaenidae and Balaenopteridae) are known from scanty Miocene and abundant Pliocene fossils; the third (Eschrichtiidae) is known only from a few Pleistocene and post-Pleistocene fossils representing the sole modern genus, *Eschrichtius*.

CLASSIFICATION

Distinguishing taxonomic features. The three suborders recognized below share the same basic body plan but differ in the degree of specialization attained. The suborders and families are separated primarily on the basis of the following characteristics: tooth structure, number, and degree of differentiation; modifications of the skull, especially the position of the nostrils, degree of telescoping of the whole skull, and extent of joining of the two halves of the jaw (rami); and degree of modification of the pelvic girdle (in the archaeocetes only).

Annotated classification. The classification presented below is based on research by cetologists F.C. Fraser, R. Kellogg, and a number of other modern authorities.

Groups marked with a dagger (†) are extinct and known only from fossils.

ORDER CETACEA

Aquatic mammals with forelimbs modified into flippers and hindlimbs lacking; pelvic girdle vestigial and not attached to vertebral column; tail laterally flattened and extended into horizontal flukes, supported by cartilage. External nares at top of head (except in sperm whales and archaeocetes); cranium telescoped variably, with elongated rostrum. Three suborders, with about 10 fossil and 9 Recent families.

†**Suborder Archaeoceti** (archaeocetes or zeuglodonts)

Fossil only; lower Eocene to middle Miocene. Anterior and posterior teeth differentiated; total teeth not exceeding 44, the basic number in terrestrial placental mammals; nostrils positioned toward the top of the head, to varying degrees. More than 12 genera described.

†*Family Protocetidae*

Lower to upper Eocene; Europe, Africa, and possibly North America.

†*Family Dorudontidae*

Upper Eocene to lower Miocene; Europe, Africa, North America.

†*Family Basilosauridae*

Upper Eocene to lower Oligocene; Europe, Africa, North America.

Suborder Odontoceti (toothed whales)

Upper Eocene to Recent; worldwide marine, a few in fresh water. Teeth relatively uniform (homodont) and numerous (up to 300), occasionally reduced. Skull asymmetrical; nostrils on top of head (except in Physeteridae) with single external opening (blowhole). Several pairs of ribs joining sternum, which is fused into a single bone only in the adult.

†*Family Agorophiidae*

Fossil only; upper Eocene of North America. Two genera.

†*Family Squalodontidae*

Fossil only; upper Oligocene to lower Pliocene; Europe, North and South America, Australia and New Zealand. More than 12 genera described.

Family Platanistidae (river dolphins)

Lower Miocene to Recent. Snout long and slender; neck vertebrae all free; sight reduced. Flippers short and broad, sternum well developed. About 10 fossil and 4 monotypic Recent genera, the latter respectively in the Ganges, Indus, and Bramaputra rivers of India; La Plata of Argentina; Amazon and Orinoco of South America; and Tung-T'ing Lake and adjacent Yangtze River, China. Adult length 1.5–2.5 metres (5–8 feet).

Family Hyperoodontidae (beaked whales)

Previously called Ziphiidae. Lower Miocene to Recent. Functional teeth greatly reduced in number, to 1 or 2 pairs in lower jaw (except for total of 90 teeth in *Tasmacetus*); vestigial (nonfunctional) teeth not uncommon. Pair of longitudinal grooves in throat region. Dorsal fin slightly more than one-third of way back along body. Tail usually not notched in middle. Flippers small. Worldwide, marine; length to about 12 metres (40 feet). About 14 fossil and 5 Recent genera; 15 Recent species.

Family Physeteridae (sperm whales)

Lower Miocene to Recent. Head proportionately large, with bulbous, squared snout; mouth narrow and ventral; lower teeth totalling 40–52, upper teeth vestigial, smaller, varying in number. Blowhole a single, asymmetrical opening on the anterior left tip of snout. Twenty fossil and 2 Recent genera; length to 19 metres (62 feet; *Physeter*) and to 3 metres (10 feet; *Kogia*) in Recent genera. Tropical and temperate oceans, and (adult males only) polar waters.

Family Monodontidae (narwhal and beluga)

Pleistocene to Recent. Dorsal fin lacking. Neck vertebrae free. Flippers broad, rounded at tips. Teeth reduced to 8 or 10 in *Delphinapterus* (beluga); all vestigial in *Monodon* (narwhal) except for 1 left tooth of male, which grows into a long, straight tusk, extending in front of animal. Two genera; length to about 5 metres (16 feet); Arctic Ocean.

Family Phocoenidae (porpoises)

Upper Miocene to Recent. Head with rostrum (forehead extending to snout); teeth with expanded spade-shaped crowns. Dorsal fin triangular (when present); tail notched posteriorly. Three fossil and 3 Recent genera. Adult length (in Recent species) to about 2 metres (6.6 feet); virtually worldwide; marine, 1 species ranging up Yangtze River.

Family Delphinidae (dolphins and killer whales)

Lower Miocene to Recent. Characteristics variable. Dorsal fin and well-defined beak present or absent. None with expanded tooth crowns. About 35 fossil and 12 Recent genera. Length 1.7 to about 9 metres (5.5 to 30 feet), worldwide, marine; 1 species in salt and fresh water (Irrawaddy River).

Family Stenidae (long-snouted dolphins)

Lower Miocene to Recent. Like Delphinidae but differing in structure of air sinus system and in shape of forehead. Three genera. Widespread in tropical oceans and rivers.

†*Families Eurhinodelphidae, Hemisyntrachelidae, and Acrodelphidae*

Three families of Miocene toothed whales; about 12 included genera, from all continents.

Suborder Mysticeti (baleen, or whalebone, whales)

Teeth lacking in adult; numerous but vestigial in embryo; baleen present. Lower jaw large, mandibles bowed outward and loosely united in front. Skull symmetrical; nasal bones relatively well developed; blowholes paired slits, slightly divergent posteriorly.

†*Family Aetiocetidae*

Upper Oligocene. Toothed but with symmetrical skull and other typical mysticete features. One genus (possibly 2); North America.

†*Family Patriocetidae*

Upper Eocene to upper Oligocene; Europe and North America; 4 genera.

†*Family Cetotheriidae* (cetotheres)

Middle Oligocene to lower Pliocene; North and South America, and Europe; about 30 genera.

Family Eschrichtiidae (gray whale)

Formerly Rhachianectidae. Head less than one-quarter of total length; neck vertebrae not fused. Dorsal fin lacking. Flippers with 4 digits. Pelvis large. One Recent species; length to about 15 metres (49 feet); found along both coasts of the North Pacific Ocean. Fossils from Pleistocene and Recent, from Atlantic Ocean.

Family Balaenidae (right whales)

Lower Pliocene to present. Skull much arched; neck vertebrae fused; baleen long, narrow, flexible strips. Ventral grooves on throat lacking. Four fossil and 2 Recent genera (4 species); length 6–20 metres (20–66 feet); polar and subpolar oceans.

Family Balaenopteridae (rorquals and humpback)

Upper Miocene to present. Skull broader and less arched than in Balaenidae; baleen plates shorter, broader, less flexible, neck vertebrae not fused. Dorsal fin present; flippers narrow. Conspicuous longitudinal grooves present on throat. Eight fossil and 2 Recent genera (8 species); length 10–33.6 metres (33–110 feet); blue whale (*Balaenoptera musculus*) is the largest animal that has ever lived. Family occurs in all oceans and, at various times, from Equator to poles; migratory.

Critical appraisal. Authorities disagree on whether the whales should be treated as one order, Cetacea (as above), two, or three (as in the classification used in the section *The class Mammalia*). The determining factor is the degree of shared ancestry, the evaluation of which remains controversial. There is a possibility that certain protocetids could have given rise to both the modern groups of whales, and it is because of this that some authorities prefer the use of a single order. However, the absence of intermediate fossils linking the baleen whales with the toothed forms supports the use of separate orders. Resolution of this problem must await the discovery of relevant fossil material.

Below the ordinal level, there is further disagreement at many points. Although there is no doubt that any recent cetacean is odontocete or mysticete, the relationships of many genera are in doubt. The long-snouted dolphins (Stenidae) are of uncertain affinities but are included in the Delphinidae by many authorities, as are the porpoises (Phocoenidae). At the species level, there is uncertainty about the specific or subspecific status of many populations. (Ed.)

Proboscidea (elephants)

The order Proboscidea comprises three suborders and about 300 species of terrestrial mammals. All but two species, the Asiatic, or Asian, elephant (*Elephas maximus*) and the African elephant (*Loxodonta africana*), are extinct. The elephants are the largest surviving land ani-

mals and, among the mammals, are exceeded only by the whales in size.

The Proboscidea are characterized by columnar limbs, bulky bodies, and elongated snouts. In recent forms, testes are internal. The snout is a long boneless proboscis, or trunk; it is a combination of the upper lips, palate, and nostrils. Some of the incisor teeth develop into tusks. One extinct suborder (Deinotherioidea) lost the upper tusks; certain others have lost the lower ones and evolved upper tusks of dentine from which the enamel has partially or completely disappeared. The canine teeth were generally repressed in all groups, and the cheek teeth developed rows of blunt cones or ridges. In later forms, the temporary teeth were replaced by permanent ones, which are pushed by an escalator-like movement along a horizontal plane, so that the front teeth were replaced by teeth moving forward from the rear. The skull, which originally was elongated, became shorter, higher, and bulkier in later forms. The back of the eye orbit remained open instead of forming a complete bony ring, and the nasal opening in all Proboscidea is at a higher horizontal plane than the eye sockets. The neck shortened as the animals evolved larger, higher bodies and an elongated trunk that also functions as a hand. The skull has enlarged out of proportion to the brain in order to serve as an anchor for the trunk and to support the heavy dentition. This order occurs in all the continents except Australia. Fossils of proboscideans provide valuable information about early humans who were their contemporaries.

GENERAL FEATURES

Size range and distribution. In Europe, the landmass that broke up to form the islands of the Mediterranean Sea harboured proboscideans. Three fossil species have been found in Malta; one had had a height of 2.1 metres, or 6.9 feet (*Palaeoloxodon mindriensis*), another a height of 1.5 metres, or 4.9 feet (*P. melitensis*), and the third was less than one metre, or about three feet (*P. falconeri*). *P. creticus* of Crete was 1.5 metres, and *P. cypriotis* of Cyprus was 0.9 metre (three feet) in height. In North America, a small *Mammuthus* isolated on Santa Rosa Island, off the coast of southern California, was probably derived from *Mammuthus meridionalis,* a species that stood 4.2 metres (13.8 feet) at the shoulders.

Early human records of elephants

Elephas maximus asurus lived in Iran and Syria. Early drawings of the animal and fragmentary skeletal remains indicate that it was the largest subspecies of the Asian elephant. The war elephants employed by Pyrrhus in 255 BC and engraved upon Roman seals show animals of unusual size. "Sarus," which signified "the Syrian," was the outstanding animal in the elephant battle squadron of the Carthaginian general Hannibal. In 1500 BC elephants (*Elephas maximus rubridens*) existed in China as far north as Anyang, in northern Honan Province. Writings from the 14th century state that elephants were still to be found in Kwangsi Province.

Man as well as other environmental factors exterminated the woolly mammoth (*Mammuthus primigenius*) and the imperial mammoth (*M. imperator*) about 10,000 years ago. Several races of the living species of Asian and African elephants also died out by about 1500 BC. The small North African race became extinct by the 2nd century AD, and some of the American mastodons, such as *Cuvieronius postremus* of South America, died out as recently as the 4th century AD. The large African bush elephants (*Loxodonta africana*) were exterminated from the Transvaal in South Africa early in the 20th century, but they still occur over much of the continent south of the Sahara Desert. A smaller elephant inhabits the forests of western equatorial Africa, particularly in the Congo region. It is considered by some to be a subspecies (*Loxodonta africana cyclotis*) of the African elephant; others believe it to be represented by several subspecies; still others consider it to be a separate species (*L. cyclotis*).

In Asia, elephants have been exterminated from Iran, Iraq, Afghanistan, the northwestern part of India, and from much of the Malay Peninsula, Java, and the greater part of Borneo and Sri Lanka (formerly Ceylon). Isolated colonies remain in forest areas of Mysore in the peninsular part of India, in Assam, Nepal, Burma, Malaya, southern China, Sri Lanka, Sumatra, Borneo, and other islands of the East Indies.

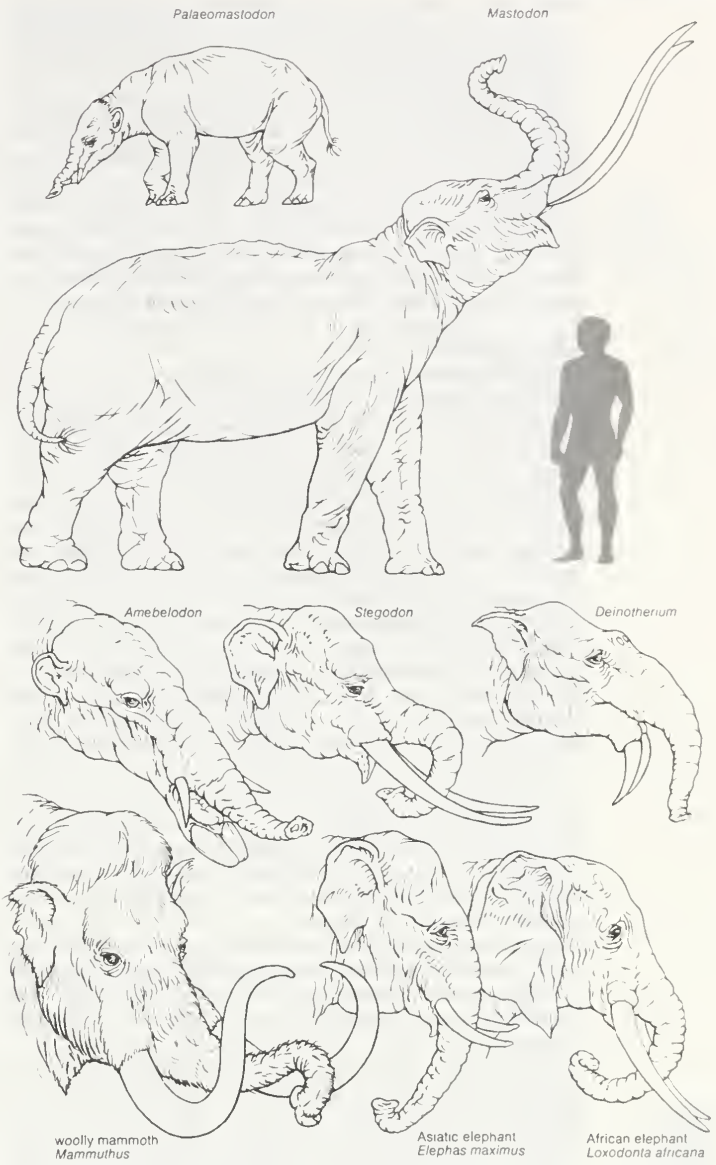

Figure 44: Representative fossil and living proboscideans.
Drawing by Christian D. Olsen

Importance to man. Elephants constitute the chief source of commercial ivory. Because of the continuing demand for this commodity, the animals are in danger of extermination. Elephant "pearls" consist of concentric layers of ivory deposited over a foreign object that has been intruded into the soft ivory at the base of the growing tusk. From early times elephants have been used as beasts of burden in India and Burma. Since they do not breed freely in captivity, new stock for domestication is often captured from wild herds. One method is to drive them through a funnel-shaped stockade into a small enclosure; trained tame elephants help to subdue, noose, and train young captives for service. The training and handling of an elephant are usually entrusted to one man, called the mahout in India and the *oozie* in Burma; an elephant and its keeper frequently became inseparable companions.

Capture of elephants

Trained elephants carry humans in a howdah, or miniature hunting lodge, on their backs. They are used to move timber or other heavy materials.

In modern times, African elephants have been trained for labour only since late in the 19th century; however, they were used by the Carthaginians in wars with the Romans. Both species were tamed at that time. Elephants were used as executioners, in amphitheatres, and for military pageants. They are still used in exhibitions at circuses, carnivals, and zoological parks. In warfare elephants have

been used to drag heavy equipment, especially through mud and up steep slopes. As late as World War II, they were of value in military movements over the mud-clogged roads of Southeast Asia.

The association between man and elephants goes far back into mythology, and a rich folklore has developed. Bracelets of hairs from the tail of a freshly-killed or living elephant are prized as good-luck charms.

Attempts to locate the legendary "graveyards" to which old elephants allegedly resort when near death have been, for the most part, unsuccessful. The groups of buried elephant remains that have been found probably represent sites where elephants drowned in bogs or quicksands.

NATURAL HISTORY

Reproduction and life cycle. Tuskers, or tusked bulls, occasionally fight brief, savage duels that may end in death for the defeated animal. A duel between tuskless elephants may last for days, with occasional periods of rest. The female selected from the herd by the winner often makes an apparent attempt to escape from him. After a brief preliminary courting, the male mounts the female from behind, leaning over her back and either gripping her body or resting his forefeet upon her pelvis, and assumes a standing posture. Copulation lasts for about 20 seconds, with very little movement or noise. Mating continues promiscuously for about two days, after which the most powerful bull drives off the others and remains with the cow for about three weeks. The period of gestation varies from 20 months for a female calf to 22 months for a male. When parturition is about to occur, the herd surrounds the cow, who assumes a squatting position while giving birth.

In regions where large carnivores, such as tigers, prey upon newborn elephants, the cow seeks a female associate. The mother and the other elephants in the herd blow dust upon the moist, newborn calf to dry it. Two hours after birth, the baby is able to stand and is suckled. The mother and calf then join the herd.

Tame cows begin breeding at the age of eight or nine years; tame bulls begin when about 11 or 12 years of age. The interval between the birth of successive calves is about four years. In captivity cows are known to continue bearing calves until 60 or 70 years of age.

Appearance of elephant calf

The newborn elephant is about one metre (three feet) high and weighs about 90 kilograms (200 pounds). It is covered with yellow and brown hair. After a few months the hair on some parts of the body is as long as that in the extinct mammoth. In *E. maximus* there is also a pinkish patch around each eye, and when the calf is about five months old, a faint whitish patch develops on each cheekbone. As this patch spreads, similar patches appear upon the trunk and ears. In the more easterly races of Malaya and Sumatra there are only a few gray spots. The hoof nails, which are dark at first, gradually become lighter. When the elephant is about eight years old, a thick oily secretion known as musth, or must, begins to flow from a gland in the temporal, or temple, region. It occurs in both sexes, but is more active in males. The secretion increases each year until it drips into the elephant's mouth. Some authorities believe that the function of the secretion is to inhibit feeding; others believe it has some effect on sexual activity.

An elephant is not fully grown until it is about 25 years old. In the wild, the average life-span is about 60 years, but under optimum conditions an elephant may live for 80 years.

Behaviour. The organization of an elephant herd is often according to age and sex. In *Elephas*, although herds of 10 or 15 females and their young may appear to be under the leadership of a large female, and their organization matriarchal, young adult males are always in the vicinity, as is the real leader of the entire group, a large male. The leader may be accompanied by one young adult male who acts as a scout, warning the leader of danger. The herd also has a system of scouts, and, before emerging into an open area, one of the scouts usually explores it. If no danger is apparent, he signals by trumpeting to the herd to advance. Individuals often serve as guards while the rest of the herd feeds or bathes.

The herd is held together both by blood relationship and by a strong sense of companionship. If an individual is injured, three or four others surround it, shielding it from danger, supporting it, and helping it to move away. A calf that has lost its mother is adopted by the other cows in the herd even if they have their own calves to raise.

Ecology. Elephants clear paths through forests that are too dense for other animals. Many modern roads in elephant-inhabited countries originated in this manner. Elephants browse to a height of about five metres (16 feet), thereby increasing the amount of sunlight available for shrubs. Their uprooting of grass and roots aerates the soil and stimulates the growth of plants that replace the ones devoured. Mud wallows frequented by elephants are fertilized by their excreta.

Feeding habits

An elephant may destroy or discard as much vegetation as it consumes. An adult may eat between 250 to 350 kilograms (550 to 770 pounds) of solid food each day. When grazing, the animal uses its trunk or forefoot to gather grass, which is slapped against a forelimb to rid it of sand. In rainy weather, when soil is more difficult to shake off, the animal browses. Asian elephants break off branches; African elephants are more likely to push over trees. The wood apple (*Feronia elephantorum*) is a favourite food of the Asian elephant. The animal also eats wild rice that grows in forest lakes and various other aquatic plants. The African bush elephant eats the fruit of various palm trees. The spongy wood of the baobab tree provides some water during periods of drought.

FORM AND FUNCTION

Extant forms. The adult elephant has a tuft of hair at the tip of the tail and sometimes a patch of hair on the head. The limbs are adapted for bearing great weight: the legs are straight and pillar-like, and the bones of the joints are flat at the articular surfaces. Each toe has a heavy hoof nail; the weight is borne on thick pads behind the toes. The nose and upper lip are extended into a long trunk, which contains the nasal passages and has nostrils at the tip. Water for drinking is sucked into the trunk and then discharged directly into the mouth. The trunk is used for placing food into the mouth, for spraying and dusting the body, for lifting or moving heavy objects, and even for throwing objects at man.

The upper second incisors are typically developed into ivory tusks, the longest and heaviest teeth of any living animal. Canine teeth are absent. The complex molars are of the high-crowned type, with transverse rows of enamel ridges on the grinding surface, which is often traversed by a longitudinal median groove. There is normally only one complete functional tooth and half of a second one at a time on each side of each jaw. These are replaced horizontally from the rear as they wear away.

The Asian elephant (*Elephas maximus*) and its races are distinguished from the African elephants by being somewhat smaller and by having relatively small ears with the upper edge curled forward. The head is more domed, is structurally more complex, and has a greater development of diploe, or bony cell cavities. *E. maximus* also has high-crowned teeth and a relatively smooth trunk with a single fingerlike projection at the tip. Adult bulls weigh up to 5,450 kilograms (six tons) and commonly stand three metres (10 feet) at the withers. Only the males develop tusks, which average 1.5 metres (4.9 feet) in length, the pair weighing about 32 kilograms (70 pounds). These develop flat, longitudinal planes of wear near the tip. Tusks 2.7 metres (8.9 feet) long and 68 kilograms (150 pounds) in weight have been recorded. About 90 percent of the males of the Ceylonese race lack tusks; Sumatran elephants are of slighter build and have longer trunks.

In contrast to the Asian species, the African bush elephant is generally larger. This and the forest form have extremely large ears (one metre in breadth), with the upper edge curled backward, and a roughened, heavily ringed trunk with two projections at the tip. The molars are of coarser construction, have fewer ridges, are less crenulated (scalloped), and consist of a thicker surface of enamel over thick plates of dentine. The top of the head is not domed, and the forehead is more convex.

The tusk tips are usually conical, the legs are longer, and the eyes are relatively larger than those of the Asian elephant.

The average height of adult bull bush elephants is 3.3 metres (10.8 feet) at the shoulder, and the average weight is six tons. Cows are about 0.6 metre (two feet) shorter. Both sexes possess tusks, which average about 1.8 metres (5.9 feet) long, the pair weighing 36 to 55 kilograms (79 to 121 pounds). A pair of tusks in the British Museum weighs about 133 kilograms (293 pounds); the larger one of the two is 3.5 metres (11.5 feet) long, with a basal circumference of 46 centimetres (18 inches). The largest elephant on record, a bull bush elephant killed in the Cuando river district of southeastern Angola in 1955, is on display at the Smithsonian Institution in Washington, D.C.; it probably weighed 8,200 kilograms (nine tons) when alive and stood four metres (12 feet) at the shoulder. Adult forest elephants are about 2.1 metres (6.9 feet) tall and weigh 1,225 kilograms (2,700 pounds), with slender tusks that are often more than three metres long. The ears are relatively small and smoothly rounded at the margins.

Albinos

Albino, or "white," elephants occasionally occur, especially in Thailand and Burma, where they are regarded by some as semisacred.

The mammoth. The genus *Mammuthus* contains some of the largest members of the family Elephantidae. Certain ones reached a height of over 4.2 metres (13.8 feet) at the shoulders. One was *M. meridionalis* of Asia and Europe, and the other was *M. imperator,* which entered North America during the upper Pleistocene.

The genus also contains one of the most specialized members of the family, the woolly mammoth, *M. primigenius,* which probably became extinct about 10,000 years ago. It inhabited the sub-Arctic area of Asia and Europe and eventually entered North America over the Bering Strait; it travelled southward across western North America almost to Wyoming, then spread eastward toward Lake Michigan. Its height of 3.3 metres (10.8 feet) at the shoulders equalled that of a large *Elephas maximus,* but the body was relatively shorter, and the hindquarters sloped downward. Its skull was compressed from front to back. As an adaptation to its cold environment, the woolly mammoth evolved small ears, a short goatlike tail, and a coat of dense, furry, short hair overlain by longer, bristly hair. It also had a humplike reserve of fat upon the top of

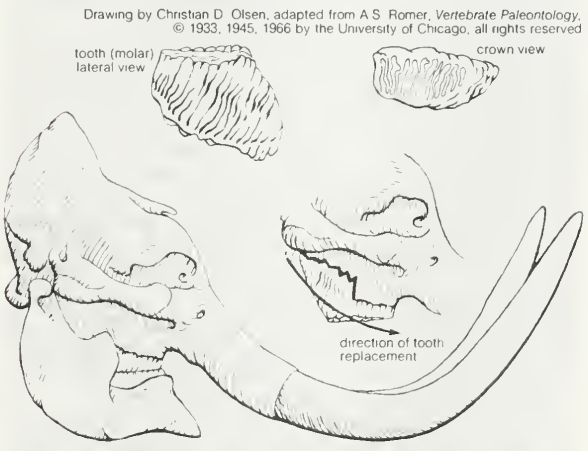

Figure 45: Skull and tooth movement in the woolly mammoth (*Mammuthus primigenius*).

the head and on the shoulders. A subcutaneous layer of fat about eight centimetres (3.1 inches) thick covered the body. The molars had as many as 27 lamellae, or plates. The tusks of the male were about 4.8 metres (15.7 feet) long. Their almost circular curvature and great size suggest that they may have functioned as shovels for exposing vegetation buried under snow. The mammoth is one of the few extinct proboscideans in which the carcass has often been completely preserved. Among the best known are two from Siberia—one discovered near the mouth of the Lena River in 1804; the other in the bank of the Beresovka River in 1900.

EVOLUTION AND CLASSIFICATION

Historical development and paleontology. The order Proboscidea has evolved from unknown ancestors that were not much larger than pigs. They flourished during the Paleocene Epoch (65,000,000 to 54,000,000 years ago). During the course of evolution, the lower jaw elongated beyond the upper, and the tusks projected well beyond the upper ones. At this stage the nose, palate, and upper lips developed into an elongated fleshy cover to the projecting lower jaw. It is probable that the nostrils opened well above the extremity of this flap and were near the eyes. A longer lower jaw proved less useful than a shorter one, so the upper flap was converted into a multipurpose tubular proboscis. Because the nostrils shifted to the tip of the proboscis, the animal was able to breathe while submerged in water. When so submerged, the animal had to rely on its sense of smell more than sight to detect approaching predators.

Origin of the proboscis

The suborder Deinotherioidea, consisting of one genus, is an early branch of the main proboscidean stock of the Eocene Epoch (54,000,000 to 38,000,000 years ago). They lost their upper tusks and developed a downward-hooked, tusk-tipped mandible. Numerous species of the suborder occurred in Asia, Europe, and Africa and persisted into Pleistocene times (2,500,000 to 10,000 years ago). The largest was the European *Deinotherium gigantissimum,* which reached a height of 3.8 metres (12.5 feet) at the shoulders and existed during the Pliocene Epoch (7,000,000 to 2,500,000 years ago).

In the suborder Mastodontoidea, the family Gomphotheriidae comprises 15 genera, including the earliest members of the order, *Phiomia* and *Palaeomastodon.* The former were the size of donkeys, but the latter were as large as a modern Asian cow elephant. In this family the skull and neck are elongated, and the teeth low crowned. The second incisors are enlarged; the upper ones are compressed and vertical, and they retain a band of enamel. In the later evolved genera, the lower pair are bent forward, depressed, and expanded into shovellike structures that do not meet the upper tusks. The canines are absent. Among this family are *Cordillerion* of North America and *Cuvieronius* of South America. The latter became extinct as recently as AD 200 to 400.

Phiomia, which occurred in Egypt and India, was an archaic shovel-tusked form with an elongated neck. It flourished during the Oligocene (38,000,000 to 26,000,000 years ago). The mandible and its tusks became more shovellike in *Amebelodon* and *Platybelodon* of the Miocene (26,000,000 to 7,000,000 years ago).

In *Palaeomastodon* the skull shortened, and the tusks assumed a cylindrical shape. The genus occurs in middle Oligocene deposits of Egypt. In some later genera, such as *Anancus* and *Stegomastodon,* the jaws shortened and the lower tusks disappeared. In some shovel-tuskers, the mandible remained enlarged and continued to function as a shovel for digging plant bulbs. It was probably protected by a horny pad.

Mastodontidae contains the single genus *Mastodon.* It lacked lower tusks. The tusks were about two metres (seven feet) long. Some species attained a height of about three metres (10 feet), and were covered with hair. Parts of carcasses of the recently extinct American species *Mastodon americanus* have been discovered in peat deposits and swamps.

The earliest proboscideans in Asia are *Phiomia, Gomphotherium, Platybelodon,* and *Serridentinus,* of the family Gomphotheriidae, and *Stegolophodon,* of the family Elephantidae. All occurred in the Miocene of China and some in Burma and India.

In the suborder Elephantoidea, *Stegolophodon* is intermediate between the mastodons and elephants proper. Although this genus first appeared during the Miocene of Europe, Asia, and Africa, it persisted into the upper Pleistocene of these continents.

Stegodon, which occurred during the Pliocene in Asia and during the Pleistocene in Africa and Asia, evolved from *Stegolophodon.* The skull enlarged, the jaws shortened, and the lower tusks disappeared. *Stegodon zhaolongensis* of China was a large species with the most primitive teeth

in the genus. The tusks of some species such as *Stegodon magnidens* of India were about 3.3 metres (10.8 feet) in length; in others, however, they were feeble. The molars were usually low crowned, and the depression between each pair of dental folds or plates was Y-shaped, rather than V-shaped or U-shaped as in other elephants.

The genus *Mammuthus* includes all species formerly placed under *Archidiskodon, Metarchidiskodon, Parelephas,* and *Stegoloxodon.* Its species occurred in the Pleistocene of Asia, Europe, America, and Africa. Several species had great bulk and heavy tusk development.

Development of pygmy forms

On various occasions during the Pleistocene Epoch, normal-sized elephants that inhabited a continent were isolated when a part of the landmass was separated into islands by the submergence of low-lying land. As these isolated colonies of elephants multiplied, their fodder supply decreased, and the animals gradually became smaller—an unsuccessful measure against extinction. This process is evident in the East Indies and Philippines, in the islands of the Mediterranean Sea, and in certain islands off the coast of southern California.

Classification. *Distinguishing taxonomic features.* The proboscideans are classified largely according to body size; shape of the skull; dentition; and the shape, size, and degree of reduction of enamel in the tusks. Groups marked with a dagger (†) are extinct and known only from fossils.

Annotated classification.

ORDER PROBOSCIDEA

Oligocene to present; North America, Eurasia, and Africa. Heavy-bodied (graviportal) animals with snout prolonged into a fleshy proboscis (trunk). Tusks developed from upper or lower incisors or both; canines absent; cheek teeth with transverse rows of blunt cones or ridges. Skull short, high; nasal openings at a higher horizontal plane than eyes. Body size medium to large; shoulder height from about 1 m (about 3 ft) to more than 4 m (13 ft). About 300 species, all extinct but two.

†Suborder Deinotherioidea

†*Family Deinotheriidae*

Lower Miocene to upper Pleistocene; Europe, Asia, Africa. Upper tusks lacking; lower tusks curving downward from tip of lower jaw. One genus (*Deinotherium*); many species; height to about 3 m (10 ft).

†Suborder Mastodontoidea

†*Family Gomphotheriidae*

Lower Oligocene to Recent (AD 200–400); Europe, Asia, North and South America. Skull and neck elongated. Teeth low-crowned; succession vertical. Later genera with protruding, shovellike lower incisors, others with substantial upper tusks and no lowers; premolars with 2 transverse crests, molars with 3. About 15 genera, several dozen species; shoulder height about 1 to 3 m (3 to 10 ft).

†*Family Mastodontidae* (mastodons)

Lower Miocene to upper Pleistocene (possibly to early historic times); Europe, Asia, Africa, North America. Molars with rounded prominences, but no ridges; lower tusks absent, but upper incisors substantial, reaching over 2 m (6.6 ft) in length in males of some species. One genus (*Mastodon*), many species; shoulder height to at least 3 m (10 ft).

Suborder Elephantoidea

Family Elephantidae (elephants and mammoths)

Lower Miocene to present; fossils from Europe, Asia, East Indies, Africa, and North America; Recent species from Africa (*Loxodonta*) and southern Asia (*Elephas*) which have probably evolved from *Stegolophodon.* Six genera, with several dozen fossil and 2 Recent species; shoulder height from 1 to about 3.5 m (3 to 11.5 ft). The epiphyses (ends of long bones in limbs) do not fuse until the last molars appear. The molars are replaced at least three times. Marrow disappears from the limb bones early in adulthood.

(P.E.P.D.)

Sirenia (dugong, manatees)

Sirenians are a group of large aquatic mammals that have become rare or extinct as a result of exploitation by man for meat and oil. The largest, Steller's sea cow (*Hydrodamalis gigas*), which reached lengths of about eight metres (about 26 feet), was eaten out of existence by hungry seal hunters within a few decades of its discovery in 1741 in the Bering Sea. The remaining forms, to which the common name sea cow is also sometimes applied, are the dugong (*Dugong dugon*) and manatees (three species of *Trichechus*), which, if their stocks were allowed to rebuild themselves, could again become of economic importance. Being the only large aquatic herbivores, other than some turtles, they could provide meat from the vast expanses of marine and freshwater vegetation, at present quite unused by man, and so bring another marginal area into production.

Extinction by hunting

Dugongs and manatees are both usually seen up to lengths of three to four metres (10 to 13 feet), but larger specimens, up to six metres (20 feet), have been mentioned in tales of early travellers.

The dugong seems to have had a wider distribution in the past, but in recent times it has been restricted to the warm coastal waters of the Indo-Pacific region. Throughout most of its range it is now much depleted in numbers but exists from the Solomon Islands in the east to the head of the Red Sea in the west and from the Philippine Islands and the Persian Gulf in the north to Brisbane, Perth, and Mozambique in the south. It is entirely marine and rarely even enters estuaries. Manatees, however, seem more adaptable and inhabit the coastal, estuarine, and riverine waters of the tropical and subtropical Atlantic region: *T. senegalensis* from West Africa; *T. manatus,* with two subspecies, from the Caribbean; and *T. inunguis,* landlocked in the Amazon Basin.

Natural history. Sirenians tend to live in groups, and dugongs particularly may be highly gregarious at times. An enormous herd, three and a half by one and a half miles in extent, was recorded off Brisbane, Australia, early in the last century. Both genera are totally aquatic, living almost continuously submerged, and this, coupled with their wary and surreptitious habits, makes them exceptionally difficult to study. They are unable to come out of the water, but manatees placed on land nearby may just manage to return to their natural environment by vigorous wriggling of the body. Breathing is by frequent brief visits to the surface, where the tip of the snout is protruded and the nostrils are silently opened by muscular valves. A manatee has been known to last as much as 16½ minutes between taking breaths. Manatees may also be seen lying at the surface, usually with only their backs visible above the water. Even when basking thus, they are easily frightened by sound or disturbance and will silently submerge. On occasion both dugongs and manatees will thrust their heads entirely out of the water, and they sometimes may even disport themselves like cumbersome seals.

Aquatic behaviour

Extremely little is known of the breeding biology of sirenians and particularly of the time scale involved. Manatees are known to be long-lived, and dugongs are believed to have similar lifespans. But there is no information about age of maturity, rate of growth, or number of young produced in a lifetime. Mating in manatees has been observed with the animals in very shallow water lying on their sides. Gestation is known to occupy more than 152 days, and the normal birth is a single calf, which receives much maternal care. Very occasionally twin fetuses are found in dugongs. Suckling from the single pair of pectoral mammary glands normally occurs in a horizontal position, but the occasional suckling of a young one held vertically by a flipper may have given rise to the mermaid myth. There is no marked difference in size between the sexes.

Sirenians are totally herbivorous. Whereas Steller's sea cow fed on marine algae, the dugong and manatees feed entirely on green higher plants, a circumstance that limits their distribution to relatively shallow waters. The habit of the dugong is to feed where there is good growth of "dugong grass" (*Zostera,* etc.), the leaves and underwater stems of which are pulled off by the animal's powerful lips. Manatees seem prepared to feed on marine or freshwater plants whether growing on the bottom, floating at the surface, or even growing on banks of rivers up to a foot above water level. It is this catholicity that has led to the experimental use of manatees in Guyana to keep clear irrigation and transport channels in cane fields that otherwise must be cleared by hand. Virtually the sole enemy of both the dugong and manatees is man. There does not seem to be any commercial exploitation of these

animals at present, but both are hunted sporadically and locally for food with the use of nets or harpoons. The dugong still has a considerable residual stock off northern Australia and with protective legislation enforced, could have a valuable future. Manatees, because they come into more confined waters, are still in danger of extermination.

Form and function. Sirenians have torpedo-shaped bodies and, like whales, have lost all external trace of hindlimbs. Their tails likewise are flattened horizontally and provide the main propulsive force in swimming. The forclimbs are small and may help in turning and manoeuvring. Though usually somewhat sluggish, sirenians are capable of considerable speeds for short distances.

Distinguishing features

The main distinguishing characteristics between the dugong and the manatees are that the former have a downturned snout and a forked tail, while the latter have a straight snout and rounded tail. Both have immensely thick, tough skin, which is nearly hairless. In the dugong

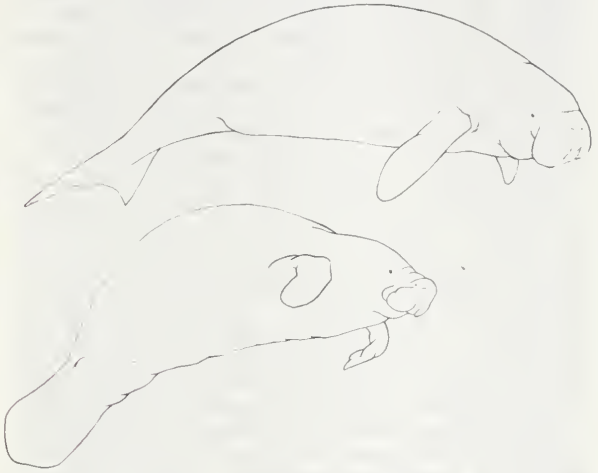

Figure 46: *Body plans of two major sirenian groups.* (Top) dugong (*Dugong dugon*); (bottom) manatee (*Trichechus manatus*).

there are individual hairs about six millimetres (0.24 inch) long, spaced five to seven centimetres (two or three inches) apart. There is no substantial layer of blubber beneath the skin, but the body contains much fat. The eyes are small and circular, without lids, and the minute external ear openings are to be found only by careful examination. All of the bones are of exceptional density. Sirenians, particularly the dugong, have a much enlarged and intensely muscular upper lip, the corners of which serve to pluck the vegetation on which the animal feeds. In the dugong there are remains of two incisors, the second of which becomes large in the adult, remaining unerupted in the female and erupting to form a tusk in the male. There are basically six cusped molars in each jaw, which fall out progressively from the front so that only two remain in the adult. These teeth, together with horny pads at the front of each jaw, crush the food. In manatees each jaw has a series of 20 to 30 crushing molars, which move progressively forward during the life of the animal. Manatees are also exceptional in having only six vertebrae in the neck, instead of the seven standard in mammals. Almost nothing is known about the physiological processes of these animals.

Classification and paleontology. Sirenians comprise the order Sirenia of the superorder Subungulata, which also includes elephants and hyraxes. Two points of resemblance with elephants are the mode of tooth succession and the pectoral position of the mammary glands. The extensive fossil record indicates that the Sirenia date from the Eocene, about 50,000,000 years ago. More than 20 genera of fossil sirenians have been described. They seem to have been widespread near the coasts of the warmer seas of the world, and some think that the manatee is of more recent origin and has replaced the dugong in the Atlantic region.

(G.C.L.B./C.K.B.)

Perissodactyla (horses, asses, zebras, tapirs, rhinoceroses)

The order Perissodactyla is a group of herbivorous mammals characterized by the possession of either one or three hoofed toes on each hindfoot. The name (Greek *perissos*, "odd," and *daktylos*, "finger") was introduced to separate the odd-toed ungulates from the even-toed ones (Artiodactyla), all of which had previously been classified as members of a single group.

GENERAL FEATURES

The Perissodactyla comprise three families of living mammals: six species of horses (Equidae), four species of tapirs (Tapiridae), and five species of rhinoceroses (Rhinocerotidae). These families are remnants of a group that flourished during the Tertiary Period (from 65,000,000 to 2,500,000 years ago), a time when it was much richer in species and in variety of form than at present and played a dominant role in the fauna of the world.

The horses, asses, and zebras are long-legged, running forms with one functional digit in each foot and with high-crowned, molariform (*i.e.*, modified for grinding) cheek teeth. The tapir is a rather rounded, piglike, semiamphibious forest and woodland animal with a small proboscis (trunklike snout) and a coat of short, bristly hairs. Tapirs have primitive features, such as four hoofed toes in the forefoot and three in the hind, and they have rather simple molar teeth. Rhinoceroses are massive, graviportal (ponderous) creatures with a thick and nearly hairless hide and three digits on each foot. They bear hornlike structures on the head.

The Perissodactyla are of particular scientific interest because their fossil history is so well-known. The evolution of horses from the tiny "dawn horse" (*Hyracotherium*, formerly *Eohippus*) to the present form is a classic sequence, knowledge of which has played an important role in evolutionary thought. The order also provides a notable example of parallel evolution. Following completely different evolutionary paths, both perissodactyls and artiodactyls (*e.g.*, cattle, antelope, swine) independently evolved features such as high-crowned grinding teeth and elongated limbs with a reduced number of digits, in adaptation to a similar running (cursorial), herbivorous mode of life.

Living perissodactyls are of medium or large size. Asses and tapirs, the smallest representatives of the order, attain a length of approximately two to 2.5 metres (6.6 to 8.2 feet), stand one metre or more at the shoulder, and weigh up to 250 or 300 kilograms (550 to 660 pounds). The largest forms are the Indian and square-lipped rhinoceroses (*Rhinoceros unicornis* and *Ceratotherium simum*, respectively), which are four to five metres (13 to 16.4 feet) long and measure up to two metres at the shoulder. The maximum weight has not been well established, but a figure of 2,070 kilograms (4,550 pounds) has been recorded. *Baluchitherium*, relative of the rhinoceroses known from the Oligocene (about 30,000,000 years ago), was the largest known land mammal, standing about 5.5 metres (18 feet) at the shoulder.

Indian and square-lipped rhinoceroses

Ecologically, the Perissodactyla were the dominant large herbivore group during the Tertiary, a position now held by the Artiodactyla. All feed either by grazing (*i.e.*, cropping grasses) or by browsing (taking shoots and leaves from trees and bushes). The Equidae in particular were abundant and important members of the Old World fauna until their numbers were reduced by modern man. Zebras are still numerous and ecologically important in a few parts of Africa. The importance of the domestic horse and the ass in the history of mankind is very great indeed. Both have served extensively as pack, draft, and riding animals. The horse is sometimes eaten by man, and its flesh is widely used as pet food; through centuries of domestication, it has been developed into a number of different breeds (for more information on domesticated horses, see HORSES AND HORSEMANSHIP).

The living wild Equidae are confined to the Old World. Zebras and the true wild ass (*Equus asinus*) are African, with the zebras confined to the southern and eastern parts,

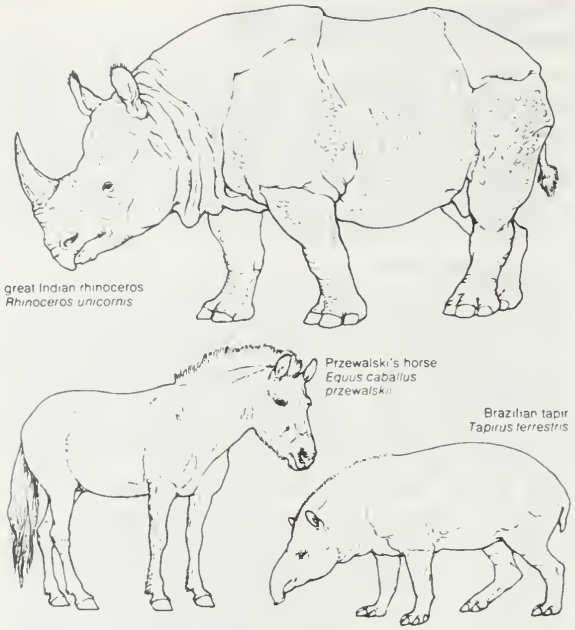

Figure 47: Major body plans among perissodactyls.
Drawing by R. Keane

while the ass originally ranged over northern and northeastern Africa.

The wild horse (*Equus caballus*), ancestor of the domestic horse, occupied the low country north of the great mountain ranges from Europe across central Asia; it may now be extinct as a wild animal. The half-asses, races of *E. hemionus,* were found in the arid zone of Asia from Persia to the Gobi Desert, as well as in Arabia, Syria, and northwestern India.

The living rhinoceroses are also Old World forms, with two species in Africa and three in Asia. There are three species of tapirs in the New World tropics, one in Middle America and two in South America. The fourth species of tapir is Asiatic.

NATURAL HISTORY

Distribution, ecology, and conservation. The Equidae are highly specialized for a cursorial, herbivorous mode of life. They are absent from forests and other densely vegetated regions, but apart from this limitation, the range of the group is relatively unrestricted by the type of vegetation, climate, and topography. The species replace one another geographically for the most part, and each occupies a somewhat different habitat.

Dietary needs as range factors

Grass plays a major role in the diet; the zebras, for example, are known to feed on tall, coarse grasses avoided by most antelopes. Some species also take shrubs, herbs, and even bulbs. Water requirements vary in different species. In South Africa, Burchell's zebra has been found to drink about once every 36 hours. By contrast the mountain zebra (*Equus zebra*), Przewalski's horse (*Equus caballus przewalskii*) and the half-ass, all living in semidesert areas, are reported to survive if they can drink once in three or four days. The ass, too, can manage with less water than the horse. The mountain zebra and Przewalski's horse dig for water in dry riverbeds and depressions.

Zebras. The mountain zebra occupies parts of the arid rocky escarpment separating the interior plateau of the southern African subcontinent from the coast lowlands. The race *E. z. hartmannae,* still relatively numerous over much of its original range in South West Africa and southern Angola, enjoys legal protection and is represented in game reserves. Conflict between these zebras and farm livestock for the meagre pasture of the semidesert regions, however, has led to a reduction in zebra numbers. The race *E. z. zebra* was originally common in the mountain ranges of the Cape Province, but now survives only as a remnant of perhaps 100 animals. About one-half of these have sanctuary in a national park.

Burchell's zebra (*E. quagga*) formerly inhabited a great area of grassland and savanna from the Cape to the southern Sudan. The southernmost race (*E. q. quagga*), which was only partly striped, became extinct in the 19th century. The populations of the other races have been much reduced in many places and the range of the species has shrunk considerably. There are large populations in reserves, however, and the species is not in any immediate danger of extermination. Grevy's zebra (*E. grevyi*), which shares a narrow zone in northern Kenya with Burchell's zebra, is confined to sparsely wooded, semidesert plains and low hills in northern Kenya, southern and eastern Ethiopia, and western Somaliland. Its status appears to be generally satisfactory.

Asses. The true ass (*Equus asinus*), ancestor of the domestic donkey, is the equid of arid North Africa whose range extends south to approximately 6° N latitude. Its natural distribution probably included all habitable parts of North Africa. At present, asses are known from semidesert country extending from the east bank of the Nile (in the Sudan) to the Red Sea, and in parts of Eritrea, Ethiopia, and Somalia. There are also isolated pockets in the Tibesti Mountains in the Sahara, and in the countries of central and western Africa. There is a great deal of uncertainty about the identity of all asses now described as "wild." Some may be merely feral (escaped or released) donkeys, and interbreeding with feral donkeys is likely to have occurred in many, if not all, existing populations.

The two surviving races of wild horses

The wild horse. The wild horse was widely distributed in Eurasia north of the mountain chains. The Romans encountered it in Spain. Two races have survived to modern times. A gray race, known as the tarpan, was the horse of southern Russia. It became extinct in the Ukraine during the mid-19th century. The endangered Przewalski's horse (*E. c. przewalskii*), a small, reddish-brown race (considered a species by some authors), was last seen in the wild in 1968 in the remote, semidesert steppe country on the boundary between Mongolia and China. Wild horses enjoy legal protection in Mongolia and China, but nomadic pastoralists have been encroaching on previously uninhabited country and competing with the horses for pasture and the scarce water supplies.

The half-asses, races of *Equus hemionus,* occupied the dry belt from Mongolia through Central Asia to Syria, with a northern limit at about 50° N latitude. The chigetia or kulan (*E. h. hemionus*), which was formerly widespread over an immense region of the Gobi, now occurs only in semidesert steppe country in central Mongolia. Hunting and competition for water by pastoral tribesmen are responsible for its decline. The kulan is slightly smaller than the kiang (*E. h. kiang*), which is found on the cold, arid steppes of Nepal, Sikkim, and western Tibet at altitudes of 4,270 metres (14,000 feet) and more. The kiang is now said to be rare but not endangered. The Persian onager (*E. h. onager*) lives in a lower semidesert or desert environment, with a range that formerly included northeastern Iran, northwestern Afghanistan, and Russian Turkestan. It is now extremely rare and unlikely to survive outside northeastern Iran and the Badkhyz Reserve in Turkmeniya. A small nucleus has sanctuary in the semidesert salt plains of the recently established Kavir Protected Region in Iran. The Indian wild ass is a closely related, probably identical, form sometimes distinguished as the race *E. h. khur.* A fairly small population occupies salt flats in the Rann of Kutch, a remnant of the thousands found there at the end of World War II. The Syrian onager (*E. hemionus hemippus*) is the smallest member of the group and stands about one metre (three feet) at the shoulder. It was once found in the desert region of Palestine, Syria, and Iraq, and was domesticated by the ancient Sumerians before the introduction of the domestic horse into Mesopotamia. This race may survive in the Djezireh Desert, Syria, or north of the Syrian–Turkish border; if so, the number must be extremely small.

"White" and "black" rhinos of Africa

Rhinoceroses. The two African species of rhinoceros are the black or prehensile-lipped rhinoceros (*Diceros bicornis*) and the white or square-lipped rhinoceros (*Ceratotherium simum*). The terms black and white are misleading, since both species are grayish to brownish, but the names are well established in common usage.

The black rhinoceros was originally widespread from the Cape to southwestern Angola and throughout eastern Africa as far as Somalia, parts of Ethiopia and The Sudan. Its range also extended westward through the northern savanna zone to Lake Chad, the northern Cameroons, Volta, and the northern Ivory Coast. The animal was extremely numerous in some parts. It now occupies a much smaller area, within which it is found in scattered pockets, many of them in parks and reserves. South Africa has an important population of some 300 of them in its Zululand reserves. The species still occurs in northern South West Africa and southwestern Angola, Rhodesia, Mozambique, Malawi, Zambia, and Zaire. Northern Tanzania and Kenya have more black rhino than any other country but the future of the animals outside the parks and reserves is far from secure. The species is also found in parts of Somalia, Ethiopia, northern Uganda, and The Sudan, and remnants remain in the Central African Republic and northern Cameroon. The decline in numbers is largely the result of expanding human settlement and of poaching to obtain the horns, which fetch high prices.

The black rhinoceros occupies a variety of habitats, frequenting open plains, sparse thorn scrub, savannas, thickets, and dry forests, as well as mountain forests and moorlands at high altitudes. It is a selective browser, and grass plays a minor role in its diet. Succulent plants, such as euphorbias, assume great importance in dry habitats, and where these plants are abundant the animals appear to be able to survive without free water. Where water is available, drinking is regular and frequent; the animals also may dig for water in dry riverbeds.

The much larger white rhinoceros is a grazing species with a broad, square muzzle. It prefers short grasses seven to 10 centimetres (about three to four inches) high. The animal makes much use of shade trees for resting and is dependent on surface water. The range of the white rhinoceros is markedly discontinuous. South of the Zambesi River it was once extremely common over a fairly large area of bushveld. It has since become confined to the game reserves in Zululand, where the population has risen to some 1,700; some of the animals have been redistributed to several other parks and reserves in southern Africa.

A northern race formerly inhabited the southern Sudan and adjacent areas of Uganda and Zaire, extending westward into the Central African Republic. It has also been much reduced, but considerable populations still survive in the Parc National de la Garamba (Zaire) and in the Bahr el Ghazal region of The Sudan, and a small remnant has found sanctuary in the Ruwenzori National Park, Uganda.

The smallest living rhinoceros

The smallest of the three Asian rhinoceroses (also the smallest living member of the family) is the Sumatran, or Asiatic, two-horned rhinoceros, *Didermocerus* (or *Dicerorhinus*) *sumatrensis*, standing one to one and a half metres (three to five feet) at the shoulder. It was originally found from eastern Pakistan and Assam throughout Burma, much of Thailand, Indochina (Cambodia, Laos, and Viet Nam), Malaya, Sumatra, and Borneo. Small isolated populations still occur in a few widely separated localities in Burma, Thailand, Malaya, Sumatra, and Sabah, and possibly in other nearby territories. The total population is thought to number between 100 and 170. Some of the survivors in Sumatra are protected in reserves.

The Javan, or lesser one-horned, rhinoceros (*Rhinoceros sondaicus*) occupied the islands of Java, Borneo, and Sumatra, the Malay Peninsula, and a region extending northwards through Burma into Assam and eastern Bengal. It is now restricted to the Udjung-Kulon Reserve in western Java where there are at least 25 and perhaps as many as 50 to 60 animals.

Both the Sumatran and Javan rhinoceroses inhabit forests as well as marshy areas and regions of thick bush and bamboo, climbing actively in mountainous country. They are mainly browsers.

The great Indian, or one-horned, rhinoceros (*Rhinoceros unicornis*) is more or less equivalent in size to the square-lipped rhinoceros and is distinguishable from the smaller Javan rhinoceros by the presence of a large horn, tubercles on its skin, and a different arrangement of skinfolds. It previously occupied an extensive range across northern India and Nepal from Assam in the east to the Indus Valley in the west. It is found in a range of habitats—open grassland, savanna, forests, and hilly country—and appears to be mainly a grazer, raiding grain fields in some areas. Hunting and the pressure of expanding human populations have greatly reduced both the range and numbers of this animal. It is now found almost entirely in eight reserves or sanctuaries in India, notably the Kaziranga Sanctuary in Assam (estimated population 300) and in the Rapti Valley region of the Nepal Terai. The total population is estimated at about 600 animals, and the prospects for survival appear to be reasonably good.

Tapirs. The Malayan tapir (*Tapirus indicus*), largest member of the family Tapiridae, is found in Sumatra and the Malay Peninsula, as far north as the Burmo-Siamese border in latitude 18° N. It is found from sea level to high altitudes and occupies forests and thickets but may feed in more open areas. It is still abundant and widespread.

Distribution of New World tapirs

The three New World species occupy distinct, nonoverlapping but contiguous ranges. The mountain tapir (*Tapirus pinchaque*), the smallest and most primitive, inhabits the temperate-zone forests and bordering grasslands of the Andes in Colombia and Ecuador and in northern Peru, up to altitudes of nearly 4,600 metres (about 15,000 feet). Agricultural and pastoral expansion have resulted in some decline in the status of this species, but it is still fairly common. The Central American, or Baird's, tapir (*T. bairdii*) is the largest of the American species. It is essentially middle American, with a range extending from Mexico into coastal Ecuador, and it occupies undisturbed climax rain forest. It is shy and adjusts poorly to the disturbance caused by settlement. This disturbance, together with the destruction of habitat accompanying human occupation, has greatly reduced its range and numbers. The species is said to be much in need of active conservation. The most widespread species is the Brazilian tapir (*T. terrestris*), which is found throughout the Brazilian subregion east of the Andes and in a small area west of the Andes in northwestern Venezuela and northern Columbia. Like the other species, it is largely a forest form requiring the proximity of water. The three New World tapirs are mainly browsers and are remarkably similar in habits.

Behaviour. *Expression and communication.* The Equidae communicate by means of calls and changes in facial expression. Six different sounds are made by Burchell's zebra. A whinny, consisting of a series of two- or three-syllabic "ha" sounds, serves to maintain contact between members of a group. The repertoire includes an alarm call ("i-ha"), an alarm snort, a drawn-out snort of satisfaction, and a squeal of pain and fear. Other species utter similar sounds, the whinny of the horse and the bray of the ass being well-known examples. Characteristic facial expressions have been described for greeting ceremonies (mouth open, ears up), threat (mouth open, ears back), and submission (mouth open, nibbling movements, ears down). In all species studied except the horse, females assume a particular expression ("mating face") when permitting the male to mount.

In the rhinoceroses and tapirs snorting, squealing, bellowing, and, in some forms, whistling sounds play a major role in communication. Visual signals are not well developed in these nonsocial animals, but a few facial expressions are used.

Feeding. The Perissodactyla are mainly grazers or browsers. The quality and quantity of grasses available to grazing species may vary considerably with the season and the area. The animals may accordingly move great distances to reach attractive sources of food. Migrations of Burchell's zebras to succulent pastures during the rainy season are a feature of the Serengeti Plains and the Etosha National Park in Africa. The distribution of asses, half-asses, and horses inhabiting arid areas largely follows that of rainfall and pasture.

The food of the browsers is fairly readily available throughout the year; thus, species in this category are relatively sedentary. The browsing rhinoceroses may break down trees and shrubs, and use their forelimbs to help get at otherwise inaccessible leaves and twigs. Food is plucked

with the lips. In the tapirs, the upper lip is fused with the short proboscis. The rhinoceroses (excluding the white) have a pointed upper lip with a fingerlike process that is used to pluck leaves and twigs. The white rhinoceros, with its broad square muzzle, is the most specialized grazing rhinoceros, feeding on grass.

Herd behaviour among equids

Social organization and territory. In both the mountain and Burchell's zebras the family group is the basic social unit. It generally consists of a single adult male and two or three adult females with their foals. The groups are stable, apparently because of strong mutual ties among the females rather than because of herding by the male. The stallion is dominant, and there is a hierarchy among the mares, the highest ranking (alpha) animal usually leading the group. Other males are either solitary or live in bachelor groups of two or three, sometimes up to 10. Juveniles leave the family group when they attain sexual maturity at one and one-half to two years. When large aggregations occur on favoured grazing grounds, the groups retain their identity. Among Grevy's zebras and wild asses, territorial males and groups of mares and foals and of stallions are found. There is no evidence for territorial behaviour among any of the zebras except Grevy's. Individual groups occupy home ranges that overlap to some degree with those of other groups.

The social organization of other equids is not as well documented. Observers studying the wild horse and half-asses have noted that females and juveniles form a group dominated by a single stallion, which keeps them together by active herding; the unattached males are solitary or live in small herds.

The pattern of social organization among the rhinoceroses is quite different from that of the Equidae. Dominant adult males of the white rhinoceros occupy territories that, in the Natal reserves, average about 200 hectares (500 acres). Within its area a male may tolerate subadult or aged bulls, which have subordinate status. Adult females accompanied by their calves inhabit home ranges encompassing the territories of six or seven dominant bulls. Juveniles consort with other juveniles or with calfless females, but groups of more than two usually do not stay together long.

The black rhinoceros is basically solitary. Adults of both sexes usually occupy home ranges of 1,000 hectares (2,500 acres) or more, the size depending on the characteristics of the environment; occasionally the ranges may be as small as 200 hectares, however. There is a good deal of overlap in the utilization of these home ranges.

The Asiatic rhinoceroses also are essentially solitary, but detailed information on the nature of the areas they inhabit is not available. Individual great Indian rhinoceroses are said to occupy tracts as small as eight to 20 hectares (20 to 50 acres).

Little is known about the social organization or territorial behaviour of the tapirs. All species are reported to be found alone or in pairs.

Scent marking and territories

Male zebras and horses follow mares in estrus. The stallion, after smelling the spot where a mare has urinated or defecated, exhibits "flehmen" (a characteristic display in which the head is lifted and the upper lip raised) and then urinates or defecates on the same spot. In similar fashion, members of stallion groups often urinate or defecate consecutively; communal dung heaps formed by five to eight animals often arise in this way. The significance of such behaviour is not clear.

Among the Rhinocerotidae excretory products play an important role in marking territories and home ranges. Dominant male white rhinoceroses defecate almost entirely on heaps within their territories. They then scatter the material by kicking vigorously, presumably leaving an individual scent mark in this manner. In addition, they urinate in a ritualized fashion, spraying the urine in powerful jets in a manner peculiar to them and shown by no other sex or age group. Other members of the population also use dung heaps (either in territories or in communal areas, such as along paths) but not exclusively, and they do not scatter dung.

In the black rhinoceros, dung-scattering behaviour does not appear to be exclusive to dominant males. The function of the communal heaps may be mainly to establish the presence of the inhabitant in his home range, and to maintain contact between known animals.

Dung heaps and urine spraying are also observed among other species of rhinoceroses and among tapirs; their significance is presumably of a similar nature.

Fighting. The pattern of fighting is related to the amount of lethal equipment the various groups possess. The Equidae, unarmoured, do not employ stylized fighting techniques to reduce the danger of serious injury—as among certain other species. Fighting is largely confined to adult males competing for estrous mares. Various techniques occur in the zebras, which may serve as an example of the family. Circling, neck fighting, biting (either in a standing or sitting position), rearing combined with biting and kicking, and kicking on the run all are used, either alone or in combination. No set pattern is followed.

Fights among rhinoceroses consist of charges and striking with the horns, usually accompanied by vocal threats. Goring is not common, the stylized pattern having probably been evolved to minimize the danger of serious injury from the formidable horns.

Mutual grooming and greetings

Amicable behaviour. Mutual grooming is well known among horses. Two animals stand facing in opposite directions and groom each other by nibbling at the root of the tail and the base of the neck. Burchell's zebra behaves similarly and so, presumably, do other members of the family.

Zebras greet each other simply by nose-to-nose contact, except that adult stallions go through a ceremony involving nose-to-genital contact. Nose-to-nose greeting is also characteristic of tapirs and rhinoceroses. The latter also rub their bodies together.

Courtship and mating. Courtship is relatively simple among the social equids. The true ass is apparently exceptional. The partners are strangers when the first approaches are made and the female requires violent subjugation by the male, which bites, kicks, and chases her before she will stand for him. This may be the result of separation of the sexes outside the mating season. The wild horse and Burchell's zebra are not at all violent. The stallion often grooms the mare before attempting to mount. The estrous mare (especially, or exclusively, young mares in the case of Burchell's zebra) adopts a typical posture with legs slightly apart, tail lifted, and, except in the horse, a characteristic facial expression (the "mating face" already mentioned).

The more or less solitary rhinoceroses and tapirs go through a more elaborate courtship, presumably because the partners are strangers. After a chase, the male and female may engage in low-intensity fighting, ending with the male laying his head on the female's rump and then mounting and copulating for an extended period. Several males may mate with an estrous female.

Relations between parent and offspring. The perissodactyls bear well-developed (precocial) young, usually a single offspring. After the mother has assisted in removing the placenta and has licked her offspring in the usual mammalian fashion, the young animal soon attempts to stand. A Burchell's zebra foal has been observed to stand quite firmly 14 minutes after birth, and a black rhinoceros calf 25 minutes after birth.

Newly born equids follow any nearby object during the first few days of life. At this time, zebra mares drive away all other zebras from their foals. The behaviour ensures that the foal will form a bond with its mother during the initial period of imprinting. Foals follow their mothers closely and are groomed frequently.

Although precocial, black rhinoceros calves appear to have a lying-out period; that is, an initial period when they rest quietly in thick cover except when being suckled. Thereafter they follow their mothers closely. A young white rhinoceros tends to walk ahead of the mother and may be guided by her horn.

Most young perissodactyls remain with their mothers until the next offspring is born. A young rhinoceros may, therefore, accompany its mother until it is two and one-half years old, or older. Although grazing starts early, suckling proceeds for a considerable time, perhaps for its psychological rather than its physiological value.

Running games and mock fighting

Play. As in other mammals, play is a prominent form of behaviour among young perissodactyls. Zebras up to the age of one year frequently engage in running games. Foals gallop wildly about on their own, jumping and kicking up their heels, sometimes chasing other animals, such as gazelles, mongooses, or birds. In groups they play catching games, running after one another in close succession. Mock fighting sometimes takes place. Groups of adults have also been seen to chase foal groups in play, and indeed stallion groups carry out playful gallops. Stallions also engage in play greeting and in mock fights.

Playful romping and mock fighting with the horns are common among rhinoceros calves. Young tapirs play running games.

Rolling and wallowing. Behaviour for the care of the body is widespread among the perissodactyls. Equids frequently roll in dry, loose soil forming rolling hollows—a common feature of zebra country.

Wallowing, which may help regulate body temperature, probably is mainly a form of self-grooming; it is practiced by all species of rhinoceroses. They often spend hours lying in pools during the middle of the day in hot weather. Mud of suitable consistency induces wallowing, which may be followed by sand bathing. Prolonged rubbing on tree trunks or suitable stumps follows a wallow; old rubbing stumps and stones may take on a shine from repeated use.

Tapirs may have the most pronounced tendency to bathe and wallow, but few details of their behaviour are known. They are also said to enter water when disturbed.

Reproduction. Female equids of all the species for which information is available attain puberty at about one year, but are not normally successfully mated before the age of two to two and one-half years, and possibly as late as three to four years in the case of Grevy's zebra. Zebras probably breed until about 20 years of age. The domestic species are seasonally polyestrous (repeatedly fertile), coming into breeding condition in spring and, unless mated, undergoing repeated estrous cycles at intervals of approximately three weeks until the end of the summer. The wild species studied also tend to mate seasonally; most young are born in spring and summer.

Reproductive potential of equids

The gestation period of equids is between 11 and 12 months. In most species a postpartum estrus occurs, usually within two weeks of the birth of the young; thus, the maximal potential reproductive rate is one young per year. This potential is not always attained. Only about 50 percent of domestic mares that are mated produce foals, and nearly half of a study group of Burchell's zebra mares bore only one foal in three years.

The gestation period of three species of rhinoceroses is about 15 to 17 months. For the Sumatran rhinoceros the period is said to be only seven months. No information is available for the Javan rhinoceros. Female white and black rhinoceroses attain sexual maturity at the age of four to five years and are capable of calving at intervals of approximately 2½ years. Rhinoceroses probably breed until between 30 and 40 years old. The white tends to have a mating peak in spring, corresponding with the flush of green grass, and a calving peak in autumn.

The Malayan and Brazilian tapirs have gestation periods of 13 months' duration. The Brazilian tapir is reported to mate before the onset of the rainy season.

FORM AND FUNCTION

Integument. The skin of rhinoceroses is extraordinarily thick. The great Indian and Javan rhinoceroses are covered with large, practically immovable plates, separated by joints of thinner skin to permit movement. The two species differ in the arrangement of the folds. The hair of all rhinoceroses is sparse or absent except that of young Sumatran rhinoceroses, which have a dense coat of crisp, black hair. The skin of the tapirs is also thick with a sparse covering of short hairs arranged in irregular groups. The equids have a normal hide with a well-developed hairy coat.

Structure of rhinoceros horns

The "horns" of the rhinoceroses are noteworthy structures of epidermal origin. The horn is composed of a mass of fused epidermal cells that are impregnated with a tough, fibrous protein (keratin) and that rest on a roughened bony cushion on the fused nasal bones. The male Javan rhinoceros has a short horn about 25 centimetres (10 inches) long; the horn of the female is rudimentary. The great Indian rhinoceros has a single horn up to 60 centimetres (25 inches) long. The other species of rhinoceroses have a second horn that stands on a protuberance of the bones (frontals) between the eyes. Hornlike structures were also present in the titanotheres and extinct rhinoceroses.

In all living perissodactyls the terminal digital bones are flattened and triangular, with evenly rounded free edges, and are encased by keratinous hooves derived from the integument. The single hoof of the equids—the only mammals to walk on the tips of single digits—is the most highly developed structure of this kind among mammals. The keratinous wall is analogous to the nail of mammals that have claws or nails.

Skeleton. *Backbone.* The vertebral column acts as a firm girder, with high dorsal (neural) spines on the thoracic vertebrae, above the forelimbs and ribs. Spines and ribs serve as compression struts above and below. The column balances largely on the forelegs and is pushed from behind by the hindlegs, which are the main propellants. This skeletal structure permits running and also enables great weights to be borne in such animals as the rhinoceroses. There are never fewer than 22 thoracolumbar (trunk) vertebrae.

The neck, or cervical, vertebrae are opisthocoelous; *i.e.*, with the bodies (centra) of the vertebrae hollowed behind to take the convex heads of the succeeding centra. This feature facilitates rotatory movement of the neck and is most highly developed in the horses.

Limb girdles. The shoulder blade is long and narrow with a small coracoid process (a ridge to which muscles are attached) and a low spine. There is no clavicle (collarbone). The pelvic girdle has a broad, vertically raised ilium to which are attached the large gluteal (thigh) muscles, important for locomotion, and the abdominal muscles, which carry the weight of the belly.

Limbs. There is a clear evolutionary tendency in the Equidae for the limbs to become long and slender, with a reduction in the number of digits in the swift-running forms. These changes are accompanied by an increase in rigidity and specialization for movement fore and aft. The upper (proximal) segments, the humerus of the forelimb and the femur of the hindlimb, have remained short. In contrast the lower (distal) parts, consisting of an anterior radius and posterior ulna in the forelimb and an anterior tibia and posterior fibula in the hindlimb, have become longer and slimmer. The humerus is short and broad. Its articulation with the radius and ulna only permits fore-and-aft movement. The proximal end of the stout femur has a third projection, or trochanter, in addition to the usual mammalian two, which serves as an additional point of attachment for the large locomotory muscles of the hindlimbs.

Evolution of swift-running forms

The anatomical feature of the order now considered most significant is that the axis of symmetry of the limbs passes through the third or middle toe, the most strongly developed and the one on which most of the weight is borne. This is called the mesaxonic condition and is contrasted with the paraxonic condition of the Artiodactyla, in which the axis passes between the third and fourth toes.

Originally the five toes of the limb were held in the semidigitigrade position—*i.e.*, with the weight of the body being borne on the soles of the toes and on the lower ends of the elongate metacarpal and metatarsal bones of the forefeet and hindfeet. The upper (proximal) ends of these bones were raised above the ground, a condition still to be seen in the tapirs.

As the third digit became increasingly dominant, it became longer and thicker. The upper ends of the third metacarpus and metatarsus broadened and forced the other digits to the side. The first (inner) digit was the first to disappear. The earliest known forms already bore only three digits on the hindfoot. The loss of the first toe on the front foot led to the four-toed condition common in the Eocene; the fifth digit persisted, although it was somewhat

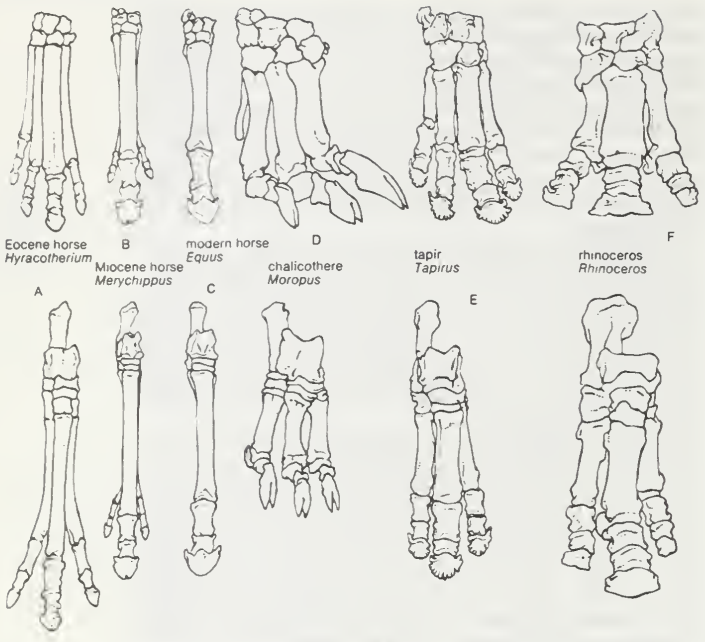

Figure 48: Forelimbs (above) and hindlimbs (below) of some recent and fossil perissodactyls.

weak. The tapirs, with four toes in front and three behind, have retained this early condition.

The fifth digit of the hindfoot was the next to disappear in the evolutionary sequence, and all known forms beyond the lower Oligocene had only three toes in each foot. The living rhinoceroses illustrate this condition. A massive limb with a broad foot is essential in such heavy animals. The feet have cushions of elastic connective tissue well suited to bear the weight of the body.

In the most highly specialized forms, the second and fourth digits also underwent reduction. These digits are retained in the living Equidae only as functionless, vestigial slivers of bone on either side of the third metacarpal and metatarsal.

Growth of the third digit's terminal joint

With reduction in the number of digits, the third has assumed a progressively more vertical position. Its terminal joint, or phalanx, has become larger and the hoof surrounding it bigger and thicker. At the same time the ulna, the smaller bone of the forelimb, decreased in size until, in the modern Equidae, its upper end fused with the radius and its lower end remained merely as part of the articulating surface of the radius with the wrist bones (carpals). In the hindlimb, the fibula became reduced in similar fashion. It articulates with the ankle bones (tarsals) only in a few extinct forms, such as the titanotheres. In the tapirs and rhinoceroses it is slender. In the equids the proximal end remains as a small splint of bone, while the distal end has fused with the tibia.

The arrangement of the small bones of the carpus ("wrist") and tarsus (ankle) is another characteristic feature of perissodactyl limbs. In most other mammalian orders, the carpals and tarsals provide the limbs with regions of flexibility. Their development in the perissodactyls has been toward increasing rigidity, following the trend in the limbs as a whole. The basic mammalian arrangement is one of three rows of bones: a proximal row of three, adjacent to the lower arm and leg bones; an intermediate row of four (the centralia); and a distal row of five (carpalia of the forefoot, tarsalia of the hind), one to each digit. The centralia, carpalia, and tarsalia are numbered one to four or five, beginning on the side of the thumb and big toe. In all orders the number of wrist and ankle bones has been reduced. Usually only one of the centralia, known as the navicular, remains, while there are the same number of carpalia and tarsalia as there are digits.

An interlocking plan is characteristic of the Perissodactyla. In the forefoot, the third distal carpal (the magnum or capitate) is enlarged and interlocks with the proximal carpals. The elongated third metacarpal thrusts up against these interlocked bones. In the equids, distal carpal I (the trapezium) is absent, and the arrangement in the hindfoot is similar. In the most advanced, modern forms metatarsus III thrusts against the enlarged and flattened tarsal III (ectocuneiform), and this in turn is in contact with the large, flat navicular (centrale II and III). The navicular abuts on the flattened astragalus (or talus), the intermediate bone of the proximal row. The articulation between the upper surface of the astragalus and the tibia is pulley-like and permits only fore-and-aft movement of the limb.

Teeth. The full complement of mammalian teeth consists of three incisors, one canine, four premolars, and three molars in each half of each jaw. The arrangement may be expressed by the formula $\frac{3 \cdot 1 \cdot 4 \cdot 3}{3 \cdot 1 \cdot 4 \cdot 3} = 44$ teeth. The figures represent the number of incisors, canines, premolars, and molars in each half of the upper (above the line) and lower (below) jaws, respectively.

Fully-toothed early hoofed mammals

The Condylarthra, a group of mammals that first appeared in the Paleocene (about 65,000,000 years ago) and were ancestral to most of the later and recent hoofed mammals, had a full complement of teeth. In many of the early perissodactyls, only the first lower premolar had been lost. The subsequent evolutionary sequence led to losses and specializations of the incisors and canines. Lengthening of the facial part of the skull resulted in the formation of a gap, the diastema, between the incisors and the premolars. The first upper premolar was reduced or lost in consequence. The canines, when present, were situated in this diastema, as they are in male horses.

Among the living perissodactyls, the tapirs have the least specialized battery of teeth. In this, as in many other features, they have remained primitive. The dental formula of the family Tapiridae is: $\frac{3 \cdot 1 \cdot 4 \cdot 3}{(2-3) \cdot 1 \cdot 3 \cdot 3} = 40–42$ teeth. The first upper premolar is noteworthy in being the only premolar with a milk, or deciduous, predecessor.

The cutting teeth are reduced in the Rhinocerotidae. Incisors and canines are absent in the two African forms. The Asiatic species have one or two upper, but generally no lower, incisors in each half of the jaw. They have no upper canines; the Javan and Sumatran rhinoceroses have one short, sharp lower canine on each side. There are three upper and lower molar teeth in all five species. The white and Sumatran rhinoceroses have three premolars, and the others have three or four premolars. The dental formula for the family is set up, therefore, as follows: $\frac{(0-2) \cdot 0 \cdot (3-4) \cdot 3}{0 \cdot (0-1) \cdot (3-4) \cdot 3} = 24–30$ teeth. The dental formula of the Equidae is $\frac{3 \cdot 1 \cdot (3-4) \cdot 3}{3 \cdot 1 \cdot 3 \cdot 3} = 40–42$ teeth.

The form of the premolars and molars is of great interest and their evolutionary history has been studied in some detail. Primitive, browsing members of the order had brachydont cheek teeth (*i.e.*, with low crowns and long, narrow root canals), with separate low, rounded cusps—the bunodont condition. Increasing specialization for grazing resulted in fusion of the cusps into ridges (lophs), thus teeth of this kind are called lophodont. Lower molars typically have two transverse lophs, the protoloph and the metaloph. In the upper molars these ridges are fused with a longitudinal ridge (ectoloph), which runs along the outer edge of the tooth. Further development leads to a convoluted arrangement of the lophs, such teeth being termed selenolophodont.

Associated with these changes in the tooth surfaces is a tendency for the crown to become higher. High-crowned teeth are termed hypsodont. The hollows between the lophs of hypsodont teeth are filled with a deposit of secondary cement, which strengthens the teeth and makes them more resistant to wear. A further evolutionary trend is for premolars to become as large as molars. Where the process of molarization is complete, as in horses, all grinding teeth are identical.

The Tapiridae have primitive brachydont premolars and

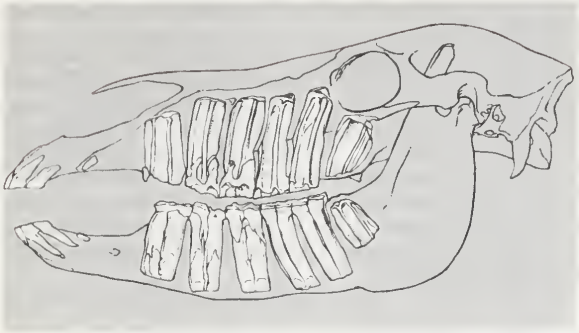

Figure 49: Skull and dentition of horse, *Equus caballus*, cut away to show roots of teeth.

molars. They possess two simple transverse lophs, and are thus termed bilophodont. They lack secondary cement on the crowns.

The Sumatran rhinoceros, the most primitive of the living rhinoceroses, and the Javan rhinoceros have similar brachydont, lophodont cheek teeth. The great Indian rhinoceros, which is less of a specialized browser, has hypselodont (hypsodont and selenodont) premolars, with a layer of cement on the crowns. The black rhinoceros has brachydont and lophodont teeth, with a thin layer of cement. The white rhinoceros is more specialized, for the cheek teeth are hypselodont and have a thick cement layer.

The grinding teeth of the Equidae are highly specialized, high crowned, with a complicated selenodont surface and thick cement deposits.

Comparative size of the stomach

Digestive system. The stomach of perissodactyls is small, simple, and undivided. In the horse its capacity is only 8.5 percent of the whole digestive system. The comparable figure for the ox is 71 percent. The intestine is very long and the cecum (blind gut) and colon are huge and sacculated (*i.e.*, with many blind pockets). Here food is macerated and fermented and the fibrous portions are dissolved. The liver has no gall bladder.

EVOLUTION AND PALEONTOLOGY

The Perissodactyla appeared early in the Eocene, about 55,000,000 to 40,000,000 years ago. Together with most other ungulate mammals, they were probably derived from the Condylarthra. The condylarths were abundant in Europe and North America, mainly during the Paleocene (65,000,000 to 55,000,000 years ago). Condylarths were unspecialized mammals, rather carnivore-like in appearance. The larger species attained the size of tapirs. The limbs were fairly short and primitive but the third toe was somewhat enlarged and the phalanges ended in hooves. There was a full complement of teeth with some specialization of bunodont molars for herbivorous diet.

Horses. The earliest horses appeared during the lower Eocene in Europe and North America. They are generally known as *Eohippus* ("dawn horse"), but *Hyracotherium* is the correct taxonomic designation. Some species of these little forest-dwelling, browsing animals were no larger than a terrier. They had moderately long, slender limbs with only four toes in the forefoot and three in the hindfoot, all equipped with hooves. The molars were essentially bunodont (with low, rounded cusps) and the premolars simple.

Hyracotherium-like animals persisted in Europe until the end of the Eocene. Another group, the paleotheres or "native" European horses, evolved as a specialized side branch, which died out in the Oligocene. North America was the centre of horse evolution. During the Eocene, *Hyracotherium* was succeeded by forms such as *Orohippus* and *Epihippus*, which are known only from that epoch.

The Oligocene (40,000,000 to 26,000,000 years ago) saw a major change with the appearance of three-toed horses, *Mesohippus*, *Miohippus*, and others. All of the premolars were similar to the molars, low-crowned but lophodont (ridged). *Anchitherium* was an early Miocene form as large as a modern pony, which migrated from North America to Europe. These primitive three-toed horses or anchitheres survived until Pliocene times, some of their descendants attaining the size of a rhinoceros.

The main course of horse evolution entered a third stage in North America in the Miocene Period (26,000,000 to 7,000,000 years ago). A line of grazing horses developed, almost certainly to exploit the new grasslands that were spreading over the surface of the earth. The degree of lophodonty of the molariform teeth increased, changing the pattern of the crests on the surface and increasing their grinding efficiency. Of greater importance, these teeth became hypsodont (high-crowned) and thus maintained a good grinding surface as grinding of the harsh, siliceous grass caused them to wear down. Another substance, cement, came to supplement the dentine and enamel forming the teeth of earlier types, and provided additional material to resist abrasion. The evolution of these specialized teeth was a tremendous advance.

Trends in horse evolution

The limbs of the grazing horses became increasingly rigid and specialized for fore-and-aft movement, better fitting the animals for running in open country. In *Merychippus* the ulna was fused with the radius and the fibula was much reduced. In some advanced forms the central toe was much larger than the two lateral toes and carried most of the weight of the body on a hoof much like that of modern horses.

A number of evolutionary lines developed during the Pliocene, which lasted from 7,000,000 to 2,500,000 years ago. *Pliohippus* of North America is probably the line from which modern horses have come. The genus *Equus* is characteristic of the Pleistocene when it developed in North America and spread to all continents except Australia. By the end of the Pleistocene, horses had become extinct in the New World.

Titanotheres. Another group entirely, the titanotheres (Brontotheriidae), evolved independently from *Hyracotherium*-like ancestors and became abundant in North America during the Eocene and Oligocene, but disappeared by the Miocene. They were also found in Asia and Eastern Europe. The end forms, such as *Brontops* and *Brontotherium*, were huge, the largest standing 2½ metres (eight feet) at the shoulder. They had long, low skulls and a small brain. Many species bore a pair of large, hornlike processes on the front of the head.

Chalicotheres. The chalicotheres (Chalicotheriidae) were moderately large animals that appeared in Eurasia and North America during the Eocene. Thereafter they evolved mainly in the Old World, disappearing from America in the mid-Miocene, but persisting in Asia and Africa until they died out in the Pleistocene. Early mem-

Figure 50: Reconstruction of fossil Perissodactyla. *Brontops*, an Oligocene titanothere, some individuals of which were about 2.5 metres (eight feet) at the shoulder. Detail of a painting by Charles R. Knight.

bers of the group such as *Paleomoropus*, from the lower Eocene, resembled contemporary equids. The Miocene *Moropus* typifies the peculiar characteristics of later forms. It was horselike, but the front legs were longer than the rear. Each foot bore three toes which ended in large, fissured phalanges bearing claws that may have been used for digging up roots and bulbs.

Tapirs. The fossil and living tapirs, together with similar extinct forms such as the lophiodonts, constitute a small, fairly uniform group.

Homogalax, Lophiodon and other tapir-like animals appeared in the Eocene. Some were close to the ancestry of both rhinoceroses and tapirs, and other evolutionary lines left no descendants. *Protapirus* from the Oligocene of Europe and North America was the forerunner of the modern tapirs. These tapirids persisted until the Pleistocene, when climatic changes led to their extinction.

Rhinoceroses. The fossil history of the rhinoceroses is far more complex. They evolved from the early tapiroids but diverged from that group. Unlike the equids, they have tended to grow large, with short, stout limbs with little reduction in the digits. Although the premolars have tended to molarize, the molar cusp pattern is simple; the teeth seldom become hypsodont, and cement occurs rarely.

The Hyracodontidae, or running rhinoceroses, from the Eocene and Oligocene of North America and Asia were the most primitive. *Hyracodon* had long, slender legs with three toes on each foot and typically rhinocerotid cheek teeth.

The amynodonts are known from the late Eocene and Oligocene of Eurasia and America and lived in Asia until the Miocene. They were a side branch, perhaps derived from primitive hyracodonts. *Metamynodon* and some other forms were about as large as hippopotamuses and may have lived in rivers. The premolars were simple and the incisors reduced, but canines and molars were enlarged.

True rhinoceroses are probably also descended from early hyracodonts. They became numerous in the Oligocene as large animals with molariform premolars. Many side branches evolved. *Trigonias* still had four front toes but *Caenopus*, another Oligocene representative, had the three toes common to all later rhinoceroses. Like its relatives of that period, *Caenopus* was fairly small, about the size of a tapir, and hornless.

One spectacular group contained giant hornless creatures, such as *Baluchitherium* and *Indricotherium* from the Oligocene and Miocene of Asia; the largest of known land mammals, they stood 5.5 metres (about 18 feet) high at the shoulder and had a long neck and long forelegs.

Rhinoceroses died out in North America during the Pliocene, but in Eurasia many different species survived to the Pleistocene. One of the most familiar of these later rhinoceroses is the woolly rhinoceros (*Coelodonta*), which was depicted by Stone Age artists and is known from nearly intact specimens. The surviving rhinoceroses represent remnants of once varied and abundant stock; the genera have little direct relationship to one another.

CLASSIFICATION

Distinguishing taxonomic features. Skeletal features are of greatest importance in classifying the Perissodactyla. They are, of course, the only criteria applicable to fossil forms. Distinguishing characteristics of the skull include the relative length of the facial region, length and form of the nasal bones, presence of a postorbital bar and of hornlike structures. The form and number of teeth, presence of a diastema, number of molariform premolars, the height of the cheek teeth, their cusp structure and the presence or absence of cement on the grinding surfaces all are particularly valuable taxonomic features. The limb structure is also a useful aid to classification, especially the length of upper and lower portions, the degree to which the ulna and the fibula are reduced and fused, respectively, with the radius and the tibia, the number and form of carpal and tarsal bones, and the number and relative size of the digits.

Importance of skeletal features

Among living perissodactyls, body size, form of the upper lip, number and length of horns, structure of the skin and colour pattern are the most important features for classification.

Annotated classification. The classification presented here follows that of U.S. paleontologist George Gaylord Simpson, which is generally accepted but modified in some fairly minor ways by other authors. The term Mesaxonia, introduced by the 19th century paleontologist O.C. Marsh, is essentially synonymous with Perissodactyla. Simpson used it as a convenient designation for the superorder containing the single order Perissodactyla, as he used the parallel name Paraxonia for the superorder with the one order Artiodactyla.

Groups indicated by a dagger (†) are known only as fossils.

ORDER PERISSODACTYLA

Herbivorous ungulates with either 3 digits or 1, at least in the hindfeet. Early forms digitigrade, this feature either retained or completely replaced by the unguligrade condition in later representatives. The body weight borne mainly or entirely on the third digit through which the long axis of the limb passes (mesaxonic condition). The talus (heel bone) with only 1, proximal, keeled surface, articulating with the tibia, no duplication of keel on the distal surface, as in artiodactyls. Nasals broad at the posterior end, alisphenoid canal present. Posterior premolars molariform; cheek teeth bunodont in early forms, typically lophodont or selenolophodont, rectangular; wide diastema separates them from incisors and canines, which may be reduced or absent. Testes inguinal, occasionally scrotal; mammary glands inguinal, with 2 teats; uterus bicornuate. Fifteen living species, but more than 200 fossil forms.

Suborder Hippomorpha

Superfamily Equoidea

Dentition complete, upper molars with 6 tubercles, the 2 external ones united to form an ectoloph, median and internal tubercles generally fused into a single loph. Tendency to molarization of premolars and reduction of lateral digits.

†*Family Palaeotheriidae* (paleotheres or "native horses"). Lower Eocene to lower Oligocene; Europe and Asia. Size variable, from that of fox (shoulder height about 40 centimetres or 16 inches) to that of a rhinoceros; body form tapirlike. Three digits in each foot. Dentition complete or first premolars absent; premolars molariform, separated from canines by diastema. Cheek teeth brachydont, lophodont, with or without cement. Orbits without postorbital bar. Eurasian "native horses," 7 genera.

Family Equidae (horses and relatives). A progressive group with tendency to molarization of premolars and development of cement.

†*Subfamily Hyracotheriinae* (hyracotheres). Eocene; Europe and North America. Size about that of a fox; 4 toes in forefoot, 3 in hindfoot. Dentition complete, premolars simple or last 2 slightly molariform, molars brachydont, bunodont, diastema short. Skull short, without postorbital bar. Three genera. Basic stock from which other members of family evolved.

†*Subfamily Anchitheriinae* (anchitheres). Lower Oligocene to lower Pliocene. Fossils from North America, Europe, Asia. Browsing horses. Early forms collie-sized (shoulder height about 60 centimetres [23.6 inches]), end forms as large as a rhinoceros. Three toes in each foot, central toe somewhat enlarged; metapodials elongated. First premolars reduced, second to fourth molariform. Cheek teeth brachydont, lophodont; ectoloph (longitudinal outer crest) above typically W-shaped cross-lophs retained distinct cusps; hypostyle at back edge of upper molars prominent. Lower cheek teeth with 2 crescent-shaped lophs and double cusp at junction. Diastema long, no postorbital bar. Six genera.

Subfamily Equinae (horses, asses, half-asses, and zebras). Lower Miocene to Pleistocene of North America; Pleistocene of South America; lower Pliocene to Recent of Europe, Asia, and Africa. Most forms as large as ponies or modern horses. Feet with 3 toes in early forms, 1 in later forms (but metapodia 2 and 4 persist as remnants), limbs with progressively elongated lower segments and reduced or fused ulna and fibula. Calcaneum without articulating surface for fibula. First premolars reduced or absent, others molariform; cheek teeth hypsodont, selenolophodont, with cement; canines in long diastema. Skull long, with postorbital bar in upper Miocene and later forms; nasals long and narrow. Some Recent forms with striped coat.

†*Superfamily Brontotherioidea*

†*Family Brontotheriidae* (titanotheres). Lower Eocene to lower Oligocene. Fossils from North America and Asia. Early forms as large as tapirs, end forms huge, standing 2.5 metres (8.2 feet) at the shoulder. Graviportal browsers; 4 toes in forefoot, 3 in hindfoot. Dentition complete, premolars small

and simple in early forms; later forms with incisors and first premolars reduced or absent, remaining premolars only partly molarized. Molars large, bunolophodont, above with W-shaped ectoloph as in early equids, lower with double V resembling equid pattern but lacking reduplication of cusp at union of V's. Skull elongated, low, without postorbital bar, with large rough, hornlike process in later forms. About 39 genera.

†Suborder Ancylopoda

†*Family Chalicotheriidae* (chalicotheres). Upper Eocene to lower Pliocene. Fossils from North America, Europe, Asia. Early forms equivalent in size (and similar) to contemporary horses, *Hyracotherium;* later representatives larger, up to size of a modern horse. Most with forelegs longer than hindlegs and 3 toes in each foot; rudimentary metacarpal V retained in forefoot, most with clawlike digits. Incisors of canines reduced or absent; first premolar absent, remainder small and simple. Molars bunolophodont, cusp pattern similar to Brontotheriidae. About 13 genera. Aberrant perissodactyls which may have used claws to dig for bulbs and roots.

Suborder Ceratomorpha

Superfamily Tapiroidea

Brachydont forms, molars with simple ectoloph and strongly developed transverse protoloph and metaloph. Forefoot generally with 4 toes, hindfoot with 3.

†*Family Isectolophidae.* Lower to upper Eocene. Fossils from North America and Asia. Limb structure similar to that of *Hyracotherium,* teeth already tapiroid. Four genera.

†*Family Helaletidae.* Lower Eocene to middle Oligocene. Fossils from North America and Asia. Skull advanced in structure; premolars much simpler than molars, molars of simple lophodont form. Ten to 12 genera.

†*Family Lophiodontidae* (lophiodonts). Lower to upper Eocene; Europe and probably Asia. Skull not tapir-like, lophs of molariform teeth oblique. About 6 genera.

Family Tapiridae (tapirs). Lower Eocene to Recent. Fossils from North and South America, Europe, Asia, Africa. Recent species in Central and South America and Southeast Asia. Limited to tropical equatorial forests of South America and Asia. Browsers. Skull greatly modified; premolars completely molarized, first sometimes absent; transverse lophs strongly developed in molariform teeth, ectoloph simple. Limb structure primitive; 4 toes in forefoot; 3 in hindfoot. Six genera but only 1 extant.

Superfamily Rhinocerotoidea

Molars brachydont, upper with 2 transverse lophs fused with a well-developed ectoloph; lower with 2 asymmetrical crescents. Premolars more or less molariform. Rough processes on nasals (for horns) frequently present; forefoot with 3 or 4 toes.

†*Family Hyrachyidae.* Lower to upper Eocene; North America and probably Asia. Small animals; forefoot 4-toed; molariform teeth with separate tubercles. Four genera.

†*Family Hyracodontidae* (hyracodonts or running rhinoceroses). Middle Eocene to upper Oligocene. Fossils from North America and probably Asia. Relatively small; feet 3-toed, legs long and slender. Molariform teeth typically rhinocerotid. About 7 genera.

†*Family Amynodontidae* (amynodonts). Upper Eocene to middle Oligocene. Fossils from North America, Europe, Asia. Hippopotamus-like; forefoot 4-toed, hindfoot with 3 toes. Skull short, heavy, premolars and incisors reduced, premolars simple, canines and molars enlarged. Six genera.

Family Rhinocerotidae (rhinoceroses). Middle Eocene to present. Fossils from North America, Europe, Asia, and Africa. Now restricted to tropical Africa and Asia. Large; most forms 3-toed. Skull elongated, raised at posterior end. Dentition incomplete, upper canines always absent, some incisors usually enlarged as cutting teeth; premolars molariform, last upper molar simple. About 34 genera, 4 extant.

Status of the chalicotheres

Critical appraisal. Systems of classification frequently differ in the status given to the chalicotheres. Simpson takes the view that their ancestry was probably equid and almost certainly hippomorph. He holds that the significance of their claws has been over-emphasized and has tended to distract attention from their true affinities. Accordingly he places them in the superfamily Chalicotheroidea of the suborder Hippomorpha. In the classification presented above they are given their own suborder, Ancylopoda, following the views of Alfred S. Romer, another authority on the group.

The forms united in the family Lophiodontidae by Simpson, followed here, are thought by some recent workers to warrant separation into three families. Romer distinguishes the families Lophialetidae, Deperetellidae, and Lophiodontidae. The affinities of certain primitive genera such as *Hyrachus* and *Colonoceras* remain controversial; Simpson places them in the family Hyrachyidae, superfamily Rhinocerotoidea. Romer considers them to be early tapiroids and assigns them to the Helatidae (superfamily Tapiroidea). The difference of opinion is slight, for it is generally agreed that the hyrachids are close in the common stem of the tapiroids and rhinocerotoids.

(R.C.Bi.)

Artiodactyla (pigs, goats, sheep, cattle, giraffes, deer, camels)

The mammalian order Artiodactyla, or even-toed ungulates, includes the pigs, peccaries, hippopotamuses, camels, chevrotains, deer, giraffes, pronghorn, antelopes, sheep, goats, and cattle. It is one of the larger mammal orders, containing about 150 species, a total that may be somewhat reduced with continuing revision of their classification. Many artiodactyls are well-known to man, and the order as a whole is of more economic and cultural importance than any other group of mammals. The much larger order of rodents (Rodentia) affects man primarily in a negative way, by competing with him or impeding his economic and cultural progress.

GENERAL FEATURES

Abundance and distribution. Artiodactyls were once the dominant herbivores (plant-eating mammals) of almost every continent. They are an important link in the chain by which the sun's energy, having been used by green plants, is made available to other forms of life. They tend to be medium- or large-sized animals. If they were any smaller they would compete with rabbits and the larger rodents, and if they were larger they would compete with elephants and rhinoceroses, the largest of terrestrial herbivores. The success of artiodactyls has depended on skeletal adaptations for running and on the development of digestive mechanisms capable of dealing with plant foods; none is adapted to flying, burrowing, or swimming. The individual species tend to be fairly narrowly adapted, in comparison with other mammals, but many of them nonetheless have broad distributions.

Native artiodactyls are absent only from the polar regions and from Australasia, but many have been introduced into Australia and New Zealand. In Australia, the position of medium and large herbivores is occupied by kangaroos. Through most of its evolutionary history, the order was absent from South America; only within the last few million years have some groups entered that continent. The occurrence of the majority of living artiodactyls in the Old World is a recent phenomenon; a considerable variety once inhabited North America.

Families of living artiodactyls

The order Artiodactyla contains nine families of living mammals, of which the Bovidae (antelopes, cattle, sheep, and goats) is by far the largest, containing nearly 100 species. There are five Eurasian and four African species of pigs (family Suidae) and two Central and South American species of piglike peccaries (Tayassuidae). The two hippopotamus species (Hippopotamidae) are African. The more familiar large species were until recently widespread throughout Africa south of the Sahara and in the Nile Valley; the pygmy hippopotamus has a restricted distribution in West Africa. The camel group (Camelidae) was formerly abundant in North America, the now extinct North American stocks having produced the camelids of South America (wild guanaco and vicuña, domestic llama and alpaca) and the Old World dromedary and Bactrian camel.

The remaining artiodactyls (*i.e.,* the suborder Ruminantia) are all ruminants (cud chewers), the most primitive of which are the chevrotains (Tragulidae), with three species in Asia and one, the water chevrotain, in West Africa; the chevrotains are clearly remnants of a group that was once more numerous and widespread. Deer (Cervidae) are basically Eurasian and have not spread into sub-Saharan Africa, although they have reached the Americas. There are about 30 species, the greatest number being concen-

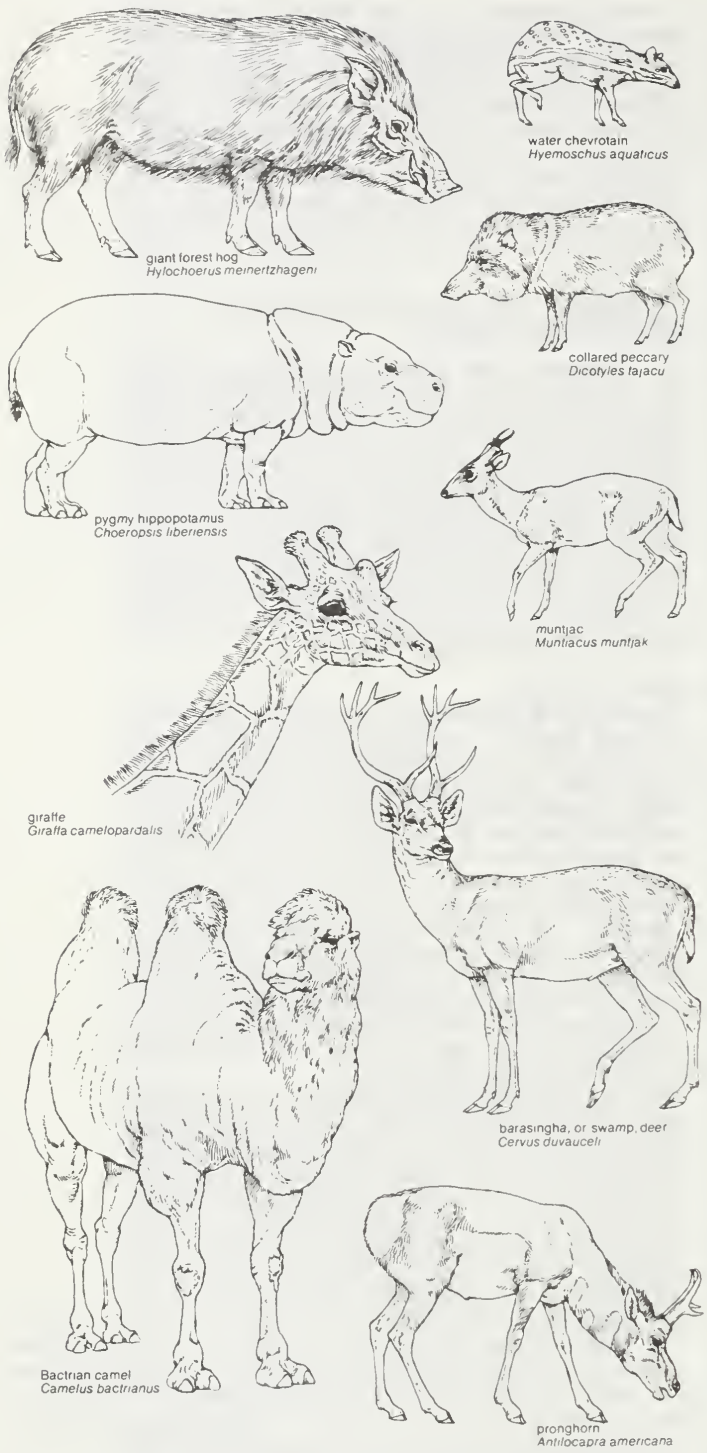

Figure 51: Representative non-bovid artiodactyls.
Drawing by R. Keane

trated in South America and tropical Asia. The giraffe and the okapi (Giraffidae), two distinctive African species, are closely related to deer. The pronghorn (Antilocapridae), although sometimes called pronghorn antelope, is not a true antelope; it is the only survivor of a stock of ruminants that was very successful in the later part of the Tertiary Period in North America (about 2,500,000 to 65,000,000 years ago). The family Bovidae is primarily African and Eurasian, with a few members in North America. Bovids are advanced artiodactyls, many of which live in open grassland and semi-arid areas.

Importance to man. Artiodactyls have long been exploited by man for economic purposes. At Olduvai Gorge in East Africa there is clear evidence of the use of antelopes for food almost 2,000,000 years ago. In Europe during Paleolithic times (about 30,000 years ago) Cro-Magnon man depended heavily on the reindeer. By this time the use of animals other than as food had become established; skins were used as clothing and footwear, and bones were used as tools, weapons, and accessories.

The domestication of animals was a major advance in human history. Domestication of herd animals probably arose gradually, perhaps before agriculture. Domesticated goats and sheep are first known from the Near East at some date close to 7000 BC. Cattle and pigs were domesticated at some subsequent date but certainly before 3000 BC. In South America the llama, now used for transport, and the alpaca, which provides a source of wool, were developed from guanacos by the Incas or their predecessors. The dromedary (*Camelus dromedarius*), domesticated in Arabia, was introduced into the Southwestern United States, southwestern Africa, and inland Australia in the 19th century. A large feral population now exists in Australia.

In addition to providing meat, milk, hides, and wool, artiodactyls have served man in a number of other ways. In Kashmir, the underfleece, or pashm, of the Siberian ibex (*Capra ibex*) and of local domesticated goats has been used as the basis for the manufacture of cashmere shawls. In southwestern France, pigs have been used to locate underground truffles (the fruiting bodies of certain edible fungi).

No group of mammals is more extensively hunted than the artiodactyls. Sport hunting of various deer supports a multimillion-dollar industry in North America and Europe. In many cultures hunting has been reserved for monarchs or the aristocracy. In the centuries after the Norman Conquest of England, the forest law provided severe punishment for the slaughter of deer and boars. Père David's deer (*Elaphurus davidianus*) of China now survives only because it was preserved first in the hunting park of the emperors of China and later by the Duke of Bedford after the slaughter of the Chinese herds at the end of the 19th century.

Wild ungulates were the primary source of meat for human populations long before the appearance of modern man. Prehistoric man hunted the large mammals of his environment with an ever increasing effectiveness that was certainly instrumental in his survival. The extent to which man was involved in the extinction of some of the larger Pleistocene animals (*i.e.*, those that were abundant 10,000 to 2,500,000 years ago) is still being investigated. There is now known to have been a wave of late Pleistocene extinction of large mammals, including artiodactyls; in North America this wave reached its zenith about 9000 BC. Many animals also became extinct in Africa, where long-horned buffalo and large relatives of hartebeests survived until very recently. More of the large mammals have survived in Africa than elsewhere, but the reason for their survival is not known. A second, probably final, wave of extermination of the larger mammals has taken place with the spread of European culture and firearms in the past 300 years. It has been marked by wanton slaughter and has ultimately produced an interest in conservation. It now seems, however, that the unprecedented demands on the environment being made by rapidly expanding human populations will result in a nearly complete extinction of large wild mammals.

NATURAL HISTORY

Behaviour. *Migration.* Many artiodactyls undertake seasonal migrations between their breeding grounds and feeding areas or between different feeding areas. They can then take advantage of the seasonal changes in different areas. This means that larger populations, and hence a larger biomass (*i.e.*, the total weight of all individuals in an area), can be supported than if all passed their lives in one area. The North American mule deer (*Odocoileus hemionus*) comes from its summer pastures at high altitudes as the first snow falls and returns at the end of winter, several weeks after the snow has melted. Seasonal changes

Social behaviour. Although the popular image of artiodactyls is one of great herds numbering thousands of individuals, some species are solitary, and many others form only small family groups. The maternal family unit, in fact, is the most cohesive one, providing the basis for

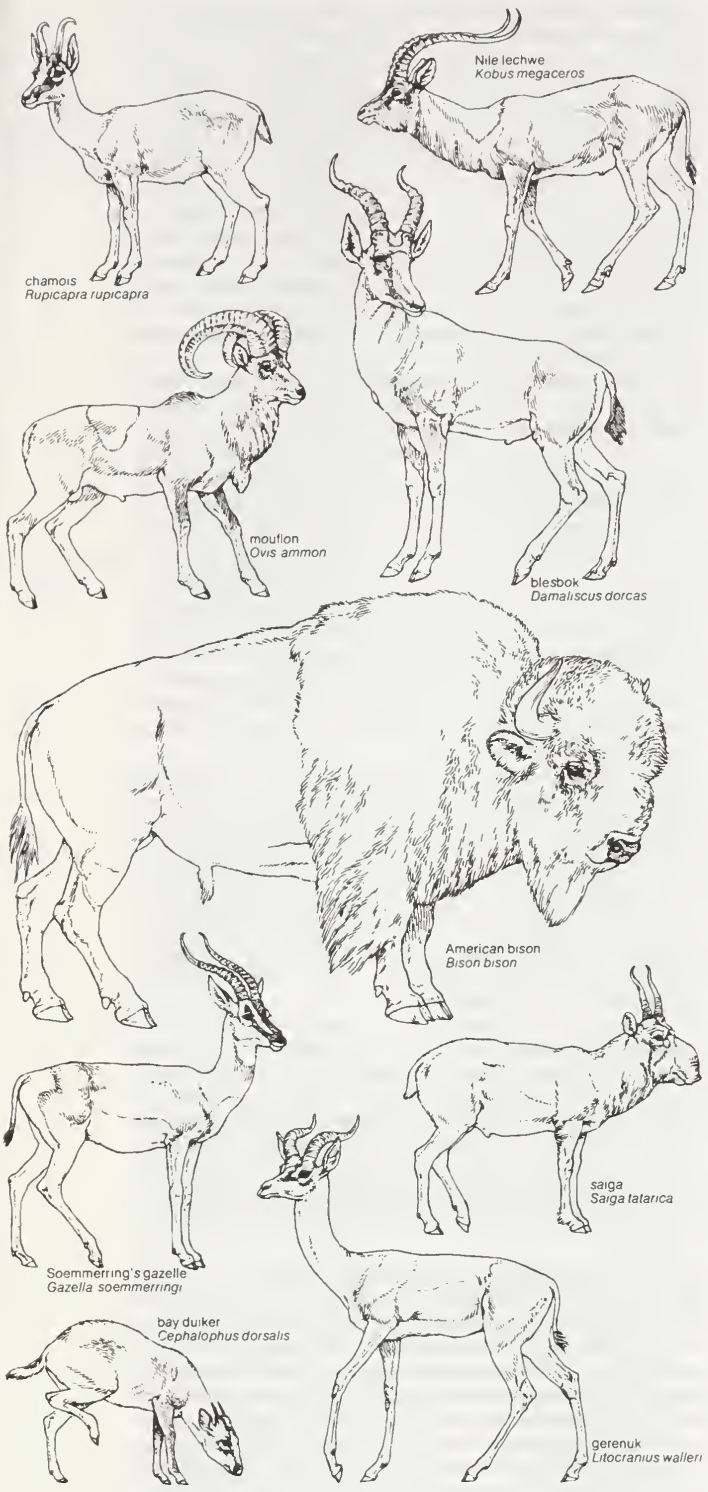

Figure 52: Body plans of bovid artiodactyls.
Drawing by R. Keane

herd formation. Most artiodactyls are more or less social, and grazing forms may be found in especially large aggregations. It appears that the practice of aggregating gives protection, favouring those members of the species that are the most active contributors to the gene pool (thus the most available to natural selection), since the individuals most frequently taken by predators are old, solitary males, males maintaining territories, and animals of either sex separated from the herd.

The advantage of herd behaviour

Social facilitation (the instigation of collective behaviour) takes place in herds. After one animal flees, all of the others flee, and the predator may thus not catch any. Social facilitation may also promote a restricted season for births; this helps survival of the young by denying these easy-prey individuals to predators through much of the year, and keeps the predator population lower than if young were available throughout the year. Another advantage of herding is that the older generation in a herd can guide migrations to water, feeding areas, or mating grounds.

Females and young are usually in herds separate from those of the younger males, but territorial (the older, proven) males may accompany the females. There are some variations of this behaviour. In the Eurasian roe deer (*Capreolus capreolus*), for example, the basic unit includes the doe, her litter of two, and often the young of the previous year. During the rutting (mating) season males associate with females in heat but do not gather harems. The female herds of red deer (*Cervus elephas*) are separate from the males except in the breeding season, when the stag will defend his female herd against other males. Among cattle and related species, the males associate with the females and young, but the bulls are ranked below a so-called master bull, each defending its place within the rank order. Female hippopotamuses and their young form a group in water and have a favourite resting and basking sandbank. The males have their resting places around this area. Each male's rank in the social hierarchy determines how close to the females he may be.

There can be some flexibility of social organization within a species. During the rutting season the male Rocky Mountain goat (*Oreamnos americanus*) makes little effort to herd females within a fixed area if there is little snow, but he does drive off other males. When there is much snow, he neither fights other males nor defends individual females.

Forest-dwelling artiodactyls often live singly, as does the okapi (*Okapia johnstoni*) of central Africa; individuals meet only for mating. Female moose (*Alces alces*) with calves are intolerant of their own young of the previous year and of adults, so even small herds do not form.

Territoriality

The territory of an animal is an area from which the possessor attempts to exclude other individuals of the same species (and occasionally other species). An animal in an area lacking its own scent is more timid and ready to flee. Among solitary artiodactyls the territory holder defends an area sufficient to meet his needs for food and shelter. Among social artiodactyls the territorial system is interwoven with breeding activities, and territories are normally defended only by certain males. Other males are driven off, and a percentage of males are prevented from mating.

The most simple territorial organization among artiodactyls is that of the common wild pig (*Sus scrofa*), which lives within a home range including resting, feeding, drinking, and wallowing places. There is little sign of territorial defense, and the herd (called the sounder) may move to a new area. At the other extreme, male Uganda kob antelopes (*Kobus kob*) hold territories, for breeding only, that are as small as 15 to 30 metres (50 to 100 feet) in diameter. There are 30 to 40 territories on the breeding ground of a herd, and groups of females and young move about the territories despite the efforts of individual males to detain them. The semi-arid Serengeti plains of northern Tanzania contain nomadic aggregations of blue wildebeest (*Connochaetes taurinus*), males of which defend temporary territories only while an aggregation remains stationary.

In territorial defense an aggressive encounter between males is generally preceded by visual signalling of intentions. Chital deer (*Cervus axis*), for example, have several sorts of threatening displays. When sharp, potentially lethal horns appeared in early ruminants, intimidating displays rather than combats would doubtless have been favoured. Horns or antlers eventually functioned to maintain head contact during struggles rather than to bruise, slash, or gore. This stylized fighting, in which the competing males interlock horns or antlers and try to "outwrestle" each other, minimizes the danger of killing an opponent of the same species (conspecific). It evolved in two ways: further development of the wrestling, found in stags and some of the antelopes, and ramming, as in sheep. In sheep the horns are the sole organs of display. They increase in size throughout life and parallel the dominance order of the males, so that unnecessary fighting is minimized. Ramming may have intermediate forms; goats, for example, butt with a sideways hooking motion. In the fighting of hornless artiodactyls, such as pigs, the combatants may be

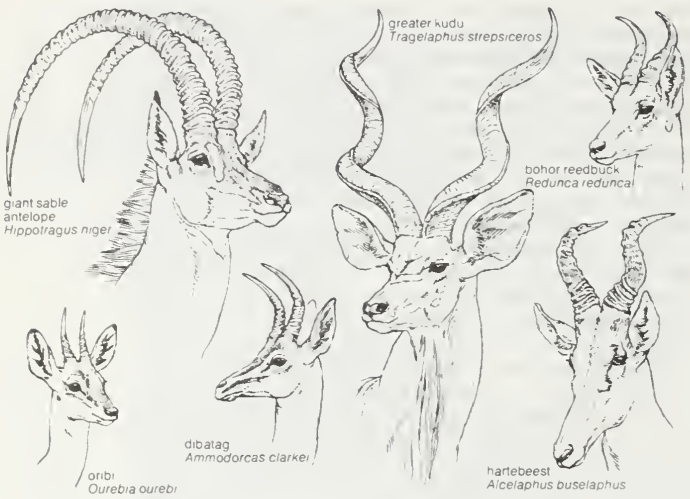

Figure 53: Horn variation in African antelopes.
Drawing by R. Keane

badly mauled or even killed. The fighting behaviour of camels retains primitive elements of biting, kicking, and neck wrestling.

Reproduction. Many advanced artiodactyls have elaborate courtship behaviour, a regular component of which is for the male to sniff or lick the female's urine, and afterward to raise his head slightly with upcurled lips. This behaviour, which has been called *flehmen*, apparently enables the male to recognize females in heat. In the mating ceremonies of tragelaphine antelopes (kudus, bushbucks, and others) the male follows the female, nuzzling her neck several times. When he mounts, he lays his neck along hers so that their heads touch. In Thomson's gazelle (*Gazella thomsoni*), following the *flehmen* behaviour, the male runs close behind the female and finally taps her hindleg with his foreleg. Similar leg contact also occurs in some other antelopes. Its function could be to test the female's readiness to mate, to habituate her to contact, or to heighten her readiness to mate. It appears to be equivalent to the neck contact of tragelaphines. During mounting, the male Thomson's gazelle holds his head high and does not touch the female's flanks with his forelegs; the pair may continue walking. This is probably a more advanced pattern of events than that in tragelaphines. The kob antelope has elaborate displays after mating. These and the specialized sexual displays seem to be a consequence of this species' tightly clustered territories on the mating grounds. Another pattern occurs in the normally solitary Indian hog deer (*Cervus porcinus*); as many as 20 or 30 aggregate loosely in a certain area, then females and males leave in pairs and usually remain together until they have mated. Mating in artiodactyls often intensifies toward dawn and dusk.

Gestation periods

Gestation periods vary and are related in part to the size of the animal. They range from four months in the small chevrotain to 14 months in the Bactrian camel (*Camelus bactrianus*) and over 14 months in the giraffe. Females of normally gregarious species become solitary a few days before giving birth. The female chital, or axis deer, for example, remains near a patch of dense bush and high grass to which she can retreat if endangered. The female collared peccary (*Dicotyles tajacu*) withdraws to a burrow. The European wild pig gives birth in a rough nest.

In temperate regions, birth takes place in spring or early summer, and in tropical areas there are often more births during or just after the rainy season. The absence of a well-defined breeding season in a species may indicate less rigorous environmental conditions, which sometimes vary in different parts of a species' range. Warthogs have one restricted breeding season in most of eastern and southern Africa, while elsewhere two seasons or year-round breeding have been recorded. The breeding season of the waterbuck (*Kobus ellipsiprymnus*) is continuous in Uganda, but in Zambia its breeding season shows a sharp peak at the height of the rains.

Most modern artiodactyls have one young at each birth, but there are some well-known exceptions among ruminants. The Chinese water deer (*Hydropotes inermis*) bears twins or triplets, but during gestation carries even more fetuses; early records (now known to be incorrect) of large litters were based on observations of dead pregnant females containing the large number of fetuses. The mule deer, white-tailed deer (*Odocoileus virginianus*), roe deer, pronghorn (*Antilocapra americana*), nilgai (*Boselaphus tragocamelus*), four-horned antelope (*Tetracerus quadricornis*), and saiga (*Saiga tatarica*) commonly bear twins. In the white-tailed and mule deer and in the saiga, a higher percentage of twins are borne by the older females; this is probably true in other species. The number of young is usually three in the warthog, five in the European wild pig, and two in peccaries.

The female wild pig almost ignores her young, which free themselves from their birth membranes and seek a teat. Female camels show comparatively little maternal attention and do not eat the afterbirth (the fetal membranes and placenta). Ruminants generally eat the afterbirth, as well as the dung and urine of the young, thus helping to prevent discovery of the young by predators. Licking of the young tends to facilitate its recognition by the mother.

Precocity in offspring

An artiodactyl is normally precocious (well developed) at birth and may weigh one-tenth as much as its mother. An extreme example of precocity is the wildebeest calf, which rises within five minutes of birth, follows its mother within another five minutes, and can move as fast as an adult in 24 hours. Young deer fawns "freeze" during danger but rejoin the herd when the danger is long past or when retrieved by the mother.

Pigs and hippopotamuses are weaned after a few months, but among higher artiodactyls, lactation lasts longer. Wildebeest, for example, suckle for almost a year, although they start to eat grass when only a few days old. This may either maintain a bond between parent and offspring and form the base for larger social groupings or help to "develop" the four-chambered stomach. Higher artiodactyls eat soil when they begin to eat solid food, probably to establish a normal flora and fauna in the rumen (the first of the four stomach chambers).

Locomotion. Artiodactyls are preyed upon by carnivores and therefore need speed and agility to escape death. They have an added disadvantage in the sheer weight of their very large stomachs, which they need in order to digest plant food. Running ability reaches an extreme in advanced artiodactyls living in open country. The hippopotamus, with an adult weight of 2,500 to 3,000 kilograms (5,500 to 6,600 pounds), is the only living artiodactyl big enough to need heavy, pillar-like limbs for support.

In the normal walking of artiodactyls the legs move in the following order: (a) left front, (b) right rear, (c) right front, (d) left rear. This basic pattern is masked in faster walking or trotting by each foot being lifted off the ground before the one ahead of it in the sequence reaches the ground, resulting in telescoping the first (a and b) and second (c and d) pairs of movements. In galloping or fast running the two front legs leave the ground one immediately after the other, then the two back legs. The chief propulsive force in locomotion comes from the back legs, except in the giraffe (*Giraffa camelopardalis*), in which the front legs provide the main propulsive power.

Camels often amble, both legs of each side moving together, and the giraffe and the okapi always use this walking gait. Here the middle two (b and c) and the first and last (a and d) actions of the normal walking pattern occur together. The giraffe, having a short body and great height, could not adopt the normal ruminant gait without tripping. The long neck moves back and forth in time with the strides and helps smooth the movement. Galloping by the giraffe is of the normal ungulate type.

Artiodactyls living among bush or rocky cover may develop a bounding sort of gait in which the legs are pulled up very sharply during each stride. Deer and some antelopes are examples. When walking, species in such habitats are supported by the diagonally opposite legs for a greater length of time in each stride than are fast-running, open-country ruminants. This is a more primitive stable

position and allows an easier leap from hidden danger. Some bovids, notably goats in Eurasia and the klipspringer (*Oreotragus oreotragus*) of Africa, are especially agile on rocky slopes and precipitous ground.

Maximum speeds of locomotion

The maximum speeds of some artiodactyls are: warthog, 48 kilometres (30 miles) per hour; camel, 14–16 kmph (9–10 mph); giraffe, a little over 48 kmph (30 mph); Cape buffalo (*Syncerus caffer*), 56 kmph (35 mph); Thomson's gazelle, 80 kmph (50 mph).

Ecology. *Food habits.* Most artiodactyls are closely tied to the resources of their environment. They are dependent, for example, on feeding areas not being covered by too much snow or shrivelled under a drought, and on the regulating effects of fire or other herbivores on the seasonal succession of vegetation. Various grazing species feed on grass at different heights. Browsers, those that feed on the foliage of shrubs and trees, show more extreme variation in feeding height, the maximum being that of the giraffe.

Herbivorous animals need less initiative and intelligence to collect food than do the meat-eating, hunting carnivores, but digestion is more difficult. Advanced artiodactyls have evolved the ability to bolt food and to ruminate it (chew it more thoroughly) at a later time or while resting in an area where they may be less obvious to predators and can conserve energy. Tropical artiodactyls frequently have adaptations for water conservation, having developed to a high degree internal physiological regulation (homeostasis).

Primitive artiodactyls were probably omnivorous but favoured plant foods, a characteristic still found in pigs. The latter dig with the snout and, to a lesser extent, with the front legs and upper tusks (canine teeth). The wart-hog of Africa (*Phacochoerus aethiopicus*) has a modified method of gathering food. When food is scarce it forages for young grass shoots under very low bushes; its tusks and localized thickening on its skin protect the eyes and muscles from thorn damage, and small incisors enable it to pluck food.

Hippopotamuses (*Hippopotamus amphibius*), although they spend a great deal of time submerged in lakes or rivers, do not feed in the water. They graze at night, wandering over well-used trails, sometimes far from water, often damaging crops.

Most members of the camel family are found in arid habitats. The vicuña (*Lama vicugna*) of the South American Andes lives at high altitudes where it grazes on soft grasses and herbs. It has much the same food requirements as domestic sheep.

Chevrotains live in dense undergrowth close to water or in marshes, where they browse on soft vegetation, roots, and tubers, following a way of life probably not unlike that of their ancestors.

The other ruminants browse or graze. They may take many plant species in the course of the year, but at any one season a large part of the diet consists of only five or six plants. Some ruminants are strongly specialized. The reindeer of the Arctic (*Rangifer tarandus*), for example, eats a variety of sedges, grasses, and herbaceous plants in summer but, as the long winter approaches, gradually shifts to a diet of lichens. It uses its front feet to scrape snow away from lichens to a depth of about 60 centimetres (two feet). The females are unique among deer in possessing antlers, which are thought to help them get scarce food in late winter by driving off the males that have by then shed their antlers. Reindeer may eat lemmings. The red deer, on the other hand, has catholic feeding habits. In woods it browses on lichens, berries, fungi, and the leaves of most deciduous trees; in open country it eats grass, heather, berries, and lichens. Shrubs and trees are used more in winter. When the red deer lives in the same areas as other ruminants it can be a serious competitor for food.

The importance of grasses in the ruminant diet

Grasses form a substantial part of the diet of many ruminants. Young grass consists of about 5 percent protein, 1 percent fat, 3 percent minerals, and 20 percent carbohydrates; the remaining percentage is water. The most noticeable changes as grass ages are an increase in carbohydrate content to 75 percent and a large decrease in the amount of water. Such food, especially when coated with silica, as are many grasses, or when covered with dust, would be impossible for nearly all nonruminant herbivores to eat or digest. The major evolutionary trend in ruminants has been to make use of grasses and grasslands, and the higher ruminants have evolved largely in adaptive balance with one another. This adaptive balance was shown during a study of the change from plains to thickets of scrub growth in an area in the eastern Congo over a period of about ten years. There was an accompanying decrease in numbers of antelopes and warthogs, no change in buffalo, and an increase in elephants and hippopotamuses.

There is not usually a one-to-one dependence of any artiodactyl species on one plant. The plant species that constitute the major part of the diet may vary with the season, and similar parts of different plants may be eaten in preference to other parts of the same plant. Food resources in an area are thus parcelled out among the various artiodactyls present. Sometimes behavioral differences minimize competition between closely related species in the same area. A study has shown that in central Africa the roan antelope (*Hippotragus equinus*), a grazer, favours open areas with taller, ranker perennial grasses and is more or less sedentary within a small area; the sable antelope (*H. niger*), also a grazer, prefers savanna woodland or the edges of open areas, and herds follow a more or less cyclic annual route over an area of about 500 square kilometres (200 square miles). When pasturage is restricted, sheep will cut grass very short, and goats will damage trees and bushes. An American zoologist, George B. Schaller, has observed that, in Kanha Park in central India in the hot season, blackbuck (*Antilope cervicapra*) continue to graze on grass shoots in open areas; chital deer seek out tender grass blades, especially along forest edges, and also feed on leaves and fruits; barasingha (*Cervus duvauceli*) eat dry and moderately coarse grass along ravines; sambar deer (*Cervus unicolor*) browse on leaves and crop coarse grasses in the forest; and gaur (*Bos gaurus*) graze on tall, coarse grass and break down saplings to get at the leaves. The choice of habitat also varies: chital avoid steep terrain and forests with an unbroken canopy; blackbuck require less water than the others and thus remain in drier regions; sambar and gaur are less specialized in habitat requirements, and both are active primarily at night; barasingha prefer reed beds but also enter forests and climb hills.

It has also become evident that grazing successions are one of the mechanisms that enable the maximum use to be made of environmental resources. On the Serengeti plains, for example, the wildebeest grazes on ground already covered by the zebra and leaves the grazed grass in a condition suitable for the Thomson's gazelle. Interactions take place between artiodactyls and some plant species. It has been noted in the Tarangire area of northern Tanzania that *Acacia* seedlings germinate only where the impala (*Aepyceros melampus*) has left its dung. In parts of southern Peru plants growing on or close to the dung of the vicuña are different from those of the surrounding pasture.

Artiodactyls often favour the boundary zone between habitats. In Rhodesia, Lichtenstein's hartebeest (*Alcelaphus lichtensteini*) is usually found at the edge of clearings adjacent to woodland.

Areas of distribution. Some artiodactyls have surprisingly small ranges; Hunter's hartebeest (*Beatragus hunteri*) and the dibatag (*Ammodorcas clarkei*), for example, are found in two very restricted areas in eastern Africa. Others have extremely large ranges, such as the roe deer, which lives from the western shores of Europe to the eastern shores of Asia, or the red deer, which is found in a similar band across Eurasia and is regarded by many as conspecific with the North American wapiti or elk (otherwise called *Cervus canadensis*). Sometimes a considerable area may be occupied by a chain of related species, an example being the oryxes; the beisa and gemsbok (races of *Oryx gazella*) occur in South and East Africa, the scimitar-horned oryx (*O. dammah*) in West Africa, and the Arabian oryx (*O. leucoryx*) in Arabia.

The influence of climate on the distribution of artiodactyls

It is well known that climate is one of the factors limiting the ranges of artiodactyls. A number of South African antelopes differ, at the species level, from their ecological counterparts farther north in Africa. The bontebok and blesbok, races of *Damaliscus dorcas*, are found in the south and the sassaby (*D. lunatus*) farther north; the black

wildebeest (*Connochaetes gnou*) occurs in the south and the blue wildebeest (*C. taurinus*) farther north. This probably is a result of climatic or climatically influenced factors; each species evidently functions best in a certain temperature and aridity range. Wide distributions can occur more easily along lines of latitude than they can by spanning the tropics to temperate or polar regions. Species that cross lines of latitude are often associated with mountain chains, examples being the Rocky Mountain goat, with its wide latitudinal range in western North America, and the goral (*Nemorhaedus goral*), found from Indochina to the Amur River. Climatic effects on distributions sometimes occur with regard to altitude. In Central Asia, the goa (*Gazella picticaudata*) is found in valleys from 3,000 to 3,660 metres (10,000 to 12,000 feet) above sea level, the chiru (*Pantholops hodgsoni*) and the yak (*Bos mutus*) are on the very high steppe between 5,500 and 6,100 metres (18,000 and 20,000 feet).

South America has a more impoverished artiodactyl fauna than Africa, being limited to deer and camelids. This arises in part from the late arrival of the artiodactyls (deer in middle to late Pliocene, about 4,000,000 years ago, camelids perhaps a little later) and in part because a number of large rodents compensate for the shortage of large herbivores. The cervids in South America have not shown the same capacity for radiation in open country as have bovids in the Old World.

Influence of pests on distribution

The areas of distribution and numbers of individuals are determined by complicated interweaving of effects not yet completely understood. Bloodsucking flies are thought to be the main reason that red deer in Scotland ascend to higher feeding grounds in June, and reindeer are afflicted by horse flies (*Tabanus*) and other dipteran pests. It is questionable whether the level of artiodactyl populations is controlled by predation, by availability of food, by reproductive rate, by disease, by climate, or by competition, insofar as these can be regarded as separate factors. It is known that undernourishment increases the susceptibility of an animal to the effects of parasites. If such an infected animal, say a pig, is caught by a leopard, it would be an oversimplification to assign a single reason for its death; it could have died from starvation, parasites, or predation. There is no evidence that artiodactyls are affected more than marginally by predators during most of their mature lives. Mortality is greatest among juvenile and aged animals. In a study of central African warthogs, it was estimated that a 60 percent loss occurred during the first six months of life in an expanding population and 95 percent in a declining one. Although predation was thought to be the main cause, another was the fact that the piglets had only limited control over their body temperatures and were thus more at the mercy of environmental temperature change. Food supply may sometimes be decisive, either directly or through the indirect action of intermediate agencies such as drought. The year 1961 lacked long rains, causing a severe shortage of forage in the Nairobi Game Park in Kenya. Many antelopes died of starvation, populations fell, and those of the blue wildebeest had not recovered nine years later, perhaps for reasons unconnected with the initial drought. Disease has generally been considered to have only a secondary importance in regulating numbers.

Thickness of the snow cover in winter is a very important factor for Asian artiodactyls. The saiga, for example, cannot move in snow deeper than about 40 centimetres (16 inches), and the wild sheep *Ovis ammon* in snow deeper than 60 centimetres (24 inches), at the most. The snow may have other effects; a layer of ice on top of snow may damage an animal's legs and weaken the animal to the extent that it is caught by a predator. Saiga may be unable to dig through even a shallow layer of compacted snow. Hoarfrost on vegetation is especially dangerous when prolonged or when it occurs in consecutive winters, though elk may escape the worst effects by feeding in winter on bark and high shoots. Massive periodic mortalities among Palearctic (Eurasian) ungulates in winter have been known since ancient times. The saiga has adapted to these crises by migrating great distances in a short time away from snowstorms or from areas where fodder is short. It also has a very rapid maturation to a reproductive state, ensuring that populations will build up after heavy mortalities.

Population density over the range of a species is affected by social behaviour, such as the effects of territoriality, dispersal of the young, and whether the species lives in herds. Fecundity may be reduced in overcrowded conditions by effects on reproductive control mechanisms, reduced viability of the young, or retarded maturation.

FORM AND FUNCTION

General structure. Artiodactyls have larger stomachs and longer intestines than carnivorous animals because plant food is less easily digested than meat. The necessity of escaping predators and the handicap of a heavy digestive system have resulted in limb bone adaptations.

Comparison of odd- and even-toed ungulates

In all artiodactyls the main weight-bearing axis of the leg passes through the third and fourth toes together. This has been called paraxonic support and is contrasted with the mesaxonic limb support of the other great order of herbivorous mammals, the perissodactyls (rhinoceros, horse, tapir), in which the weight-bearing axis passes through the third or central toe alone. As artiodactyls evolved there was increasing development of the third and fourth toes and a parallel decline of the second and fifth toes flanking them. Progressive simplification of limb extremities has characterized the evolution of the artiodactyls, and even in the earliest known artiodactyls, the pollex and hallux (corresponding to the big toe and thumb of man) were already rare.

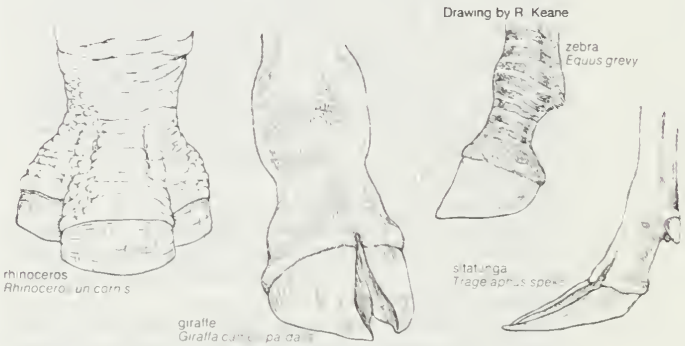

Figure 54: Comparison of even-toed (artiodactyl: giraffe and sitatunga) and odd-toed (perissodactyl: rhinoceros and zebra) ungulate feet.

The other main morphological characteristic of artiodactyls is that the astragalus, one of the bones in the ankle, has upper and lower rounded articulations (areas of contact of bones) and no constricted neck, instead of simply one rounded articulation above a neck, as in other mammals. This character is so basic to artiodactyls that it has not developed very much within the known history of the order, having already been present in long extinct members. The artiodactyl astragalus also has an articulation on its rear surface for the calcaneum (heel bone). The three articulations are in nearly parallel planes, allowing the astragalus to rotate vertically.

Other features of the limbs, skull, and dentition distinguish artiodactyls. The ulna (posterior forearm bone) and fibula (posterior bone of the lower leg) have become reduced. The humerus, the upper bone of the foreleg, is large and has a large protrusion, the greater trochanter, to which muscles are attached. The femur, the upper bone of the hindleg, has a large greater trochanter and a second, lesser trochanter, but lacks the third trochanter characteristic of perissodactyls. There are typically 19 thoracic and lumbar (upper and lower back) vertebrae. The separate lumbar region of the spine is retained with its forwardly directed transverse processes (lateral projections on the vertebrae). There is no clavicle, or collarbone, in the shoulder girdle. The hip girdle shows fore-and-aft elongation and a well-developed ischium (upper anterior bone of the pelvis). There is never a penis bone.

The large tongue is very mobile and can be thrust forward. The brain is moderately developed, with folding of the surface of the cerebral hemispheres variably developed, often less in small artiodactyls than in large ones.

The olfactory region of the brain is well developed and hearing is acute. The brains of earlier artiodactyls, such as the extinct entelodonts, were smaller than those of later forms. There are often scent glands on the head and body.

Specializations of the head. The skulls of pigs and peccaries lack a complete bony bar behind the eye (postorbital bar) as in most suiform artiodactyls and the early camels. The hippopotamuses, most camels, all ruminants, and two fossil suiform groups (entelodonts and oreodonts) have a complete postorbital bar. Any surface exposure of the periotic bone (bone around the ear) on the skull is called the mastoid, and skulls without such a surface exposure are described as being amastoid. Amastoid skulls are found in most suiform groups (including entelodonts, anthracotheres, and all living suiform groups); mastoid skulls occur in some early suiform groups, oreodonts, and all remaining artiodactyls that have lived since the end of the Eocene Epoch (about 38,000,000 years ago). Hippopotamuses have many modifications for aquatic life—large lungs, eyes and nostrils on top of the head, nostrils that can be closed by muscular control, and small ears. They are able to remain submerged for at least five minutes.

Horns and antlers Pigs, peccaries, hippopotamuses, camels, and chevrotains have no horns or antlers. In the early Miocene, Old World ruminants related to giraffes and deer first developed such appendages. The majority of deer have antlers, defined as solid, bony, branched outgrowths of the frontal bones, present only in the males (but also in female reindeer) and shed seasonally. They are not covered by a horny sheath but, during a growth period of about four months, have a fine-haired skin or "velvet." The antlers have two basic branches, the anterior or brow tine, and the posterior branch or beam. The brow tine is unbranched, except in Père David's deer, in which both it and the beam are branched, the brow tine forming the dominant part of the antler. Antlers are specialized sex characters used for fighting by males in the rutting season and to scrape or slash at trees and bushes for territorial marking.

The distinction between horns and antlers

A study of the chital deer showed that antlers increase in size up to the seventh year, remain at a constant size until the ninth year, then decline. The horn of bovids consists of a hollow, unbranched horny sheath (formed of modified skin like fingernails and toenails) that fits over a bony core; horns are often present on both sexes. If such a horn is accidentally lost it is not regenerated; this is unlike the situation in deer, in which normal shedding is followed by regrowth. In the giraffe, but not in the okapi, horn growth is mainly from the parietal bone. The pronghorn has horns in both sexes. The sheaths are shed each year after the breeding season, and new ones develop under the old ones. The sheath is two pronged, but the underlying bony core is unbranched.

Teeth. There is a complete set of teeth in early artiodactyls and in modern pigs of the genus *Sus,* consisting on each side of three upper and lower incisors, an upper and lower canine, four upper and lower premolars, and three upper and lower molars. There has been a tendency toward reduction of the front teeth and development of a gap (diastema) between them and the back teeth. There has been very little tendency for the premolars to molarize, and the first premolar often disappears. Early forms had five-cusped upper molars, but the fifth cusp (protoconule) disappeared early.

Members of the suborder Suiformes have the full complement of incisors and canines, except for peccaries, which lack the lateral pair of upper incisors. Hippopotamuses have continuously growing incisors and canines, the lower canines being very large.

The canines of pigs grow continuously. In this group the canines are weapons for offense and defense, the sharp cutting edges of the lower canines being maintained by wear against the uppers. Young camels retain the full complement of front teeth, with three incisors and one canine in the upper and lower jaws; the upper incisors are extremely small. In the upper jaw of the adult only the rear incisor and canine are present. The vicuña has continuously growing lower incisors.

The molars of pigs are low crowned (except those of the warthog) and have many cusps; those of peccaries are more simple. Peccaries have one less premolar than pigs; camels also have reduced premolars. Chevrotains have rather flattened lower premolars but have incipiently selenodont molars; *i.e.,* in which the cusps are drawn out into longitudinal crescents. Premolars of ruminants are wider, and the molars definitely selenodont. In many bovids and the pronghorn, but not in giraffes or deer, the molars are markedly high crowned.

Limb adaptations for fast running. Adaptations for fast running reach an extreme in advanced artiodactyls living in open country. In addition to the increased rotation of the astragalus, which increases the propulsive thrust at the ankle and enables a quicker recovery at the end of a stride before starting the next one, there are other features that help to increase the speed of striding. The legs of most camels and ruminants have lengthened, especially in the lower parts; the number of toes, or digits, in the feet is reduced from the original mammalian five, and ruminants walk on the tips of their toes. The muscles are inserted high on the legs; only tendons pass lower, so that a large mass is not concentrated near the tip of the limb, where its inertia would restrict speed of movement. Muscle contraction is fast. The movement of each leg is almost limited to a fore-and-aft plane. Emphasis on the fore-and-aft articulations between the limb bones is especially pronounced in many bovids, the alternating bones in the wrist (carpus) and ankle (tarsus) taking the strain of impact on uneven ground.

Pigs have four toes on each foot, but only two of them touch the ground. Their limbs are short and not very advanced. Peccaries have lost the outer accessory hind hoof in the back leg. All four toes of each foot of hippopotamuses touch the ground, and the terminal phalanges have nail-like hoofs. The toe bones of camels are completely enclosed in hardened, horny hoofs, and lateral toes spread across the broad pad which aids in walking on desert sands. Chevrotains have four hoofed toes on each foot; deer often retain the first and second phalanges (sections) of their lateral toes; but all bovids have lost the bones of their lateral toes.

The fibula bone in the back leg and the ulna in the front leg have been reduced in different artiodactyl lineages. Both are still complete in pigs and hippopotamuses, although the fibula is slender. In most other artiodactyls, the lower end of the fibula has survived, and the upper end is occasionally found, but always less noticeably. In camels the ulna has fused with the radius. Pigs, hippopotamuses, and camels have separate navicular and cuboid bones in the ankle, and magnum and trapezoid bones in the wrist; other artiodactyls have a fused naviculo-cuboid and magnum-trapezoid. In chevrotains and some deer, the adjacent ectocuneiform is sometimes joined with the naviculo-cuboid.

Modifications of the foot

The artiodactyl method of limb support through the third and fourth toes, with the attendant lengthening of lower limb bones, has frequently led to a fusion of the two principal metacarpal and metatarsal (midfoot) bones in the forelegs and hindlegs, respectively, forming cannon bones. The nearest approach to a cannon bone in the living Suiformes is the proximal fusion (*i.e.,* at the upper ends) of the two central metatarsals in peccaries. Camels have front and rear cannon bones, but the fusion does not extend right to the bottom, the lower articular surfaces being less pulley-like than in ruminants. There is a hind cannon bone in all chevrotains and, in addition, a front one in Asiatic species (*Tragulus*). All other living artiodactyls have front and rear cannon bones. Lateral metatarsals and metacarpals survive in chevrotains; splints of lateral metacarpals often survive in bovids; and either upper or lower splints of metacarpals in deer.

Modifications of the skin. *Hair and coloration.* Pigs are covered with rather sparse, coarse hairs, and peccaries with a denser coat of coarse hairs. Except for those of the warthog and the babirusa (*Babyrousa babirussa*), piglets have longitudinal stripes or flecks. Hippopotamuses are naked. Tragulids have light-coloured flecks and stripes in their fur. The coats of camelids and deer are much thicker in species living toward the polar regions, at great heights,

or in deserts, but are not noted for striking colours or patterns. Many young deer and the adults of a few species have pale flecks and stripes, and some South American deer have reddish fur. Antelopes have a wider range of coat colours, and some are strikingly marked; *e.g.*, the oryxes, bontebok, and blesbok of southern Africa.

Scent glands. External glands occur in various places on artiodactyls. Preorbital glands, immediately in front of the eyes, are present in the giant forest hog (*Hylochoerus meinertzhageni*), in all cervids except the roe deer, and, among the bovids, in duikers, many neotragines, gazelles and their allies, and the hartebeest group. These glands are apparently required in small forest forms and have disappeared in many, but not all, open-country forms. In some, the glands are definitely connected with territorial marking; a firm object is marked by rubbing, soft vegetation by swinging the head gently from side to side. Foot, or pedal, glands are present in the African bush pig (*Potamochoerus porcus*), camels, tragulids, the pronghorn, some bovids, and on the back legs only of most American deer.

Inguinal (belly) glands are found in bovids, there being two in sheep, saiga, chiru, gazelles, duikers, and blackbuck, and four in members of the tribes Reduncini and Tragelaphini. Carpal (wrist) glands are present in some pigs, some gazelles and allies, and the oribi (*Ourebia ourebi*). Glands in other positions are rather less frequent, but postcornual ones (behind the horns) occur in the Rocky Mountain goat, the pronghorn, and the chamois (*Rupicapra rupicapra*), supraorbital ones in muntjacs (several species of *Muntiacus*). There are jaw glands in the pronghorn; neck glands in camels; dorsal glands on the back of peccaries, pronghorn, and springbok; and preputial glands (in front of the genital region) in several pigs, grysbok (*Raphicerus melanotis*), and the musk deer. Tail glands are found in musk deer, pronghorn, and goats; tarsal glands in pronghorn and American deer; and metatarsal glands in camels, some deer, and the impala. Pronghorn, blackbuck, gazelles, and oribi are thus particularly well equipped with glands. The use of such glands, apart from the use of preorbital glands in some species for territorial marking, is a matter for conjecture. Chital deer, when alarmed, thump the ground several times with their hind feet, which possess glands; the scent remaining on the ground may function as a danger signal. In general, mammals often mark with their glands when they are threatening other individuals of their own species.

Digestive system. The higher artiodactyls feed only on plant matter, which consists largely of cellulose and other carbohydrates and water. This necessitates adaptations of the structure and functioning of the stomach and intestines. Even pigs have enlarged stomachs—they have a pouch near the cardiac orifice (the upper opening) of the stomach—and in peccaries the stomach is more complicated. In hippopotamuses the stomach is divided into four compartments, and micro-organisms ferment food as part of the digestive process. Unlike pigs, hippopotamuses have lost the cecum (a blind pouch) further on in the gut.

Ruminant stomach

In the most advanced ruminants, the much enlarged stomach consists of four parts. These include the large rumen (or paunch), the reticulum, the omasum (psalterium or manyplies)—which are all believed to be derived from the esophagus—and the abomasum (or reed), which corresponds to the stomach of other mammals. The omasum is almost absent in chevrotains. Camels have a three-chambered stomach, lacking the separation of omasum and abomasum; the rumen and reticulum are equipped with glandular pockets separated by muscular walls having sphincters (valves) and glands. The esophagus opens into the rumen, not into the area between rumen and reticulum; these and other differences suggest that camels evolved the ruminating habit independently of the true ruminants. The total stomach of the domestic ox (*Bos taurus*) occupies nearly three-quarters of the abdominal cavity, and, even in medium-sized cattle, the rumen alone can have a capacity of 95 to 285 litres (25 to 75 gallons), having undergone a tremendous growth in early life, with the changeover from a milk diet.

Food taken into the rumen is later regurgitated into the mouth and completely masticated, then swallowed again and passed to the reticulum, omasum, and abomasum. The regurgitation and chewing in the mouth is called rumination.

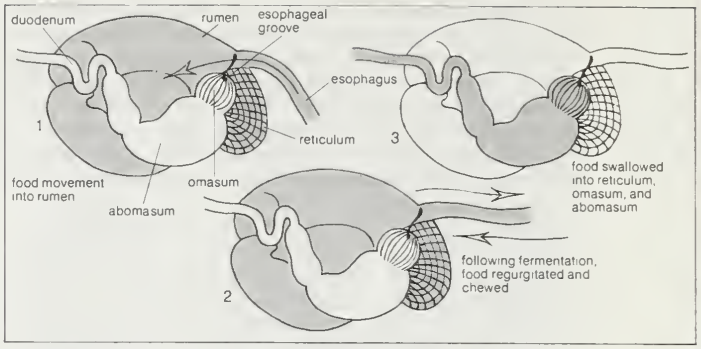

Figure 55: Stages of digestion in the four-part stomach of a representative ruminant.
Drawing by R. Keane

In the rumen many different species of minute protozoans (animals) and bacteria live without free oxygen. The digestion of the cellulose of plant cell walls is the main function of the fauna and flora in the rumen, since mammalian digestive juices are incapable of digesting cellulose. The contents of the plant cells are thus released for digestion. Large volumes of saliva are secreted into the rumen to help digestion. Soluble products of microbial action, mainly fatty acids, are absorbed through the rumen wall. In the omasum, some fatty acids and 60–70 percent of the water are absorbed; in the abomasum gastric juice containing hydrochloric acid is secreted, as in an ordinary mammalian stomach.

In the rumen any ingested protein is degraded into fatty acids and ammonia; the ammonia and other simple nitrogen-containing substances are used by the microorganisms for their own cell-protein synthesis. These organisms are ultimately digested in the abomasum and small intestine, thus providing the ruminant with protein.

Many artiodactyls are adapted to living in conditions of water shortage. The best known and one of the most spectacular examples of this is the camel. Its body temperature can fluctuate according to the outside temperature, thus minimizing water loss through sweating; it excretes rather dry dung and a concentrated urine (*i.e.*, high in urea and low in water) and is not seriously weakened by as much as a 25 percent dehydration in its body, since water is not withdrawn from the bloodstream and the continuing circulation avoids any buildup of excessive internal temperatures. The thick coat hinders the inward transference of heat from the environment (the temperature of which may often exceed the animal's body temperature); a thirsty camel can take in water very rapidly. Oryxes and gazelles are antelopes noted for needing little water, the dorcas gazelle (*Gazella dorcas*) in the Sudan depending on leaves of *Acacia* bushes for its water. The zebu (a form of domesticated cattle) needs less water than most temperate climate breeds.

Reproductive specializations. The testes of male artiodactyls descend outside the body cavity but may regress into the abdomen in the nonbreeding season. Female pigs have many teats, but ruminants have only two to four (although domestic cattle occasionally have as many as six). Among the bovids, the alcelaphines (hartebeests, wildebeests, and relatives), gazelles, and some caprines (sheep, goats, and relatives) have two, the rest have four.

The epitheliochorial and syndesmochorial placentas

The unborn mammal within its mother breathes, feeds, and excretes through an organ called the placenta, which is connected with the tissues of the mother's uterus (womb) wall. Hippopotamuses and pigs have an epitheliochorial placenta, a layer of fetal tissue merely pressed close against the uterus wall, but camels and ruminants possess a syndesmochorial placenta, in which the epithelium of the maternal tissues is eroded to facilitate intercommunication. This is an advance over the epitheliochorial placenta, but the artiodactyls are not particularly advanced, when compared with other mammals, in which there may be still closer association of maternal and fetal blood vessels

(endothelial and hemochorial placentas). Even in many syndesmochorial placentas the uterus lining may be wholly or partly restored before the end of pregnancy. Although there is no erosion of maternal tissues in the epitheliochorial placenta, the capillaries beneath the fetal and maternal surface layers may pass just beneath the surface layers, making them thin. The actual fingerlike processes (villi), through which the placenta contacts the uterus, are evenly distributed ("diffuse" placentas) in hippopotamuses, pigs, camels, and tragulids; in higher artiodactyls they are in pockets or groups called cotyledons ("cotyledonary" placentas). It is interesting that there are few of these cotyledons in deer—for instance only five in Père David's deer—but many in giraffes and bovids (up to 160 or 180 in giraffes and goats). The musk deer (*Moschus moschiferus*) is exceptional among deer in retaining a diffuse placenta.

EVOLUTION AND PALEONTOLOGY

The artiodactyls can be traced back to a probable descent from a group of early generalized mammals called condylarths, and were certainly distinct by the Eocene Epoch, which ended about 38,000,000 years ago. Fossil artiodactyls can be more or less convincingly classified in three suborders; the more primitive Suiformes, centred around pigs, the Tylopoda, centred on camels, and the Ruminantia or ruminants. The most primitive artiodactyls are the suiform group Palaeodonta, which had four functional toes on each foot, primitive, low-cusped cheek teeth, and the typical artiodactyl astragalus. The artiodactyls became more prominent in the Oligocene (between about 38,000,000 and 26,000,000 years ago) with a decline of the then dominant perissodactyls, and the later history of artiodactyls appears as successive waves of groups, each better adapted than its predecessors to the changing environment. In the suiform line, the earlier palaeodonts are succeeded by other groups such as the entelodonts, giant "pigs" of the European and North American Oligocene, characterized by very large skulls (some nearly a metre [three feet] long), very small brains, and a large, bony flange below the eyes. The functionally two-toed ruminants succeeded four-toed suiforms in the Miocene, and within the Old World ruminants of the bovid subfamily Caprinae, the zenith of the tribe Caprini, for example, followed that of the mainly Pliocene tribe Ovibovini.

The earliest artiodactyls

The artiodactyls had an interesting history in North America through the Tertiary Period. Some forms, such as the entelodonts, were shared with the Old World, but others were characteristic of North America. One very prominent New World family was the merycoidodonts (or oreodonts), which lasted until the early Pliocene (about 6,000,000 years ago). They had somewhat piglike proportions, short faces, a large upper canine and a caniniform first lower premolar, and selenodont molars. A close relative, *Agriochoerus,* had clawed feet, the function of which remains uncertain.

Camels and horses in North America

Camelids evolved in North America and, at or toward the end of the Tertiary, spread into South America and into the Old World. By the end of the Pleistocene they all became extinct in their homeland, just as horses did. The hypertragulids were a mainly Oligocene group of chevrotain-like forms related to the Protoceratidae. The latter had horns above their noses, a position unique among artiodactyls, as well as in the usual position. The North American Miocene (26,000,000 to 7,000,000 years ago) produced some ruminants, such as *Blastomeryx,* that are hard to distinguish from the early palaeomerycine relatives of giraffes and deer in the Old World, which, with the North American groups, constitute the family Palaeomerycidae. Some developed horns, and the dromomerycine *Cranioceras* even had a third horn above the back of its skull. During the Miocene and Pliocene there finally appeared relatives of the surviving pronghorn, an example being *Merycodus.* Many of these North American groups have parallels with Old World groups, and the subject of North American artiodactyl evolution is of great interest. Only further finds will indicate whether *Blastomeryx,* the dromomerycines, *Merycodus,* and the pronghorns evolved from hypertragulids already in North America or sprang from some immigrant ruminant and, if the latter, whether the supposed hypertragulid *Leptomeryx* could be such an immigrant ruminant. It is uncertain whether the hypertragulids are nearer the tragulines or the camels, and how close the oreodonts are to the anthracotheres. Of the great New World radiation there survived after the Pleistocene only three or four camelid species and the pronghorn (deer and bovids in the Americas are immigrants), whereas in the Old World as little as 200 years ago, Eurasia and Africa had abundant deer and antelopes.

Until the Miocene there were some archaic artiodactyls in Europe, the xiphodonts, which have cautiously been taken as tylopods, and the cainotheres and anoplotheres, which are classified near anthracotheres.

A possible ruminant ancestor was *Archaeomeryx* from the upper Eocene of China, a small animal that already had a fused naviculo-cuboid bone in the ankle. Tragulids occurred in Africa and Eurasia back to the Miocene, and the more advanced gelocids are known from the upper Eocene and lower Oligocene. At the end of the Oligocene, the first ruminants began to appear with teeth more advanced than those of tragulids. From early in the Miocene they began to be recognizable as giraffes, deer, or antelopes, although the last were relatively uncommon before the late Miocene. Much remains to be learned about the detailed early history of these groups. Several different giraffids lived in later Miocene and early Pliocene times, but the group has since declined to only two species. Deer gradually acquired more complicated antlers, which became very large in some lineages. Different subfamilies of bovids originated in Eurasia and Africa, and it is of zoogeographic interest that representatives of African subfamilies have been found as fossils in northern India and Pakistan.

CLASSIFICATION

Annotated classification. The following classification is principally based on that of American paleontologist George Gaylord Simpson, with alterations in the bovid subfamilies, in the placing of early relatives of giraffes and deer in a giraffoid subfamily Palaeomerycinae, and in the placing of hypertragulids and protoceratids with camels. Groups indicated by the dagger (†) are known only as fossils.

ORDER ARTIODACTYLA

Cloven-hoofed ungulates, the major group of herbivorous mammals. Weight supported mainly through 3rd and 4th toes; astragalus with upper and lower articulations rounded. Stomach compound and, with intestines, enlarged for plant digestion. About 150 species.

Suborder Suiformes

Complete dentition, bunodont (low-cusped) molars, short legs, 4-toed feet are among their important characteristics.

†Infraorder Palaeodonta

Eocene to lower Miocene. Primitive, small-brained artiodactyls. Two superfamilies, Dichobunoidea and Entelodontoidea, with 5 and 3 families, respectively, and collectively about 30 genera.

Infraorder Suina

Lower Oligocene to present. Includes the living pigs, peccaries, and their likely ancestors and extinct relatives.

Family Suidae (pigs). Lower Oligocene to present; Old World. Small to moderate size; shoulder height to about 100 cm (39 in.). Coarse hair. Omnivorous, with sharp-edged tusks. Five Recent and about 22 fossil genera.

Family Tayassuidae (peccaries). Differ from pigs by having 1 fewer incisor and premolar, smaller canines, less advanced cheek teeth; hindleg with a cannon bone, more complicated stomach and more densely haired coat.

Infraorder Ancodonta

†Family Anoplotheriidae. Eocene and Oligocene; Europe; uncertain relationships.

†Family Anthracotheriidae. Eocene to Pleistocene. Mainly Old World, a few in North American Oligocene. Large, with cheek teeth showing beginnings of selenodonty.

Family Hippopotamidae (hippopotamuses). Middle Pliocene to present. Thought to be derived as late as the Pliocene from anthracotheres. Old World, now restricted to Africa. One large (shoulder height to 170 cm [67 in.]; weight to 3,000 kg [6,600

lb]) and one small species (height to 90 cm [35 in.]). Feed on land but frequently resort to water.

†*Family Camotheriidae.* Mainly Oligocene; small European forms of uncertain relationships.

†Infraorder Oreodonta

†*Family Merycoidodontidae* (North American oreodonts). Eocene to early Pliocene. No suppression of upper incisors, an incisiform lower canine, selenodont cheek teeth, short faces and short limbs.

†*Family Agriochoeriidae.* Eocene to lower Miocene. Close to the above family but with clawed feet.

Suborder Tylopoda

Some reduction of upper incisors, reduced premolars, selenodont cheek teeth; cannon bones present. Feet became 2-toed early in the geological history of the group.

†*Family Hypertragulidae.* Upper Eocene to lower Miocene; North America. Like Old World Tragulina (see below) but with a canine-like first lower premolar. Fused naviculo-cuboid in the ankle.

†*Family Protoceratidae.* Oligocene to lower Pliocene; North America. Some with horns on the top and at the front of the skull. Later ones with hindleg cannon bone. Generally considered close to hypertragulids, but failed to fuse navicular and cuboid bones.

Family Camelidae (camels and lamoids). Upper Eocene to present; now a relict group, represented in southern South America, in Asia, and in North Africa. Red blood corpuscles oval. Gallbladder absent. The hump of the 2 Old World camels is composed of fibrous connective tissue and fat.

†*Family Xiphodontidae.* Eocene and lower Oligocene of Europe. Already 2-toed, despite their antiquity, and tentatively placed with the camels.

Suborder Ruminantia (ruminants)

Upper incisors lacking; lower canine incisor-like; cheek teeth selenodont. Fused magnum-trapezoid bone in the wrist. Two-toed feet evolved within suborder.

Infraorder Tragulina

†Superfamily Amphimerycoidea

†*Family Amphimerycidae.* European Eocene and Oligocene of Europe; poorly known. Asian *Archaeomeryx*, usually placed in the Hypertragulidae, but may fit here; it retained upper incisors and had a fused naviculo-cuboid in the hind leg.

†*Family Gelocidae.* Eocene-Oligocene of Europe and Asia.

Superfamily Traguloidea

Family Tragulidae (chevrotains). Miocene to present. Sabre-like upper canines in males; incipiently selenodont molars. Bony carapace often develops above the pelvic girdle in males.

Infraorder Pecora

Mostly with horns or antlers and without upper canines. Hollowed auditory bullae. Four-chambered stomach.

Superfamily Giraffoidea

†*Family Palaeomerycidae.* Upper Oligocene to upper Pliocene; North America, Europe, Asia, Africa. Three subfamilies, the Palaeomerycinae (Old World basal stock for giraffes and deer), Blastomerycinae, and Dromomerycinae (the last two New World).

Family Giraffidae (giraffes and okapi). Miocene to present; Old World, now confined to Africa. Living giraffes long-necked and long-legged; the okapi more compact. Giraffes may be up to 5.5 m (18 ft) in total height. Extinct relatives including the large, short-legged, and grotesquely horned sivatheres. Living species have no gallbladder.

Superfamily Cervoidea

Family Cervidae (deer).

Subfamily Moschinae (musk deer). Pleistocene and present; Asia. One recent species, the musk deer (*Moschus moschiferus*) with sabre-like upper canines, gallbladder present (lacking in most other deer).

Subfamily Muntiacinae (muntjacs). Lower Miocene to present; southern Asia. Includes the living muntjacs (*Muntiacus*), with small, 2-pronged antlers above a long, skin-covered base; and tufted deer (*Elaphodus cephalophus*) with tiny antlers. Eurasian fossil genus *Dicrocerus* had larger, 2-pronged antlers. All have large, curved upper canines.

Subfamily Odocoileinae. Pliocene to present. Characterized by the persistence of the lower ends of the lateral metacarpals, thickly haired skin between the hoofs, and in all except the moose a large interdigital gland in at least the hindfoot. The vomer is fused far back posteriorly with the palate in the American deer and in the reindeer. Includes moose (Eurasian elk), reindeer, roe deer, perhaps the Chinese water deer (which has long canines but no antlers), and the deer of North and South America other than the wapiti (American elk), a cervine.

Subfamily Cervinae. Pliocene to present. Top ends of the lateral metacarpals persist. Smooth skin between the hoofs; interdigital glands lacking. Branching of beam of antler differs from that in New World deer; red deer and wapiti, fallow deer, chital, sika, Père David's deer.

Superfamily Bovoidea

Family Antilocapridae (pronghorn and merycodonts). Miocene to present; North America. Smooth, branched horns consisting of hollow sheaths over bony cores; only sheaths shed annually; in fossil Merycodontinae, 1 or more burrs at base of cores. Teeth high-crowned.

Family Bovidae (cattle, sheep and goats, antelopes). Wild cattle, sheep, and goats were ancestral to domestic livestock not differing in any fundamental characters from antelopes. Great variety in horn shape. Many with high-crowned teeth.

Subfamily Bovinae (cattle and some antelopes). Miocene to present. African tribe Tragelaphini, with keeled, spiral horns and not very advanced teeth, includes eland, kudu, nyala, and bushbuck. Tribes Bosclaphini and Bovini, mainly Eurasian, former including the Indian nilgai, the 4-horned antelope, and some extinct forms, the latter including cattle, bison, and buffaloes. Bovini are descended from extinct Boselaphini; large size, up to 180 cm (71 in.) at the shoulder. Teeth specialized for grazing. Animals wallow frequently.

Subfamily Cephalophinae (antelopes). Mostly small, with tiny horns set toward the back of the head. Gallbladder lacking. Generally forest-living. African duikers.

Subfamily Hippotraginae (antelopes). Moderate-sized, stocky, mainly grazing antelopes; shoulder height 60–160 cm (24–63 in.). High-crowned teeth. Tribe Hippotragini includes the roan, sable, oryx, and addax antelopes; and Reduncini the reedbuck, kobs, lechwes, and waterbucks. Oryx and addax inhabit arid areas; others near water with adjacent cover or high grass. All except nearly extinct Arabian oryx are now native only to Africa, but the subfamily formerly occurred in India.

Subfamily Alcelaphinae (antelopes). African wildebeests, hartebeests, topis, and several extinct lineages. Long-faced, plains-living, grazing antelopes. Sometimes included in the Hippotraginae.

Subfamily Antilopinae (antelopes). Tribe Neotragini includes some small African antelopes, and Antilopini include gazelles, springbok, and the Indian blackbuck. Graceful, long-legged antelopes of arid, open country. Subfamily may also include the saiga and the Tibetan chiru (tribe Saigini), hitherto classified with Caprinae.

Subfamily Caprinae (sheep, goats, and relatives). Mainly Eurasian. Moderate-sized, shoulder height often 90–100 cm (35–39 in.). High-crowned teeth. Agile animals; many species in mountains or on steep, rocky slopes. Tribe Caprini comprises sheep and goats; Ovibovini the musk-ox (*Ovibos*), the Chinese takin, and some bizarre extinct forms; Rupicaprini the chamois, serow, goral, and Rocky Mountain goat.

Critical appraisal. The great 18th-century classifier Carolus Linnaeus recognized the camels and ruminants as associated but placed some nonartiodactyls with them. It was the French naturalist Henri de Blainville who, at the beginning of the 19th century, first recognized the complete order of artiodactyls as it is accepted today. Nine discrete groups exist among the living forms: pigs, peccaries, hippopotamuses, camels, chevrotains, deer, giraffes, pronghorn, and bovids; their classification presents no great problems, apart from a few genera. Fossils, however, bring confusion to various schemes.

The relationship of North American Tertiary artiodactyls to those of the Old World is a basic question in the study of their zoogeography, history, and classification. It can be agreed that the camels evolved in North America and are as old as the tragulines, which in the Old World were ancestral to ruminants. Most paleontologists today believe that the hypertragulids, protoceratids, and oreodonts were related to the camels, but others have linked the first two groups with the tragulines and the oreodonts with the anthracotheres. Other questions affecting the higher levels of artiodactyl classification are the placing of the North American native ruminants and whether the earliest Old World pecorans should be taken as giraffoids or cervoids.

The subdivisions of the Bovidae remain controversial. Modifying a classification proposed by German zoologist Max Schlosser, some authorities have grouped the Bo-

vinae, Cephalophinae, and Hippotragineae as the Boödontia and the Alcelaphinae, Antilopinae, and Caprinae as the Aegodontia, to indicate phyletic lines believed to have arisen early in bovid history. Boödonts and aegodonts have evolved differently in Africa and Eurasia, and there is much to be said for developing a classification that reflects these geographical relationships. Until additional evidence of phylogenetic relationships is available, however, the modified version of Simpson's classification above will remain favoured by most taxonomists. (A.W.G.)

BIBLIOGRAPHY

Mammalia. The literature on the biology of mammals is vast. The following list includes only a sample of available sources, with emphasis on those in the English language. Standard general references on the mammals are: F.E. BEDDARD, *Mammalia* (1902); W.H. FLOWER and R. LYDEKKER, *An Introduction to the Study of Mammals, Living and Extinct* (1891); and J.Z. YOUNG, *The Life of Mammals* (1957).

Less technical accounts include: F. BOURLIERE, *Vie et moeurs des mammifères* (1951; Eng. trans., *The Natural History of Mammals,* 1954); and L.H. MATTHEWS, *The Life of Mammals* (1970). Widely used textbooks in mammalogy are: E.L. COCKRUM, *Introduction to Mammalogy* (1962); and D.E. DAVIS and F.B. GOLLEY, *Principles in Mammalogy* (1963). The only thorough up-to-date treatment in English of the families of living mammals is S. ANDERSON and J.K. JONES, JR., (eds.), *Recent Mammals of the World: A Synopsis of Families* (1967). E.P. WALKER *et al., Mammals of the World,* 3 vol. (1964), is a semitechnical work including illustrations of representatives of most living genera; the third volume is a classified bibliography. Perhaps the most comprehensive reference on the biology of mammals is P.P. GRASSE (ed.), *Traité de zoologie,* vol. 16–17 (1967–68, 1955).

The morphology and classification of early mammals is reviewed by J.A. HOPSON and A.W. CROMPTON, "Origin of Mammals," *Evolutionary Biol.,* 3:15–72 (1969); and J.A. HOPSON, "The Classification of Nontherian Mammals," *J. Mammal.,* 51:1–9 (1970). A standard reference on the classification of mammals is G.G. SIMPSON, "The Principles of Classification and a Classification of the Mammals," *Bull. Am. Mus. Nat. Hist.,* 85:1–350 (1945); the evolution of major mammalian groups is treated by A.S. ROMER in *Vertebrate Paleontology,* 3rd ed. (1966), and *Notes and Comments on Vertebrate Paleontology* (1968). See also JASON A. LILLEGRAVEN, *et al.,* (eds.), *Mesozoic Mammals: The First Two-Thirds of Mammalian History* (1979).

Basic references on the status of endangered species of mammals are: F. HARPER, *Extinct and Vanishing Mammals of the Old World* (1945); and G.M. ALLEN, *Extinct and Vanishing Mammals of the Western Hemisphere with the Marine Species of All the Oceans* (1942).

Summaries of specialized topics in mammalogy include: H.T. ANDERSEN (ed.), *The Biology of Marine Mammals* (1969); S.A. ASDELL, *Patterns of Mammalian Reproduction,* 2nd ed. (1964); L.S. CRANDALL, *The Management of Wild Mammals in Captivity* (1964); R.F. EWER, *Ethology of Mammals* (1968); C.P. LYMAN and A.R. DAWE (eds.), *Mammalian Hibernation* (1960); W.V. MAYER and R.G. VAN GELDER (eds.), *Physiological Mammalogy,* 2 vol. (1963–64); A.G. SEARLE, *Comparative Genetics of Coat Colour in Mammals* (1968); GEORGE G. SIMPSON, *Splendid Isolation* (1980), a study of South American mammals.

Some widely known journals that publish papers dealing exclusively with mammals are: *Journal of Mammalogy, Mammalia,* and *Säugetierkundliche Mitteilungen* (all issued quarterly), and *Zeitschrift für Säugetierkunde* (6/yr.). Additional technical literature is published by university and public museums and government agencies. Semitechnical and popular accounts of mammals appear in a wide variety of publications of state game departments, museums, and zoological gardens.

Monotremata. The following are popular works on monotremes: H. BURRELL, *The Platypus* (1927); D. FLEAY, *We Breed the Platypus* (1944), and "Observations on the Breeding of the Platypus in Captivity," *Victorian Nat.,* 61:8–14 (1944); M. GRIFFITHS, *Echidnas* (1968). Works of a more technical nature are: M.L. AUGEE, E.H.M. EALEY, and H. SPENCER, "Biotelemetric Studies of Temperature Regulation and Torpor in the Echidna, *Tachyglossus aculeatus,*" *J. Mammal.,* 51:561–570 (1970); J.H. CALABY, "The Platypus (*Ornithorhynchus anatinus*) and Its Venomous Characteristics," in W. BUCHERL, E.E. BUCKLEY, and V. DEULOFEU (eds.), *Venomous Animals and Their Venoms,* 1:15–29 (1968); W.K. GREGORY, "The Monotremes and the Palimpsest Theory," *Bull. Am. Mus. Nat. Hist.,* 88:1–52 (1947); K.W. ROBINSON, "Heat Tolerances of Australian Monotremes and Marsupials," *Aust. J. Biol. Sci.,* 7:348–360 (1954); K. SCHMIDT-NIELSEN, T.J. DAWSON, and E.C. CRAWFORD, JR., "Temperature Regulation in the Echidna (*Tachyglossus aculeatus*)," *J. Cell. Comp. Physiol.,* 67:63–72 (1966); H.M. VAN DEUSEN and G.G. GEORGE, "Results of the Archbold Expeditions, no. 90, notes on Echidnas (Mammalia, Tachyglossidae) of New Guinea," *Am. Mus. Novit.* no. 2383 (1969).

Marsupialia. Among general works are the following: CHARLES L. BARRETT, *Wild Life of Australia and New Guinea* (1954); CHARLES W. BRAZENOR, *The Mammals of Victoria and the Dental Characteristics of Monotremes and Australian Marsupials* (1950); ALBERT S. LE SOUEF and HARRY BURRELL, *The Wild Animals of Australasia, Embracing the Mammals of New Guinea and the Nearer Pacific Islands* (1926); BASIL J. MARLOW, *Marsupials of Australia* (1962); ELLIS TROUGHTON, *Furred Animals of Australia,* 8th ed. rev. (1966); ERNEST P. WALKER *et al., Mammals of the World,* 3 vol. (1964; 2nd ed., vol. 1, 1968); F. WOOD JONES, *The Mammals of South Australia,* 3 vol. (1923–25).

Journal and magazine articles include: J. PEARSON, "Some Problems of Marsupial Phylogeny," *Rep. Meet. Aust. N.Z. Ass. Advmt. Sci.,* 25:71–102 (1947); H.C. REYNOLDS, "Studies on Reproduction in the Opossum (*Didelphus virginiana virginiana*)," *Univ. Calif. Publs. Zool.,* 52:223–284 (1952); G.G. SIMPSON, "The Affinities of the Borhyaenidae," *Am. Mus. Novit.,* no. 1118 (1941); and "The Beginning of the Age of Mammals in South America," *Bull. Am. Mus. Nat. Hist.,* vol. 91, art. 1 (1948); G.H.H. TATE, "On the Anatomy and Classification of the Dasyuridae (Marsupialia)," *Bull. Am. Mus. Nat. Hist.,* vol. 88, art. 3 (1947); "Studies on the Anatomy and Phylogeny of the Macropodidae (Marsupialia)," vol. 91, art. 2 (1948); and "Studies in the Peramelidae (Marsupialia)," vol. 92, art. 6 (1948); D. FLEAY, "Strange Animals of Australia," *Natn. Geogr. Mag.,* 124:388–411 (1963); J.H. CALABY, "Australia's Threatened Mammals," *Wildlife,* 1:15–18 (1963); H.H. FINLAYSON, "Mitchell's Wombat in South Australia," *Trans. R. Soc. S. Aust.,* 85:207–215 (1961); A.G. LYNE, "Australian Mammals," *Aust. Mus. Mag.,* 12:121–125 (1956); J. MCNALLY, "Koala Management in Victoria," *Wildl. Circ. Vict.,* no. 4 (1957); W.E. POOLE and P.E. PILTON, "Reproduction in the Grey Kangaroo, *Macropus canguru,* in Captivity," *C.S.I.R.O. Wildl. Res.* 9:218–234 (1964); G.B. SHARMAN, "Studies on Marsupial Reproduction. III. Normal and Delayed Pregnancy in *Setonix brachyurus,*" *Aust. J. Zool.,* 3:56–70 (1955); G.B. SHARMAN and J.H. CALABY, "Reproductive Behaviour in the Red Kangaroo, *Megaleia rufa,* in captivity," *C.S.I.R.O. Wildl. Res.,* 9:58–85 (1964); E.M.O. LAURIE and J.E. HILL, "List of Land Mammals of New Guinea, Celebes and Adjacent Islands, 1758–1952," *Br. Mus. Nat. Hist.* (1954).

Insectivora. A. CABRERA, *Genera mammalium,* vol. 1, *Insectivora,* vol. 2, *Galeopithecia* (1919–25), a Spanish classic—a still unsurpassed illustrated review of living insectivora; PETER CROWCROFT, *The Life of the Shrew* (1957), a review of the biology of the common Eurasian *Sorex araneus;* J.F. EISENBERG and E. GOULD, "The Behaviour of *Solenodon paradoxus* in Captivity with Comments on the Behavior of Other Insectivora," *Zoologica,* 51:49–58 (1966); "The Tenrecs: A Study in Mammalian Behavior and Evolution," *Smithson. Contr. Zool.,* no. 27 (1970), a technical but easily read review of the biology of this family; F.G. EVANS, "The Osteology and Relationships of the Elephant Shrews (Macroscelididae)," *Bull. Am. Mus. Nat. Hist.,* 80:85–125 (1942), a technical comparison of elephant ws, tree shrews, erinaceids, and lemuroids; GILLIAN GODFREY and PETER CROWCROFT, *The Life of the Mole* (*Talpa europaea Linnaeus*) (1960), a readable, semi-popular account of the common European mole; E. GOULD, N.C. NEGUS, and A. NOVICK, "Evidence for Echolocation in Shrews," *J. Exp. Zool.,* 156:19–38 (1964); K. HERTER, "Das Verhalten der Insektivoren," *Handb. Zool.,* vol. 8, sect. 9, pp. 1–50 (1957), a German language review of the behaviour of all insectivores; M.W. LYON, "Treeshrews: An Account of the Mammalian Family Tupaiidae," *Proc. U.S. Natn. Mus.,* vol. 45 (1913); S.B. MCDOWELL, "The Greater Antillean Insectivores," *Bull. Am. Mus. Nat. Hist.,* 115:117–214 (1958), a technical review of the relationships of solenodons to other insectivores.

Chiroptera. G.M. ALLEN, *Bats* (1939, reprinted 1962), a comprehensive view by a naturalist; K.C. ANDERSEN, *Catalogue of the Chiroptera in the Collection of the British Museum,* 2nd ed., vol. 1, *Megachiroptera* (1912), definitive taxonomy of the Megachiroptera; R.W. BARBOUR and W.H. DAVIS, *Bats of America* (1970), comprehensive coverage of North American bats, distribution, natural history, photographs, and taxonomy; A. BROSSET, *La Biologie des Chiroptères* (1966), the most complete, up-to-date review of all bats; R.G. BUSNEL (ed.), *Animal Sonar Systems,* 2 vol. (1967), the most recent important symposium on echolocation and related systems; R.B. DAVIS, C.F. HERREID II, and H.L. SHORT, *Mexican Free-Tailed Bats in Texas* (1962), the most complete published survey of a given species of bats; M. EISENTRAUT, *Aus dem Leben der Fledermäuse und Flughunde* (1957), a review of European bats by an important student of bat natural history and physiology; K. FAEGRI and L. VAN

DER PIJL, *The Principles of Pollination Ecology* (1966), the role of bats in pollination; D.R. GRIFFIN, *Listening in the Dark: The Acoustic Orientation of Bats and Men* (1958), the most recent authoritative summary of echolocation; *Echoes of Bats and Men* (1959), a paperback introduction to echolocation; A. NOVICK and N. LEEN, *The World of Bats* (1970), a recent review of bat behaviour and ecology with action photographs; L. VAN DER PIJL, *Principles of Dispersal in Higher Plants* (1969), the role of bats in dispersal of seeds; D.R. ROSEVEAR, *The Bats of West Africa* (1965), an important compilation on the bats of a particular range; H. SAINT GIRONS, A. BROSSET, and M.C. SAINT GIRONS, "Contribution à la connaissance du cycle annuel de la Chauve-souris *Rhinolophus ferrum-equinum* (Schreber, 1774)," *Mammalia*, 33:357–470 (1969), an extensive study of the biology of one European bat species; J. VERSCHUREN, *Ecologie, biologie, et systématique des Cheiroptères* (1957), the primary work on the ecology of bats; B. VILLA-R., *Los murcielagos de Mexico* (1966), an important compilation of knowledge on the bats of Mexico; W. WIMSATT (ed.), *The Biology of Bats* (1971), the definitive current work on bat biology.

Primates. *General works:* J.R. and P.H. NAPIER, *A Handbook of Living Primates: Morphology, Ecology and Behaviour of Nonhuman Primates* (1967), a comprehensive, technical book with one or more photographs of each genus; W.C. OSMAN HILL, *Primates: Comparative Anatomy and Taxonomy*, 8 vol. (1953–70), also technical and heavily illustrated, treating the primates in greater depth; W.E. LE GROS CLARK, *The Antecedents of Man*, 3rd ed. (1971), a readable scientific account of nonhuman primates; F. WOOD JONES, *Arboreal Man* (1916), a classic work that contains much useful information; I.T. SANDERSON, *The Monkey Kingdom* (1957), an extensively illustrated popular book; I. DEVORE (ed.), *Primate Behavior* (1965); and C.R. CARPENTER, *Naturalistic Behavior of Nonhuman Primates* (1964), two technical works on primate ethology; W.W. HOWELLS, *Mankind in the Making*, rev. ed. (1967), an informative book on human evolution for the general reader; S. ZUCKERMAN, *Functional Affinities of Man, Monkeys, and Apes* (1933), a technical dissertation on primate structure; IAN TATTERSALL, *The Primates of Madagascgar* (1982), a survey of many lower primates; and G.A. DOYLE, *The Study of Prosimian Behavior* (1979).

Tree shrews: W.E. LE GROS CLARK, "The Myology of the Tree-Shrew (*Tupaia minor*)," 1924:461–497; "On the Brain of the Tree-Shrew (*Tupaia minor*)," 1924:1053–1074; "On the Skull of *Tupaia*," 1925:559–567; and "On the Anatomy of the Pen-Tailed Tree Shrew (*Ptilocercus lowii*)," 1926: 1179–1309, all in the *Proc. Zool. Soc. Lond.* (1924–26), four important papers on tree shrews; R.D. MARTIN, "Treeshrews: Unique Reproductive Mechanism of Systematic Importance," *Science*, 152:1402–1404 (1966); and M.W. SORENSON and C.H. CONAWAY, "Observations on the Social Behaviour of Tree Shrews in Captivity," *Folia Primatologica*, 4:124–145 (1966), two technical papers.

Tarsioids: W.E. LE GROS CLARK, "Notes on the Living Tarsier (*Tarsius spectrum*)," *Proc. Zool. Soc. Lond.*, 1924:217–223 (1924); and H.H. WOOLLARD, "The Anatomy of *Tarsius spectrum*," *ibid.*, 1925:1071–1184 (1925), technical papers concerned with the relationships of tarsiers; H. SPRANKEL, "Untersuchungen an *Tarsius*. I. Morphologie des Schwanzes nebst ethologischen Bermerkungen," *Folia Primatologica*, 3:153–188 (1965), a summary, in German, of information on the taxonomy of tarsioids.

Lemuroids: J.J. PETTER, *Recherches sur l'écologie et l'éthologie des Lémuriens malgaches* (1962); "Ecological and Behavioral Studies of Madagascar Lemurs in the Field," *Ann. N.Y. Acad. Sci.*, 102:267–281 (1962); and "The Lemurs of Madagascar," in I. DEVORE (ed.), *Primate Behavior* (1965), technical works on a variety of lemurs; A. JOLLY, *Lemur Behavior* (1967), a readable, semipopular account, based on personal observations; A. WALKER, "Patterns of Extinction Among the Subfossil Madagascan Lemuroids," in P.S. MARTIN and H.E. WRIGHT (eds.), *Pleistocene Extinctions* (1967), a technical discussion of lemur evolution.

New World monkeys: R.I. POCOCK, "On the External Characters of the South American Monkeys," *Proc. Zool. Soc. Lond.*, 1920:91–113 (1920); and C.R. CARPENTER, "Behavior of Red Spider Monkeys in Panama," *J. Mammal.*, 16:171–180 (1935), two technical articles; L.A. ROSENBLUM and R.W. COOPER (eds.), *The Squirrel Monkey* (1968), a detailed account of the biology of one species; A. CABRERA, *Catalogo de los mamiferos de America del Sur* (1957), a broad treatment, in Spanish, of the taxonomy and distribution of South American monkeys; P. HERSHKOVITZ, "Mammals of Northern Colombia; Preliminary Report No. 4: Monkeys (Primates), with Taxonomic Revisions of Some Forms," *Proc. U.S. Natn. Mus.*, 98:323–427 (1951), a scientific treatment of some South American forms.

Old World monkeys: R.I. POCOCK, "The External Characters of the Catarrhine Monkeys and Apes," *Proc. Zool. Soc., Lond.*, 1925:1479–1579 (1925); and "The Monkeys of the Genera *Pithecus* (or *Presbytis*) and *Pygathrix* Found to the East of the Bay of Bengal," *ibid.*, 1934:895–961 (1934), two articles providing much technical information on the langur; C. G. HARTMAN and W.L. STRAUSS (eds.), *The Anatomy of the Rhesus Monkey, Macaca mulatta* (1933 and 1961), a detailed account of the morphology of this important species; J.R. and P.H. NAPIER (eds.), *Old World Monkeys* (1970), a technical but comprehensive account of the catarrhines; N.C. TAPPEN, "Problems of Distribution and Adaptation of the African Monkeys," *Curr. Anthrop.*, 1:91–120 (1960), a scientific account of the zoogeography of the catarrhines.

Anthropoid apes: C.F.M. SONNTAG, *Morphology and Evolution of Apes and Man* (1924), a comprehensive and technical book, with many illustrations; R.M. and A.W. YERKES, *The Great Apes* (1929), a classic work, written for the general reader; C.R. CARPENTER, *A Field Study in Siam of the Behavior and Social Relations of the Gibbon (Hylobates lar)* (1941, reprinted 1967); G.B. SCHALLER, *The Mountain Gorilla* (1963); and J. VAN LAWICK-GOODALL, *In the Shadow of Man* (1971), three readable accounts of the lives of individual species, based on extensive field work; V. REYNOLDS, *The Apes* (1967); and R. and D. MORRIS, *Men and Apes* (1966), well-illustrated popular books; C.P. GROVES, "Population Systematics of the Gorilla," *J. Zool.*, 161:287–300 (1970); and *Gorillas* (1970), respectively, a technical and popular work on this interesting ape; W.K. GREGORY, *The Anatomy of the Gorilla: The Studies of Henry Cushier Raven, and Contributions by William B. Atkinson and Others* (1950), a carefully illustrated, technical book; TED CRAIL, *Apetalk and Whalespeak: The Quest for Interspecies Communication* (1982).

Edentata. The following works, although broad in scope, are particularly rich in information on this group: J.C. BARLOW, "Edentates and Pholidotes," in S. ANDERSON and J.K. JONES, JR. (eds.), *Recent Mammals of the World* (1967), a discussion of the taxonomy of this order and its families; J. DORST, *South America and Central America: A Natural History* (1967), many fine photographs of edentates; E.R. HALL and K.R. KELSON, *The Mammals of North America*, 2 vol. (1959), descriptions and distributional information on North and Central American members of this order; R. HOFFSTETER, "Xenarthra," and R. SABAN, "Palaeanodonta," in J. PIVETEAU (ed.), *L'Origine des Mammifères evolution*, 2 vol., pt. 6 of *Traité de paléontologie* (1958), detailed accounts of early edentates; and E.P. WALKER, *Mammals of the World*, 2nd ed., vol. 1 (1968), an account of the natural history and distribution of every genus in the order.

Lagomorpha. J.N. LAYNE, "Lagomorphs," in *Recent Mammals of the World*, ed. by S. ANDERSON and J.K. JONES (1967), general review of characters, distribution, and habits of living lagomorphs; E.P. WALKER *et al.*, *Mammals of the World*, 2nd ed. (1968), photographically illustrated articles on living genera of lagomorphs; R.M. LOCKLEY, *The Private Life of the Rabbit: An Account of the Life History and Social Behaviour of the Wild Rabbit* (1964), semipopular work dealing with the rabbit in Britain and the disease myxomatosis; H.E. BROADBOOKS, "Ecology and Distribution of the Pikas of Washington and Alaska," *Am. Midl. Nat.*, 73:299–335 (1965), discussion of habits and habitats of North American pikas; M.R. DAWSON, "Lagomorph History and the Stratigraphic Record," in *Essays in Paleontology and Stratigraphy*, ed. by C. TEICHERT and E.L. YOCHELSON (1967), review of fossil lagomorphs and their usefulness for stratigraphic studies; A.A. GUREEV, "Lagomorpha," in *Mammals*, vol. 3, no. 10, *Fauna S.S.S.R.*, Zoologicheskii Institut Akademii Nauk S.S.S.R., New series no. 87 (1964), comprehensive treatment of the morphology and relationships of fossil and living lagomorphs (in Russian); E.R. HALL, "A Synopsis of the North American Lagomorpha," *Univ. Kans. Publs. Mus. Nat. Hist.*, 5:121–202 (1951), on the taxonomy and distribution of North American forms; A.S. LOUKASHKIN, "On the Pikas of North Manchuria," *J. Mammal.* 21:402–405 (1940), on the behaviour and habitats of Asian pikas.

Rodentia. J.R. ELLERMAN, *The Families and Genera of Living Rodents*, 2 vol. (1940, reprinted 1966), a scientific catalog of existing rodents; C.S. ELTON, *Voles, Mice and Lemmings* (1942, reprinted 1965), a popular, historical record of plagues of various rodents, followed by an analysis of the lemming population fluctuations in northern Labrador; P.P. GRASSE and P.L DEKEYSER, "Ordre des Rongeurs," in *Traité de zoologie*, vol. 17, pt. 2, pp. 1321–1525 (1955), a section from a zoological reference work dealing with the anatomy, ecology, habits, and classification of rodents, with brief descriptions down to the generic level (in French); T.G. HULL, *Diseases Transmitted from Animals to Man*, 5th ed. (1963), descriptions of diseases, with discussion of causative factors and carriers, many of which are rodents; D. MACCLINTOCK, *Squirrels of North America* (1970), an account of the ecology, habits, and relationships of North American squirrels; H.G.Q. ROWETT, *The Rat as a Small*

Mammal, 2nd ed. (1965), a student laboratory manual with detailed notes on the dissection of the rat; M. SHORTEN, *Squirrels* (1954), a study of the red and gray squirrels in Great Britain for the general reader; G.D. SNELL (ed.), *Biology of the Laboratory Mouse,* 2nd ed. (1966), a standard reference work on all aspects of mouse raising; E.P. WALKER *et al., Mammals of the World,* 3 vol. (1964), descriptions at the generic level of all living mammals, including every recognized genus of rodent, in most cases with pictures; L. WILSSON, *Bäver* (1964; Eng. trans., *My Beaver Colony,* 1968), a popular account of beaver behaviour; and S.E. WOODS, *The Squirrels of Canada* (1980), a guide to 22 species.

Carnivora. For general information on the biology of the carnivores, see E.P. WALKER *et al., Mammals of the World,* 3 vol. (1964), in which each genus is described and illustrated, along with a brief summation of its biology. The taxonomy of carnivores is discussed in G.G. SIMPSON, "Principles of Classification and a Classification of Mammals," *Bull. Am. Mus. Nat. Hist.,* vol. 85 (1945), a classic work on classification, followed by most recent mammalogists; and H.J. STAINS, "Carnivores and Pinnipeds," in S. ANDERSON and J.K. JONES, JR. (eds.), *Recent Mammals of the World: A Synopsis of Families* (1967). F.E. BEDDARD, *Mammalia* (1902), is a definitive early work on mammalian anatomy. The paleontology of the Carnivora is summarized in two works by A.S. ROMER: *Vertebrate Paleontology,* 3rd ed. (1966), fundamental to an understanding of fossil forms, and *Notes and Comments on Vertebrate Paleontology* (1968), containing additional information not found in the general text. Books devoted to particular subgroups of the carnivores include A. DENIS, *Cats of the World* (1964), an excellent summary of the status of all members of the Felidae; C.J. HARRIS, *Otters* (1968), a fine summary of the status of the otters around the world; H.E. HINTON and A.M.S. DUNN, *Mongooses: Their Natural History and Behavior* (1967), which contains much interesting information that is difficult to find elsewhere, except in scattered literature; R.J. HARRISON *et al.* (eds.), *The Behavior and Physiology of Pinnipeds* (1968), an excellent summation of recent knowledge on these aquatic carnivores; and V.B. SCHEFFER, *Seals, Sea Lions, and Walruses: A Review of the Pinnipedia* (1958), a major work on the taxonomy of the Pinnipedia.

Cetacea. G.M. ALLEN, "The Whalebone Whales of New England," *Mem. Bost. Soc. Nat. Hist.,* 8:107–322 (1916), containing much valuable information on the baleen whales; HARALD T. ANDERSEN (ed.), *Biology of Marine Mammals* (1969), a modern review of physiology, anatomy, and behaviour of cetaceans; F.C. FRASER, *Report on Cetacea Stranded on the British Coasts from 1927 to 1932* (1934), *... 1933 to 1937* (1946), and *... 1938 to 1947* (1953), information on North Atlantic cetaceans; *Handbook of R.H. Burne's Cetacean Dissections* (1952), a good source on whale anatomy; RICHARD J. HARRISON and JUDITH E. KING, *Marine Mammals* (1965), a simple guidebook on most aspects of cetaceans; R. KELLOGG, "The History of Whales—Their Adaptation to Life in the Water," *Q. Rev. Biol.,* 3: 29–76, 174–208 (1928); and "A Review of the Archaeoceti," *Publs. Carnegie Instn. 482* (1936), important papers on the evolution and adaptation of cetaceans; W.N. KELLOGG, *Porpoises and Sonar* (1961), a preliminary synthesis of studies on porpoise echolocation; N.A. MACKINTOSH and J.F.G. WHEELER, "Southern Blue and Fin Whales," *'Discovery' Rep.,* 1: 257–540 (1929); L. HARRISON MATTHEWS, "The Humpback Whale, *Megaptera nodosa,*" *ibid.,* 17:7–92 (1937); and "The Sei Whale, *Balaenoptera borealis,*" *ibid.,* 17:183–289 (1938), three papers that deal with economically important species; J.R. NORMAN and F.C. FRASER, *Giant Fishes, Whales, and Dolphins,* new ed. (1948), an excellent review of the cetacea; K.S. NORRIS (ed.), *Whales, Dolphins, and Porpoises* (1966), a readable account of the overall biology of the group; DALE W. RICE and VICTOR B. SCHEFFER, "A List of the Marine Mammals of the World," *Spec. Scient. Rep. U.S. Fish Wildl. Serv. (Fisheries No. 579)* (1968), a systematic listing of all modern cetaceans; P.F. SCHOLANDER, "Experimental Investigations on the Respiratory Function in Diving Mammals and Birds, Hvalråd Skr., 22:1–131 (1940); and P.F. SCHOLANDER and W.E. SCHEVILL, "Counter-Current Vascular Heat Exchange in the Fins of Whales," *J. Appl. Physiol.,* 8:279–282 (1955), technical papers that deal with special adaptations of cetaceans; E.J. SLIJPER, *Die Cetaceen* (1936, in Dutch) and *Walvissen* (1958; Eng. trans., *Whales,* 1962), comprehensive popular books on whales; V.B. SCHEFFER, *The Year of the Whale* (1969), a hypothetical narrative of the life history of the sperm whale, with factual information on other species; A.G. TOMILIN, *Cetacea,* vol. 9 of *Mammals of the U.S.S.R. and Adjacent Countries* (1967; orig. pub. in Russian, 1957); FREDERICK W. TRUE, "Contributions to the Natural History of the Cetaceans: A Review of the Family *Delphinidae,*" *Bull. U.S. Natn. Mus. 36* (1889), an early synthesis of cetacea that still has much validity; and ERNEST P. WALKER *et al., Mammals of the World,* vol. 2, *Cetacea,* 2nd ed. (1968), photographs and natural history data of most modern cetaceans. LYALL WATSON, *Sea Guide to Whales of the World* (1981), is a useful reference and field guide to whales, dolphins, and porpoises.

Proboscidea. L.S. DE CAMP, *Elephant* (1964), suitable for both the specialist and nonspecialist alike; RICHARD CARRINGTON, *Elephants: A Short Account of Their Natural History, Evolution and Influence on Mankind* (1958), an excellent study of living as well as extinct forms; P.E.P. DERANIYAGALA, *Elephas maximus, the Elephant of Asia* (1951), with a considerable amount of information on the Asian elephant; and *Some Extinct Elephants, Their Relatives, and the Two Living Species* (1955), reviewed by G. Gaylord Simpson, a remarkable miscellany of elephant lore and observation, ancient and recent; HENRY F. OSBORN, *Proboscidea* (1939), a comprehensive pioneering work; A.S. ROMER, *Vertebrate Paleontology,* 3rd ed. (1966), a *sine qua non* for students of proboscidean evolution; and IVAN T. SANDERSON, *The Dynasty of Abu: A History and Natural History of the Elephants and Their Relatives, Past and Present* (1962), a good all-around work.

Sirenia. G.M. ALLEN, "Extinct and Vanishing Mammals of the Western Hemisphere, with the Marine Species of All the Oceans," *Spec. Publs. Am. Comm. Int. Wildl. Prot.,* no. 11 (1942), provides information on the causes of extinction and the basis for conservation of sirenians; C. BERTRAM, *In Search of Mermaids: The Manatees of Guiana* (1963), is a readable popular account of the biology of manatees; and C.K. and G.C.I. BERTRAM, "The Sirenia as Aquatic Meat-Producing Herbivores," *Symp. Zool. Soc. (London),* no. 21, pp. 385–391 (1968), contains an extensive bibliography of the literature on the Sirenia.

Perissodactyla. Information on the ungulates as a group is contained in J. SIDNEY, "The Past and Present Distribution of Some African Ungulates," *Trans. Zool. Soc. Lond.,* vol. 30 (1965), a comprehensive account; and J.R. ELLERMAN and T.C.S. MORRISON-SCOTT, *Checklist of Palaearctic and Indian Mammals, 1758 to 1946,* 2nd ed. (1966).

The following papers are concerned with the biology of certain perissodactyls: W. VON RICHTER, "Untersuchungen über angeborene Verhaltensweisen des Schabrackentapirs (*Tapirus indicus*) und des Flachlandtapirs (*Tapirus terrestris*)," *Zool. Beitr.* Neue Folge, 12:67–159 (1966), one of the few detailed studies of tapirs; C.A.W. GUGGISBERG, *S.O.S. Rhino* (1966), a readable general account of the living rhinoceroses, their biology and conservation; H. KLINGEL, "Soziale Organisation und Verhalten freilebender Steppenzebras," and "Soziale Organisation und Verhaltensweisen von Hartman und Bergzebras," *Z. Tierpsychol.,* 24:580–624 and 25:76–88 (1967–68), descriptions of the behaviour and social organization of zebras; and G.G. SIMPSON, *Horses: The Story of the Horse Family in the Modern World and Through 60 Million Years of History* (1961), an interesting account of the natural history and evolution of the Equidae. MYRON J. SMITH, *Equestrian Studies* (1981), is a comprehensive, classified bibliography of more than 4,600 equestrian studies in English.

Artiodactyla. I.W. CORNWALL, *Bones for the Archaeologist* (1956), on the morphology and identification of bones including artiodactyls; J. DORST and P. DANDELOT, *A Field Guide to the Larger Mammals of Africa* (1970), giving summarized descriptions, habits, ecology, and distribution maps for all African artiodactyls; R.F. EWER, *Ethology of Mammals* (1968), a comprehensive text with much information on artiodactyl behaviour; V. GEIST, "The Evolution of Horn-Like Organs," *Behaviour,* 27:175–214 (1966), on the functional implications of horn shape; G.G. SIMPSON, "The Principles of Classification and a Classification of Mammals," *Bull. Am. Mus. Nat. Hist.,* vol. 85 (1945), which forms the basis for most modern classifications of artiodactyls; T. HALTENORTH in W. KUKENTHAL and T. KRUMBACH, *Handbuch der Zoologie,* vol. 8, pp. 1–167, *Klassifikation der Säugetiere: Artiodactyla* (1963), a weighty classification of artiodactyls (in German); V.G. HEPTNER, A.A. NASIMOVIC, and A.G. BANNIKOV (eds.), *Die Säugetiere der Sowjetunion,* vol. 1, *Paarhufer und Unpaarhufer* (1966), a massive work on Eurasian ungulates, most of it dealing with artiodactyls, originally published in Russian in 1961; A. KEAST, "Comparisons of the Contemporary Mammalian Faunas of the Southern Continents," *Q. Rev. Biol.,* 44:121–167 (1969), a review of zoogeography and adaptations, with further references; P.S. MARTIN and H.E. WRIGHT (eds.), *Pleistocene Extinctions: The Search for a Cause* (1967), a collection of essays on Pleistocene extinctions involving artiodactyls; D. MORRIS, *The Mammals* (1965), a general account with illustrations; G.B. SCHALLER, *The Deer and the Tiger* (1967), a study of the life of Indian artiodactyls; C.A. SPINAGE, *The Book of the Giraffe* (1968), much information well presented for the general reader; W.P. TAYLOR (ed.), *The Deer of North America* (1956), on all aspects of the life of North American deer; J.Z. YOUNG, *The Life of Vertebrates,* 2nd ed. (1962), containing a chapter on artiodactyls; and F.E. ZEUNER, *A History of Domesticated Animals* (1963), a useful source for much information difficult to find elsewhere.

Manchester

Manchester remains an important regional city of Great Britain, dominating much of northwestern England, but it has lost that extraordinary vitality and unique influence that made it such a phenomenon of the Industrial Revolution. Manchester was an urban prototype: in many respects it could claim to be the first of the new generation of huge industrial cities created in the Western world during the past 250 years. In 1717 it was merely a market town of 10,000 people, but by 1851 its textile (chiefly cotton) industries had so prospered that it had become a manufacturing and commercial city of more than 300,000 inhabitants, already spilling out its suburbs and absorbing its industrial satellites. By the beginning of the 20th century, salients of urban growth linked Manchester to the ring of cotton-manufacturing towns—Bolton, Rochdale, and Oldham, for example—that almost surround the city, and a new form of urban development, a conurbation, or metropolitan area, was evolving. By 1911 it had a population of 2,350,000. In the following years, however, the pace of growth slowed dramatically. If the 19th century was Manchester's golden age, when it was indisputably Britain's second city, the 20th century was marked by increasing industrial problems associated with the decline of the textile trades (the result of foreign competition and technological obsolescence).

This article is divided into the following sections:

Physical and human geography

THE LANDSCAPE

The city site. Manchester occupies a featureless plain made up of river gravels and the glacially transported debris known as drift. It lies at an elevation of 133 feet (40 metres) above sea level, enclosed by the slopes of the Pennine range on the east and the upland spur of Rossendale on the north. Much of the plain is underlain by coal measures; mining was once widespread but had ceased by the end of the 20th century. Within this physical unit, known as the Manchester embayment, the city's metropolitan area evolved. Manchester, the central city, is situated on the east bank of the River Irwell and has an elongated north-south extent, the result of late 19th- and early 20th-century territorial expansion. In 1930 the city extended its boundaries far to the south beyond the River Mersey, to annex 9 square miles (23 square kilometres) of northern Cheshire. Two large metropolitan boroughs adjoin the city of Manchester on the west and southwest: Salford and Trafford. Together these three administrative units form the chief concentration of commercial employment. From this core, suburbs have spread far to the west and south, chiefly within the historic county of Cheshire. To the north and east of Manchester, smaller industrial towns and villages, mixed with suburban development, merge into one another and extend as a continuous urban area to the foot of the encircling upland. Close to the upland margin lies a ring of large towns, which were traditionally the major centres of the cotton-spinning industry—Bolton, Bury, and Rochdale to the north and Oldham, Ashton-under-Lyne, and Stockport to the east.

The structure of the conurbation

The urban structure of metropolitan Manchester is determined largely by its industrial zones. By far the most important of these is the one bisecting it from east to west. This contains most of the heavier industry—petrochemicals on the Ship Canal near Irlam, electrical engineering in Trafford Park and Salford, and machine tools and metal fabrication in eastern Manchester. Industry in the south is confined to a few compact, largely planned factory estates, notably at Altrincham and Wythenshawe. North and east of Manchester, ribbons of long-established industry follow every railway, river valley, and abandoned canal. The electrochemical industries of the Irwell valley, the dyestuffs of the Irk, and, everywhere, the old textile mills (many converted to new industrial uses) are the dominant features.

Climate. Manchester's climate is most kindly described as mild, moist, and misty. The temperate climate is without extremes: winters are mild, with a January mean temperature of 39° F (4° C), and summers are cool, with a July mean temperature of 59° F (15° C). Occasional high-pressure systems produce cold, clear spells in winter or hot droughts in summer, but these rarely persist. Winds from the west and south prevail, and these bathe the city in frequent gentle rain derived from the almost constant succession of Atlantic weather systems. The annual rainfall, 32 inches (818 millimetres), is not notably high by the standards of western Britain, but it occurs on no less than half of the days in an average year. There is little reliable seasonal variation, but the months of March through May offer the best chance of prolonged dry spells.

The wet Atlantic air banked against the Pennine slopes to the east of the city produces extreme cloudiness; on about 70 percent of the days of the year, the afternoon sky is at least half covered by cloud. This limits sunshine, which was further reduced by air pollution during the decades of the city's industrial prosperity. Up to about 1960 the city centre recorded the abnormally low total of only 970 sunshine hours annually. Foul fogs were another problem of the man-made industrial climate. Manchester then had an average of 55 days of serious fog in a typical year, and the death rate from respiratory diseases surged following these fog episodes. But the city's peculiarly sunless and fog-bound winter climate was transformed by effective air-pollution control. Annual hours of bright sunshine have risen to about 1,300, and serious fogs have been reduced to about 20 days each year. This has been a major factor in reducing the incidence of two formerly endemic diseases, bronchitis and tuberculosis, which had given the city an unenviably high death rate.

Architecture and the face of the city. Manchester's extraordinary 19th-century wealth left a permanent record in an architectural variety and virtuosity that makes the city centre an outdoor museum of styles from Greek classical to early tall steel-framed structures. Commercial firms vied to commission the best architects to design offices and warehouses of ornate splendour, and the public buildings were intended to outshine London's. Thus, banks occupied Greek temples or turreted Gothic castles, and warehouses were given the facades of Venetian palaces. The offices of the Ship Canal Company were given a Grecian colonnade perched high above street level, and the Town Hall, designed by Alfred Waterhouse, is regarded as perhaps the ultimate in Victorian Gothic fantasies.

Conserving this priceless architectural heritage has pre-

sented great problems. Many of the buildings are protected landmarks but are unsuited to modern commercial needs, though some imaginative conversions have taken place. The Royal Exchange, once the hub of the textile trade, contains the old trading floor, the largest room in Europe; it now houses a freestanding theatre-in-the-round. The old Central Station, a huge glazed train shed, has been converted into an exhibition centre. A complex of buildings at Castlefield, including the world's oldest railway station, has been developed as a regional museum of science and industry.

A wave of office redevelopment in the 1960s and '70s added many steel-and-glass structures to the Manchester skyline. One of the earliest is Manchester's tallest building, the Co-operative Insurance Society tower, at 400 feet (122 metres).

As new shopping centres began to develop in outlying areas, the level of retail trade in the city centre suffered. This led to the development of a large enclosed shopping precinct, the Arndale Centre, which contains a significant proportion of the total retail activity in the city centre. As it grew, however, older shopping streets suffered by the shift of businesses, so that parts of the city core have a run-down, half-abandoned appearance; but this is part of the process by which the Victorian central business district is reshaping itself to meet modern needs.

THE PEOPLE

Greater Manchester is one of the world's most compact and crowded metropolitan areas. The overcrowded conditions explain the chief demographic trend of recent years, that of population loss by out-migration. Manchester city itself lost almost one-third of its population to migration between 1961 and 1981, one of the highest rates of migrational loss among all British cities. Natural increase is below the national average, for the migration is chiefly of young families of child-bearing age, leaving an older population in the core cities. Thus overall population decline is serious. This trend is also widespread in the other old industrial towns of the conurbation.

Much of this migration is to suburban areas, though there is also an interregional loss of population to more prosperous areas of Britain, and the "dormitory" districts of the fringes (and especially Cheshire to the south) are growing strongly. Thus, the metropolitan area is decentralizing quickly, and its overall population trend is more favourable than those of its major constituent cities. Total metropolitan population has been virtually stable since 1961, with the low rate of natural increase being entirely offset by net out-migration.

Increasingly, families living in decaying substandard housing have been rehoused. Manchester has exported population to overspill estates at Middleton and Hyde, and Salford families have moved to Worsley. All of these are large schemes, involving population transfers of at least 10,000, and all lie within the metropolitan area. There also has been movement to the New Town project at Warrington, a major development point on the Ship Canal, 18 miles (29 kilometres) west of Manchester. Within the city there has been massive redevelopment. The Hulme scheme of the early 1970s involved the rehousing of a population of almost 60,000.

Like many British cities, Manchester experimented in the 1960s with high-rise housing to accommodate families from the slum clearance zones. In the past, row houses had been the traditional housing form in low-income areas of the inner city, and the new high-rise schemes proved to be a social failure—some were demolished within a decade of construction. The emphasis of city planning was shifted from total clearance and replacement of old housing to its conservation and improvement through Housing Action Areas. Thus, old housing is given new life, and the community is kept together: where new dwellings are built, they are the modern equivalent of the traditional row houses.

Commonwealth immigration

The out-migration has been partly counterbalanced by in-migration from Commonwealth countries, particularly from the West Indies and the Indian subcontinent. Manchester itself has a multiracial immigrant community, which is chiefly concentrated in the Moss Side area. Some of the textile towns, too, have attracted Commonwealth immigrants, chiefly Indian and Pakistani textile workers. The metropolitan area as a whole has been one of the main magnets to Commonwealth immigrants in Britain.

THE ECONOMY

Industry. There has long been a contrast between the economies of the core city (Manchester itself, together with the industrial areas of Salford and Stretford) and the textile towns that form the northern and eastern margins of the urban cluster. Until the 1960s the latter had narrowly based economies largely dependent on the textile trade, which still provided more than half the employment of women. The former, however, had an economy of greater diversity: manufacturing was varied (including printing and the production of engineering and electrical products, chemicals, and clothing), and a broad range of service activities gave stability to the economy. This old pattern of contrast was breaking down in the late 20th century, as the core city lost factory employment at a rapid rate and became increasingly dependent on services while the peripheral towns acquired greater industrial diversity and thus a securer (and locally expanding) manufacturing base.

The entire metropolitan area of Greater Manchester has undergone major economic changes. The textile industry has been reduced to a mere vestige of the enormous manufacture that once underpinned the economy of the city. It continues to decline, despite diversification from cotton to man-made fibres and resultant close links with the chemical industry. The surviving mills have been reequipped for high productivity, but this, too, has had the effect of reducing labour demand. The clothing industry has declined with the textile industry but has remained a significant employer of women, chiefly in many small workshops in the inner city. Much more serious has been the sharp contraction of more modern industries that until the 1970s had served as replacements for the old industries. The decline in engineering, one of the main sources of jobs for men, is especially serious. Within the chemical industry the main growth has been in the production of fine chemicals and pharmaceuticals, with research laboratories located in parkland at Alderley, on the southern fringe. The paper and printing industry is stable, reflecting Manchester's status as the second centre, after Greater London, of newspaper production in England.

Decline of manufacturing

Manchester's economy has been moving from an industrial to a postindustrial nature. Services have become the chief employers, with the "thinking" rather than the manual services undergoing expansion. Some services, such as transport and distribution, are declining, but the professions, finance and banking, administration, and general personal services are growing with explosive force. Most of these growth points require well-qualified workers: the declining demand for manual skills and the shift to mental skills have caused selective unemployment, which is clearly a persistent social problem.

The conversion of Manchester into a service city is not an entirely new trend, since the city has been the regional capital of northwestern England for two centuries. The process, however, has been quickened by the rapid decline of industry in the inner city. Clearance of the slum tracts and their subsequent redevelopment have removed entire urban districts that once housed many hundreds of small firms. Nearly half of the employment once available in manufacturing in the inner areas has disappeared. In these districts a disadvantaged and ethnically mixed community experiences unemployment rates that are at least twice the city average.

Part of this loss of factory work in the inner city has been the result of the movement of firms to the fringe of the urban area, not only to planned industrial estates but also to the cotton mills left empty by the decline of the textile trades. Hundreds of mills have been converted to other uses, thereby providing the cheap factory-floor space necessary to young and struggling firms, so that the textile towns have in some degree replaced the inner city as an industrial nursery in which it is possible for new firms to become established.

Trade and transportation. Apart from its massive volume of retail and wholesale trade, Manchester has a number of distinctions as a regional service centre. It houses a branch of the Bank of England and the Northern Stock Exchange, the headquarters of the Co-operative Wholesale Society, and one of the major provincial crown courts. Its airport at Ringway, 10 miles south of the city, is the leading British terminal outside London in the volume of international traffic handled and in the diversity of both its European and its transatlantic services. Ringway is owned by the city and is the country's second airfreight terminal.

From 1894 to 1986 Manchester was a seaport, with a group of docks at the head of the 37-mile Ship Canal. The growth in the size of shipping, together with changes in the pattern of maritime trade, led to a slow decline in the use of the waterway, and by the mid-1980s the upper parts had been closed to traffic. The lower reaches of the canal remained open and busy, serving the needs of bankside industries, especially the huge oil-refining and chemicals complex at Ellesmere Port. New industrial and commercial uses for the derelict terminal docks have been developed.

Public transport in Greater Manchester is coordinated by a Passenger Transport Executive, and it relies heavily on an integrated system of bus routes. The system faces private competition, however, especially from flexible minibus services. A dense network of commuter rail services, largely electrified, is managed in partnership with British Rail.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. Although the metropolitan area of Greater Manchester is a single cohesive socioeconomic unit, its local government has been fragmented for much of its history. The dominant unit is the metropolitan borough of Manchester, which carries the financial burden of supplying central facilities (major museums and libraries and the airport) for the area as a whole. There are nine other metropolitan boroughs, each independent and able to develop its own social, educational, and planning policies.

Greater Manchester

The Local Government Act of 1972 (in effect from 1974) created a metropolitan county of Greater Manchester, divided into metropolitan boroughs, including the city of Manchester. The county administered a number of general services *(e.g.,* strategic planning, transport, and recreation), while the boroughs handled the main range of services (*e.g.,* education, housing, and most personal and household services). The metropolitan county of Greater Manchester lost its administrative powers in 1986, however. Some of the general services that it had provided were taken over by specialist successor authorities, but many of its administrative powers passed to the city of Manchester and the other individual metropolitan boroughs, which are in effect now unitary authorities.

Education and social services. Of all Manchester's pioneer cultural achievements, none has prospered more than the Victoria University of Manchester. After its foundation in 1851 at a site in Quay Street, the college received a charter in 1872 and began growth on its present site in 1873. By 1880 it had combined with member colleges in both Leeds and Liverpool to form a federal institution. Since becoming a separate body again in 1903, the university has grown to become one of the largest in Britain. The faculty of technology has become autonomous as an Institute of Science and Technology, and, with the establishment of the University of Salford in 1967 and the growth of a large polytechnic, there are now four institutions of higher learning in and near the city.

The city provides the complete range of social and welfare services within the British system, but its special strength lies in health services and medical education. The Victoria University of Manchester has the largest medical school in western Europe; it is linked to three large groups of teaching hospitals that provide specialist treatment. One of the most distinguished of these is the Christie Hospital, a major centre for cancer research.

CULTURAL LIFE

The cultural life of Manchester suffered some losses during the 20th century. For example, its prestigious newspaper, *The Guardian,* has (in the Mancunian view) fled to London and dropped the city's name from its title. However, the Lowry, an architecturally innovative centre for the visual and performing arts, opened in 2000 and signaled the city's cultural revival at the beginning of the 21st century. Music maintains its strength. The Hallé concerts reached their centenary in 1958, and the orchestra continues to maintain its international reputation.

The city has a large number of private, public, and specialized libraries. The municipal library, with more than 25 branches, has its headquarters at St. Peter's Square. Manchester also houses the notable John Ryland University Library (now part of the Victoria University of Manchester library) and Chetham's Library, one of the first free public libraries in Europe.

Libraries

Among the galleries and museums, the Whitworth Art Gallery and the Manchester City Art Gallery are particularly well known. The latter contains a fine collection of paintings, sculpture, silver, and pottery and is supplemented by several branch galleries. The Manchester Museum has special exhibits of Egyptian and Japanese objects, as

The Guardian, Manchester and London

Manchester skyline viewed from the mathematics building of Manchester University Institute of Science and Technology.

well as natural history collections and an aquarium. The Museum of Science and Industry highlights Manchester's industrial heritage.

There are two major association football (soccer) clubs, including Manchester United, one of the world's most famous and popular teams. At the grounds of the Old Trafford Cricket Club, test matches are played against overseas cricket teams visiting Great Britain. Manchester also has an active pop music scene, which revolved around Factory Records in the 1980s and has given rise to several influential rock bands, including Joy Division, the Smiths, and Oasis.

History

EARLY SETTLEMENT AND MEDIEVAL GROWTH

Early in the Roman conquest of Britain, a fort was established (AD 78–86) on a low sandstone plateau at the confluence of the Rivers Medlock and Irwell. In its first form, the fort was a simple field fortification of shallow ditches, earth banks, and timber palisades. By the early 3rd century, it had been rebuilt in stone and contained a number of buildings; excavations have uncovered evidence of substantial activity. A *vicus* (Latin: "row of houses") of merchants and craftsmen had grown outside the walls, along the well-made road to York. But Roman occupation left no permanent imprint, except to give the modern city its name, derived from Mamucium ("Place of the Breastlike Hill"). There is no evidence of occupation after the 4th century, and the site seems to have lain empty for 500 years. In 919 the West Saxon king Edward the Elder sent a force to repair the Roman site as a defense against the Norsemen, and some traces of this reoccupation have been discovered. By then, however, the growth of Manchester had recommenced almost a mile from the fort, at the junction of the Rivers Irk and Irwell near the present cathedral.

Early growth

The Norman barony of Manchester was one of the largest landholdings in Lancashire, and its lords built a fortified hall close to the church. During the 13th century, Manchester began its transition from village to town, and sometime before 1301 a charter was granted. Although Manchester was acquiring regional importance, it was subordinate to its near neighbour, Salford, which was the capital manor of the hundred (district) and which had an earlier borough charter. The full development of the medieval borough followed the establishment in 1421 of a college of priests to take charge of the church. Part of the college survives as Chetham's Hospital, while a free church school set up in 1506 became the Manchester Grammar School in 1515, founded by Hugh Oldham, bishop of Exeter.

EVOLUTION OF THE MODERN CITY

By the 16th century Manchester was a flourishing market borough important in the wool trade, exporting cloth to Europe via London. By 1620 a new industrial era had begun with the weaving of fustian, a cloth with a linen warp but a cotton weft. This was the origin of the cotton industry that was to transform southern Lancashire after 1770. As the trade grew, Manchester expanded and "improvements" were added, including the fine square and church of St. Ann (1712).

The industrial era

From the 1760s onward, growth quickened with the onset of the Industrial Revolution. The first canal, bringing cheap coal from Worsley, reached the town in 1762; later extended, it linked Manchester with the Mersey and Liverpool by 1776 and so served the import-export needs of the cotton industry. Manchester's first cotton mill was built in the early 1780s. By 1800 Manchester was said to be "steam mill mad," and by 1830 there were 99 cotton-spinning mills. The world's first modern railway, the Liverpool and Manchester, was opened in 1830, and by the 1850s the greater part of the present railway system of the city was complete. Despite its growth to a population of more than 70,000 by 1801, the town had no system of government and was still managed, like a village, by a manorial court leet (a court held semiannually by the lord of the manor or his steward to conduct local government). A police force was established in 1792, but not until 1838 did a charter of incorporation set up an elected council and a system of local government.

Manchester's economic history during the second half of the 19th century was one of growth and diversification. The city became less important as a cotton-manufacturing centre than as the commercial and financial nucleus of the trade; on the floor of the Royal Exchange, the yarn and cloth of the entire industry was bought and sold. From an early textile-machinery industry, many specialized types of engineering developed. Products included steam engines and locomotives, armaments, machine tools, and, later, those of electrical engineering. The opening of the 37-mile Manchester Ship Canal (1894) linked Manchester, via the Mersey estuary at Eastham, to the Irish Sea and the world markets beyond. By 1910 Manchester had become the fourth port of the country, and alongside the docks, at Trafford Park, the first (and still the largest) industrial estate in Britain was developed. New industries also took sites there, with a prominent role played by such American companies as Westinghouse and Ford, the latter moving to Essex in 1929. At its height, more than 50,000 workers were accommodated within factories of the estate, though that number later declined.

19th-century achievement

The Manchester of the 19th century was a city of enormous vitality not only in its economic growth but also in its political, cultural, and intellectual life. *The Manchester Guardian* became Britain's leading provincial newspaper, achieving international influence, while the Hallé Orchestra was its equal in the world of music. Owens College (now known as Victoria University of Manchester) became the nucleus of the first and largest of the great English civic universities, while the academic success of the Manchester Grammar School made it something of a model in the development of selective secondary education in England. Politically, Victorian Manchester often led the nation: in the agitation for parliamentary reform and for free trade, its influence was crucial. The Peterloo Massacre of 1819 arose from a peaceful political assembly, held on fields near the city, to demand parliamentary reform. In the period 1842–44 the German social philosopher Friedrich Engels lived in Manchester, and his influential book *Condition of the Working Class in England* (1845) was based on his experiences there. Among its other intellectual achievements were John Dalton's development of the atomic theory as the foundation of modern chemistry and the work of the "Manchester school" in the application of economic principles to the problems of commerce, industry, and government.

There was a price to be paid for this precocious growth. In its urban fabric, inner Manchester remained essentially a 19th-century city, and by the late 20th century it faced massive redevelopment problems. An industrial collar of obsolescent factory zones encircled the city centre, and huge areas of old slum housing survived with little renewal into the 1960s. Although the city centre was devastated by an Irish Republican bomb in 1996, much of it was rebuilt by the beginning of the 21st century. Manchester, then, is a city in transition: its face is being transformed by redevelopment, and its dependence on the insecure base of the textile industries is declining with the growth of a much broader economic structure.

Manila

Manila, the national capital and chief city of the Republic of the Philippines, is the centre of the country's economic, political, social, and cultural activity. Located on Luzon Island, it spreads along the eastern shore of Manila Bay at the mouth of the Pasig River. The city's name, originally Maynilad, is derived from that of the *nilad* plant, a flowering shrub adapted to marshy conditions, which once grew profusely along the banks of the river; the name was shortened first to Maynila and then to its present form. The city proper encompasses an area of approximately 15 square miles (38 square kilometres). In 1975, by presidential decree, Manila and its contiguous cities and municipalities were integrated to function as a single administrative region, known as Metropolitan Manila (also called the National Capital Region), with an area of 246 square miles.

Manila has been the principal city of the Philippines for four centuries, and it is the centre of its industrial development as well as the international port of entry. It is situated on one of the finest sheltered harbours in the region, about 700 miles (1,100 kilometres) southeast of Hong Kong. The city has undergone rapid economic development since its destruction in World War II and its subsequent rebuilding; it is now plagued with the familiar urban problems of pollution, traffic congestion, and overpopulation. Measures have been taken, however, to ameliorate these problems.

This article is divided into the following sections:

Physical and human geography

THE LANDSCAPE

The city site. Manila lies on the eastern shore of Manila Bay, a large inlet with access to the sea through a channel 12 miles wide to the southwest. It occupies the low, narrow deltaic plain of the Pasig River, which flows northwestward to Manila Bay out of a large lake, Laguna de Bay, southeast of the city. Manila Bay lies to the west, the swampy delta of the southward-flowing Pampanga River to the north, the mountains of the Bataan Peninsula to the west, and Laguna de Bay to the southeast. Although the city's area is constricted, it is an excellent port site because of its sheltered harbour, its access by river to inland agricultural areas, and its proximity to the Asian mainland.

Climate. The city is protected from extreme weather conditions by the hills of the Eastern Cordillera to the east and by the mountains of the Bataan Peninsula, which lies west of Manila Bay. The tropical climate is characterized by a wet season that lasts from June to November and by a dry season lasting from December to May. High humidity and thunderstorms are common in July, August, and September, when more rain is received than in other months. The average annual rainfall totals about 82 inches (2,080 millimetres). There is little monthly variation from the mean annual temperature of 81° F (27° C).

Plant and animal life. The landscape of the city of Manila is dotted with tropical trees, including the palm, banyan, and acacia; bamboo thrives in the public parks. Water buffalo, horses, dogs, pigs, and goats are common. The wealth of birdlife includes shrikes, doves, and pigeons, and Manila Bay abounds with sardines, anchovies, mackerel, tuna, snappers, and barracuda. The city's natural beauty is marred, however, by air and water pollution caused by the expansion of industry and the growing number of motor vehicles.

The city layout. The city is bisected by the Pasig River and divided into four administrative divisions comprising 14 districts. The districts developed from the original fortress city of Intramuros ("Within Walls") and the 13 villages located outside its walls. The districts of Tondo, Santa Mesa, Binondo, Santa Cruz, Quiapo, San Miguel, and Sampaloc lie to the north of the river, and Intramuros, Ermita, Malate, Paco, Pandacan, and Santa Ana are to the south. The two sections of the city are connected by several bridges. City districts

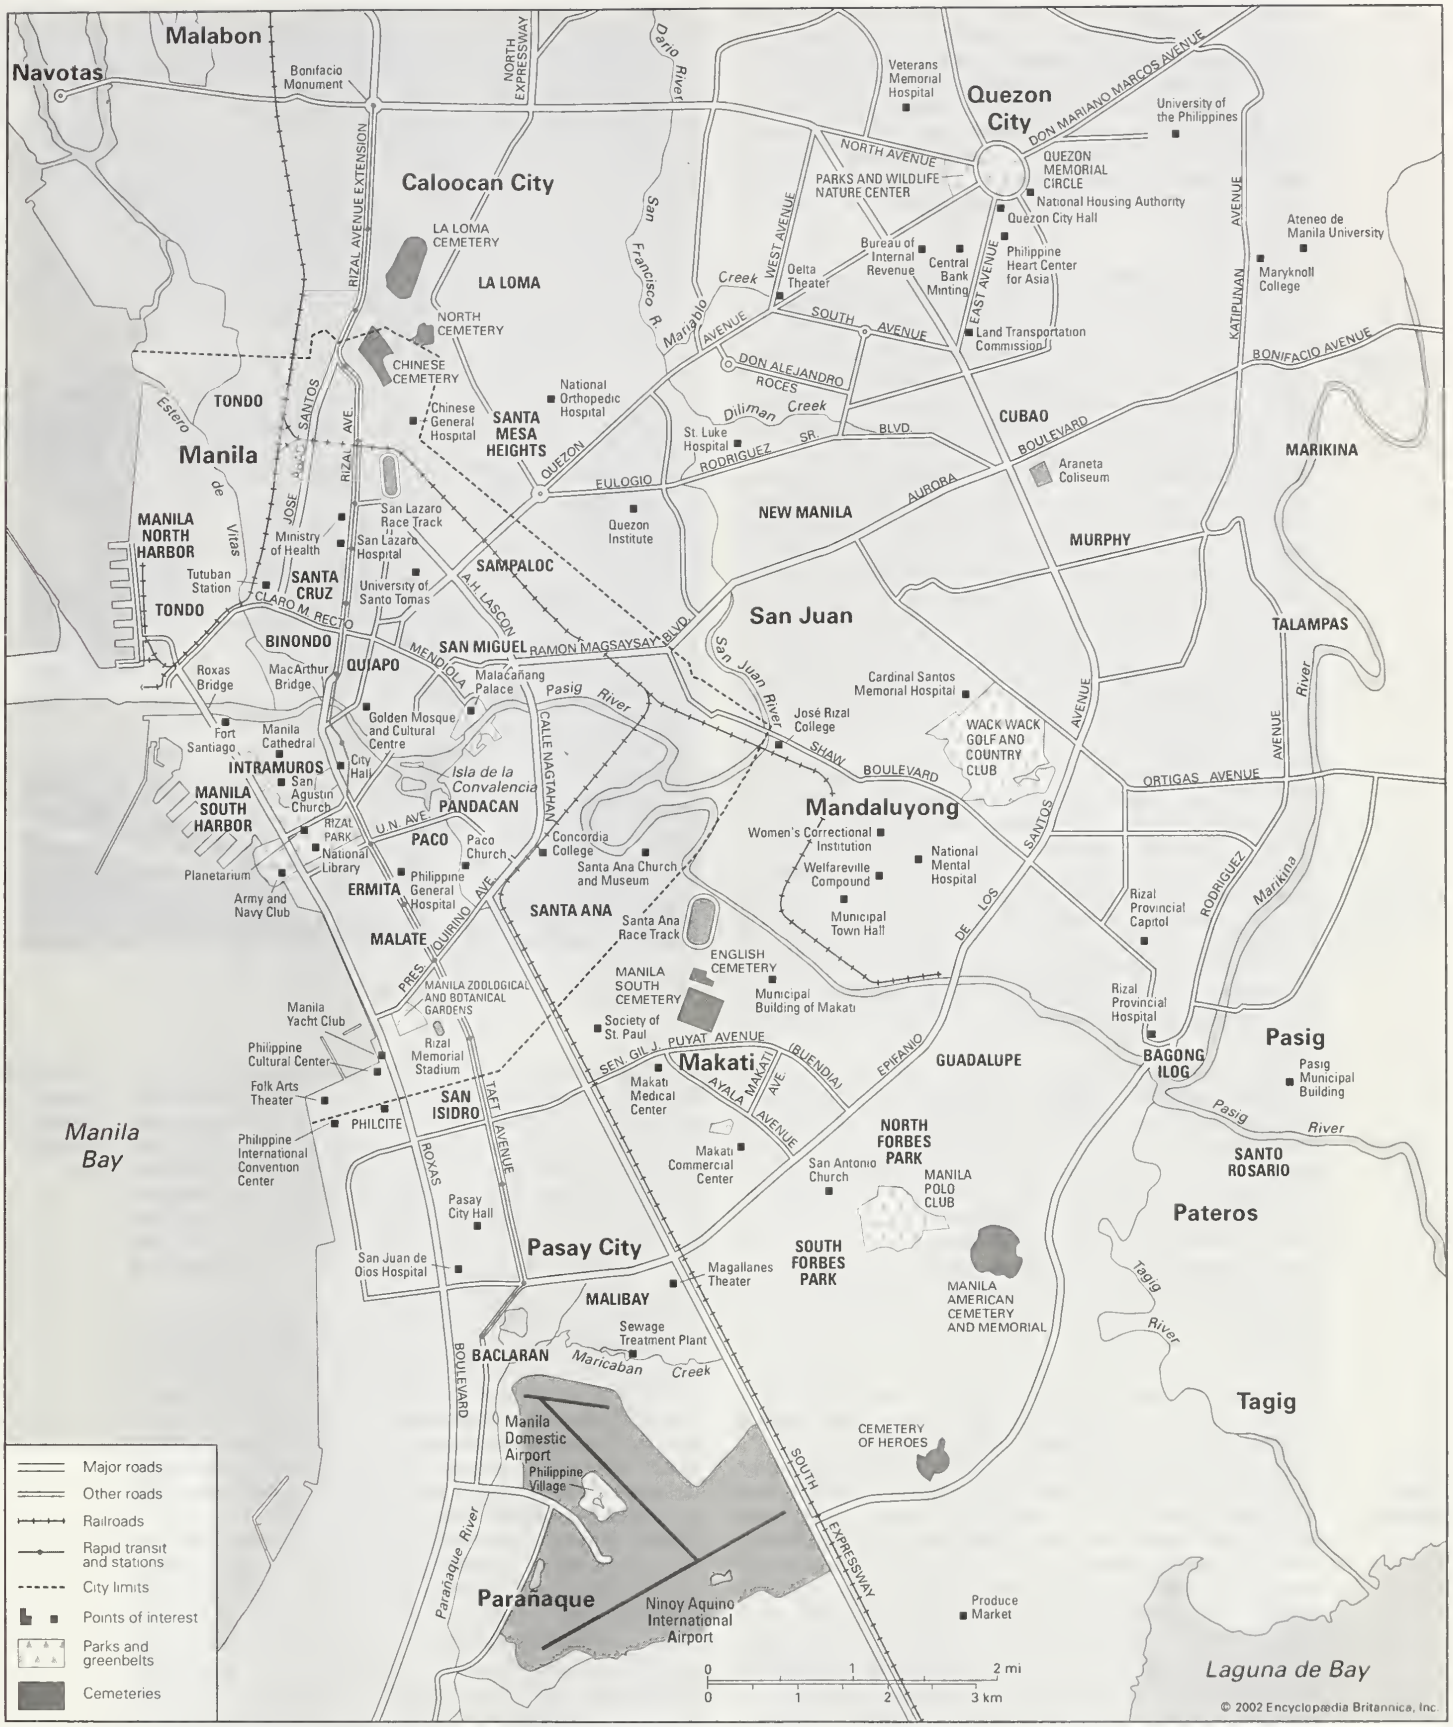
Business areas are widespread, but Makati City is the chief centre of trade and commerce. San Miguel is the site of Malacañang Palace, the presidential residence; several universities are located in Sampaloc. The shantytown district of Tondo on the northern shore is the site of Manila North Harbor, the local port, while the international port, Manila South Harbor, is on the southern shore. Intramuros is renowned for its 16th-century San Agustin church and for the ruins of its old walls and of Fort Santiago. Ermita and Malate are choice residential districts and the sites of hotels and embassies; Paco, Pandacan, and Santa Ana are middle-income residential areas.

Metropolitan Manila includes the cities of Manila and Caloocan City to the north, Quezon City to the northeast, and Pasay City (near the shore of Manila Bay) to the south and 13 municipalities. The municipalities include Makati, Mandaluyong, San Juan, Las Piñas, Malabon, Navotas, Pasig, Pateros, Parañaque, Marikina, Muntinlupa, Tagig, and Valenzuela. Metropolitan Manila was created to provide integrated services such as water supply, police and fire protection, and transport and to permit central planning for unified development.

Housing. The city has a chronic housing shortage, and tenement housing projects have been constructed by the government to help house the poor. To provide homes for squatters, the government also has developed resettlement projects around Manila that are easily accessible by land motor transportation.

Residential buildings include the single-family dwelling; the duplex for two independent households; the *accessoria*, whose dwelling units have individual entrances from the outside; the apartment building with common entrance; and the *barong-barong*, a makeshift shack built of salvaged materials (flattened tin cans, scrap lumber, cartons, or billboards) that is common in the poor area of Tondo. Types of dwellings

Architecture. Architectural styles reflect American, Spanish, Chinese, and Malay influences. Rizal Park and a number of government buildings were designed by the American architect and city planner Daniel H. Burnham. Modern buildings—including multistoried commercial houses and public and private buildings—are commonly made of reinforced concrete and hollow cement blocks. Houses of modern design—especially low, sprawling ranch houses with spacious lawns—are common in the districts of Ermita and Malate. Spanish-style houses, with tiled roofs, barred windows, and thick walls, were common be-



Manila with its adjoining municipalities.

fore World War II and have remained popular. The churches of the city are American, Spanish, or European in character. The Manila cathedral was rebuilt in the 1950s and is an important landmark. It succeeds five earlier cathedrals—the first dating from the mid-16th century—that were destroyed either by earthquakes or during wartime.

THE PEOPLE

Metropolitan Manila is densely populated and contains a large proportion of the country's population as a result of rural-urban migration. The strain on municipal services has an adverse effect on the quality of life in the urban area. To ameliorate the situation, the government has adopted a "back-to-the-farm" policy and has established

resettlement projects outside of the central urban area.

Almost all the residents of Manila are Filipinos. The largest single foreign community, representing less than 10 percent of the population, is made up of Chinese. The population of the city is predominantly Roman Catholic, although there are some Protestants, Muslims, and Buddhists. The two national Christian churches—the Iglesia ni Kristo and the Philippine Independent, or Aglipayan, Church—have small congregations. (D.C.S.)

Tsutomu Nakayama—Shostal Assoc.

THE ECONOMY

Industry. Manila's diverse manufactures include textiles and clothing, publishing and printing, food processing, and the production of tobacco products, paints, drugs, aluminum articles, rope and cordage, shoes, coconut oil, soap, and lumber. The manufacture of electronic products and components has increased. Factories vary in size from small plants located in congested districts to large facilities on the outskirts of the metropolitan area.

Commerce and finance. Metropolitan Manila is the centre of commerce and finance in the Philippines. Makati City is the most important concentration of commercial and financial activity within the metropolitan area. Ayala Avenue is lined with the high-rise headquarters of multinational and Philippine banks, industrial enterprises, and trading houses. Makati City is also one of the most important retail and shopping areas, with its many department stores, enormous shopping malls, specialty stores, and boutiques. Just northeast of Makati City, Mandaluyong, with its new shopping complexes, is emerging as another important retail district.

Trade flourishes within the metropolitan area and between it and the provinces and other countries. Most of the Philippines' imports and exports pass through the port of Manila. Financial institutions headquartered in Metropolitan Manila include such establishments as the Development Bank of the Philippines, the Philippine National Bank, the Philippine Veterans Bank, the Government Service Insurance System, the Social Security System, and many private commercial and developmental banks. Private insurance companies and the Manila Stock Exchange also contribute to the mobilization of savings for investment.

Transportation. Within the region, public transportation is provided principally by buses, jeepneys (small buses built on the chassis of jeeps), and taxis. An elevated rail line, linking Caloocan City and the city of Baclaran (to the south of Pasay City), was completed in 1984. It was the first phase of a transit system, called Light Rail Transit, that eventually will extend throughout the metropolitan area. A new line that will encircle the metropolitan area is under construction. Bus services operate routes to northern and southern Luzon; railroad services operated by the Philippine National Railways also connect the city with northern and southeastern Luzon. Interisland and international transportation is provided by shipping and by domestic and foreign airlines. Manila Domestic Airport and Ninoy Aquino International Airport are both located about 6 miles (10 kilometres) south of the city centre.

Traffic problems

Traffic congestion is serious, traffic tending to pile up at the bridges during the morning and evening rush hours. Adjacent towns serve as dormitory suburbs, and many people commute to the city, adding to the traffic problem.

The main international port is Manila South Harbor, enclosed by a low breakwater. Several heavy industries that depend upon imported raw materials are located within the port area. The piers of the local port, Manila North Harbor, are congested with heavy traffic from all ports in the Philippines. It has several warehouses for storage of goods and equipment. Additional port facilities for international shipping have been built, partially on reclaimed land, in the area between the two harbours. (D.C.S./Ed.)

ADMINISTRATION AND SOCIAL CONDITIONS

Government. With the organization of Metropolitan Manila in 1975, the mayor–council type of government was superseded by a manager–commission type. Metropolitan Manila, which is vested with the powers and attributes of a corporation (including the power to make contracts, sue and be sued, hold, transfer, and dispose of property, and similar powers), is administered by the Metropolitan Manila Commission. It is headed by a governor as the general manager, who executes policies and measures approved by the commission and is responsible for the discharge of management functions. The other members are the vice governor, as deputy general manager, and three commissioners or board members, one each for planning, finance, and operations. All members are appointed by the president of the Philippines.

The Metropolitan Manila Commission

Supplanting the city or municipality boards or councils is the Sangguniang Bayan (Municipal Assembly), created for each city or municipality, which helps the metropolitan government in administration and legislation. It is composed of the mayor, vice mayor, councillors, captains of *barangays* (neighbourhoods), and representatives from other sectors, appointed by the president upon recommendation of the local unit. The mayors are the presiding officers in their respective areas of jurisdiction.

Public utilities. Potable water comes from a supply network managed by the Metropolitan Waterworks and Sewerage System. Satisfactory sanitation conditions are maintained by surveillance of markets, restaurants, motion-picture houses, recreation halls, and slaughterhouses. Insecticides are sprayed on open sewers, uncollected garbage, and standing water; garbage is collected by a fleet of trucks that operate night and day. Moreover, workers maintain cleanliness in the metropolitan area and are also responsible for the beautification of the city as directed by the governor of Metropolitan Manila.

Health and security. Health facilities in Manila are among the best in the region. The city government maintains numerous health centres as well as San Lazaro Hospital, where patients are treated free of charge, and subsidizes a number of government hospitals. There are also many missionary and private hospitals in the city.

Police and fire services

Police and fire services are well organized, improved equipment and techniques are used, and personnel are comparatively well paid. To intensify the campaign against crime, more police precincts were created, and the Police Community Relations District was organized. *Barangay* brigades and *barangay tanods* (guards) were also created in each *barangay* of every city and municipality in Metropolitan Manila. They are volunteers and selected leaders of the *barangay* whose duty is to maintain peace and order in their community.

Education. More than 96 percent of the population of 10 years of age or older is literate. More than 100 free public schools are maintained, in addition to the night vocational and secondary schools and the city-supported University of Manila. Educational opportunities are also provided for handicapped children, orphans of school age, and adults. As the education centre of the country, Metropolitan Manila houses many of the major institutions of higher education of the country, including the University of the Philippines (with its main campus in Quezon City), the Philippine Normal College, and the Polytechnic University of the Philippines. There are several universities sponsored by religious bodies, including the University of Santo Tomas (founded in 1611), as well as nonsectarian institutions such as the University of the East and the Far Eastern University.

Manila's universities

CULTURAL LIFE

The centre of the performing arts in the country is the Philippine Cultural Center. There are also the Folk Arts Theater, facing Manila Bay, the renovated historic Metropolitan Theatre, and an open-air theatre in Rizal Park. The many libraries and museums include the National Library and the National Museum, known for its anthropological and archaeological exhibits; the National Institute of Science and Technology, with a scientific reference library and large collections of plants and animals; the geological museum of the Bureau of Mines and Geosciences; the Planetarium; Fort Santiago, which houses original works of the Philippine patriot José Rizal; and the Kamaynilaan (Manila City) Library and Museum, which contains valuable carvings, paintings, and archives.

The city's parks

The foremost outdoor recreational area is Rizal Park, with a Japanese garden, a Chinese garden, an open-air theatre, a playground, a grandstand, and a long promenade adjacent to Manila Bay. Other areas include the Manila Zoological and Botanical Gardens, the Mehan Garden, and Paco Park. Athletic facilities include the Rizal Memorial Stadium and the Jai-Alai Fronton, both located in Manila, and the Araneta Coliseum in Quezon City. Annual festivals and carnivals are held in the sunken garden fronting the City Hall of Manila.

The interweaving of indigenous, Muslim, Spanish, and American influences has given Manila a variegated culture more Western than that of most other Asian countries. The Spanish legacy is represented in the importance of Roman Catholicism in daily life and in the numerous annual fiestas, many of which commemorate patron saints. Folk art in Manila has many expressions, but among its most prominent manifestations are jeepneys, which date to the World War II jeeps left behind by U.S. soldiers. Although jeepneys are a main form of public transportation, they also serve as rolling art galleries that display colourful statues, designs, and flashing lights.

Sports are an important part of daily life in Manila. Basketball, introduced by Americans in the early 1900s, is the most popular team activity. The games of the country's professional teams have high attendance rates, and many enjoy playing basketball in public parks and elsewhere. Golf, tennis, water sports, boxing, cockfights, and Filipino martial arts (arnis, kali, and eskrima) are other activities that have a following among Manilans.

History

In the late 16th century, Manila was a walled Muslim settlement whose ruler levied customs duties on all commerce passing up the Pasig River. Spanish conquistadors under the leadership of Miguel López de Legazpi—first Spanish governor-general of the Philippines—entered the mouth of the river in 1571. They destroyed the settlement and founded the fortress city of Intramuros in its place. Manila became the capital of the new colony. Outside the city walls stood some scattered villages, each ruled by a local chieftain and each centred on a marketplace. As Spanish colonial rule became established, churches were built near the marketplaces, where the concentration of population was greatest. Manila spread beyond its walls, expanding north, east, and south, linking together the market–church complexes as it did so.

The Spanish period

The propagation of Roman Catholicism began with the Augustinian friar Andrés de Urdaneta, who accompanied the expedition of 1571. He was followed by Franciscan, Dominican, Jesuit, and Augustinian priests who founded churches, convents, and schools. In 1574 Manila was baptized under the authorization of Spain and the Vatican as the "Distinguished and Ever Loyal City" and became the centre of Catholicism as well as of the Philippines. At various periods Manila was threatened, and sometimes occupied, by foreign powers. It was invaded by the Chinese in 1574 and raided by the Dutch in the mid-17th century. In 1762, during the Seven Years' War, the city was captured and held by the British, but the Treaty of Paris (1763) restored it to Spain. It was opened to foreign trade in 1832, and commerce was further stimulated by the opening of the Suez Canal in 1869.

The Manila area became the centre of anti-Spanish sentiment in the 1890s, and the execution of Filipino patriot José Rizal in the city in December 1896 sparked a yearlong insurrection. During the Spanish-American War the Spanish fleet was defeated at Manila Bay on May 1, 1898, and on August 13 the city surrendered to U.S. forces. It subsequently became the headquarters for the U.S. administration of the Philippines.

The U.S. period and independence

The U.S. period was one of general social and economic improvement for the city. U.S. policy encouraged gradual Filipino political autonomy, and to help achieve this goal public schools were established in Manila and throughout the archipelago. The University of the Philippines, founded in 1908, became the apex of the educational system. The city developed into a major trading and tourist centre.

Upon the outbreak of World War II, Manila was declared an open city and was occupied by the Japanese in January 1942. The city suffered little damage during the Japanese invasion but was levelled to the ground during the fight for its recapture by U.S. forces in 1945.

Manila was in shambles when in 1946 it became the capital of the newly independent Republic of the Philippines. The city was rapidly rebuilt, however, with U.S. aid. A significant change in its appearance was brought about by industrialization. In 1948 suburban Quezon City was chosen as the site of a new national capital, but in 1976 Manila again became the capital and the permanent seat of the national government. (D.C.S.)

Specific treatment on population, housing, charter provisions, needs, and resources of the capital city may be found in *Philippine Yearbook* (annual). (D.C.S./Ed.)

Mao Zedong

As China emerged from a half century of revolution as the world's most populous nation and launched itself on a path of economic development and social change, Mao Zedong (Wade–Giles: Mao Tse-tung), its principal revolutionary thinker and for many years its unchallenged leader, occupied a critical place in the story of the country's resurgence. To be sure, he did not play a dominant role throughout the whole struggle. In the early years of the Chinese Communist Party, he was a secondary figure, though by no means a negligible one, and even after the 1940s (except perhaps during the Cultural Revolution) the crucial decisions were not his alone. Nevertheless, looking at the whole period from the foundation of the Chinese Communist Party in 1921 to Mao's death in 1976, one can fairly regard Mao Zedong as the principal architect of the new China.

Eastfoto

Mao Zedong, 1966.

Early years. Born on Dec. 26, 1893, in the village of Shao-shan, Hunan Province, Mao was the son of a former poor peasant who had become affluent as a farmer and grain dealer. He grew up in an environment in which education was valued only as training for keeping records and accounts. From the age of eight he attended his native village's primary school, where he acquired a basic knowledge of the Confucian Classics. At 13 he was forced to leave and begin working full time on his family's farm. Rebelling against paternal authority, Mao left his family to study at a higher primary school in a neighbouring county and then at a secondary school in the provincial capital, Ch'ang-sha. There he came in contact with new ideas from the West, as formulated by such political and cultural reformers as Liang Ch'i-ch'ao and the Nationalist revolutionary Sun Yat-sen. Scarcely had he begun studying revolutionary ideas when a real revolution took place before his very eyes. On Oct. 10, 1911, fighting against the Manchu dynasty broke out in Wu-ch'ang, and within two weeks the revolt had spread to Ch'ang-sha.

Enlisting in a unit of the revolutionary army in Hunan, Mao spent six months as a soldier. While he probably had not yet clearly grasped the idea that, as he later put it, "political power grows out of the barrel of a gun," his first brief military experience at least confirmed his boyhood admiration of military leaders and exploits. In primary school days, his heroes had included not only the great warrior-emperors of the Chinese past but Napoleon and George Washington as well.

Enlistment in revolutionary army

The spring of 1912 saw the birth of the new Chinese Republic and the end of Mao's military service. For a year he drifted from one thing to another, trying, in turn, a police school, a law school, and a business school; he studied history in a secondary school and then spent some months reading many of the classic works of the Western liberal tradition in the provincial library. This period of groping, rather than indicating any lack of decision in Mao's character, was a reflection of China's situation at the time. The abolition of the official civil service examination system in 1905 and the piecemeal introduction of Western learning in so-called modern schools had left young people in a state of uncertainty as to what type of training, Chinese or Western, could best prepare them for a career or for service to their country.

Mao eventually was graduated from the First Provincial Normal School in Ch'ang-sha in 1918. While officially an institution of secondary level rather than of higher education, the normal school offered a high standard of instruction in Chinese history, literature, and philosophy as well as in Western ideas. While at the school, Mao also acquired his first experience in political activity by helping to establish several student organizations. The most important of these was the New People's Study Society, founded in the winter of 1917–18, many of whose members were later to join the Communist Party.

From the normal school in Ch'ang-sha, Mao went to Peking University, China's leading intellectual centre. The half year he spent in Peking working as a librarian's assistant was of disproportionate importance in shaping his future career, for it was then that he came under the influence of the two men who were to be the principal figures in the foundation of the Chinese Communist Party: Li Dazhao (Li Ta-chao) and Chen Duxiu (Ch'en Tu-hsiu). Moreover, he found himself at Peking University precisely during the months leading up to the May Fourth Movement of 1919, which was to a considerable extent the fountainhead of all of the changes that were to take place in China in the ensuing half century.

May Fourth Movement

In a limited sense, May Fourth Movement is the name given to the student demonstrations protesting against the Paris Peace Conference's decision to hand over former German concessions in Shantung Province to Japan instead of returning them to China. But the term also evokes a period of rapid political and cultural change, beginning in 1915, that resulted in the Chinese radicals' abandonment of Western liberalism for Marxism-Leninism as the answer to China's problems and the subsequent founding of the Chinese Communist Party in 1921. The shift from the difficult and esoteric classical written language to a far more accessible vehicle of literary expression patterned on colloquial speech also took place during this period. At the same time, a new and very young generation moved to the centre of the political stage. To be sure, the demonstration on May 4 was launched by Chen Duxiu, but the students soon realized that they themselves were the main actors. In an editorial published in July 1919, Mao wrote:

> The world is ours, the nation is ours, society is ours. If we do not speak, who will speak? If we do not act, who will act?

From then onward, his generation never ceased to regard itself as responsible for the nation's fate, and, indeed, its members remained in power, both in Peking and in Taipei, until the 1970s.

During the summer of 1919 Mao Zedong helped to establish in Ch'ang-sha a variety of organizations that brought the students together with the merchants and the workers—but not yet with the peasants—in demonstrations aimed at forcing the government to oppose Japan. His writings at the time are filled with references to the "army of the red flag" throughout the world and to the victory of the Russian Revolution, but it was not until January 1921 that he was finally committed to Marxism as the philosophical basis of the revolution.

Mao and the Chinese Communist Party. In September

1920 he became principal of the Lin Ch'ang-sha primary school, and in October he organized a branch of the Socialist Youth League there. That winter he married Yang Kaihui (Yang K'ai-hui), the daughter of his former ethics teacher. In July 1921 he attended the First Congress of the Chinese Communist Party, together with representatives from the other Communist groups in China and two delegates from the Moscow-based Comintern (Communist International). In 1923, when the young party entered into an alliance with Sun Yat-sen's Kuomintang (Nationalist Party), Mao was one of the first Communists to join the Kuomintang and to work within it. During the first half of 1924, he lived mostly with his wife and two infant sons in Shanghai, where he was a leading member of the Kuomintang Executive Bureau.

In the winter of 1924–25, Mao returned to his native village of Shao-shan for a rest. There, after witnessing demonstrations by peasants stirred into political consciousness by the shooting of several dozen Chinese by foreign police in Shanghai (May and June 1925), Mao suddenly became aware of the revolutionary potential inherent in the peasantry. Although born in a peasant household, he had, in the course of his student years, adopted the Chinese intellectual's traditional view of the workers and peasants as ignorant and dirty. His conversion to Marxism had forced him to revise his estimate of the urban proletariat, but he continued to share Marx's own contempt for the backward and amorphous peasantry. Now he turned back to the rural world of his youth as the source of China's regeneration. Following the example of other Communists working within the Kuomintang who had already begun to organize the peasants, Mao sought to channel the spontaneous protests of the Hunanese peasants into a network of peasant associations.

Peasants and the revolution

The Communists and the Kuomintang. Pursued by the military governor of Hunan, Mao was soon forced to flee his native province once more, and he returned for another year to an urban environment—this time to Canton, the main power base of the Kuomintang. But, though he lived in Canton, Mao still focused his attention on the countryside. He became the acting head of the propaganda department of the Kuomintang—in which capacity he edited its leading organ, the *Political Weekly,* and attended the Second Kuomintang Congress in January 1926—but he also served at the Peasant Movement Training Institute, set up in Canton under the auspices of the Kuomintang, as principal of the sixth training session. Chiang Kai-shek had become the leader of the Kuomintang after the death of Sun Yat-sen in March 1925; and although Chiang still declared his allegiance to the "world revolution" and wished to avail himself of Soviet aid, he was determined to remain master in his own house. He therefore expelled most Communists from responsible posts in the Kuomintang in May 1926. Mao, however, stayed on at the institute until October of that year. Most of the young peasant activists Mao trained were shortly at work strengthening the position of the Communists.

In July 1926, Chiang Kai-shek set out on what became known as the Northern Expedition, aiming to unify the country under his own leadership and to overthrow the conservative government in Peking as well as other warlords. In November Mao once more returned to Hunan; there, in January and February 1927, he investigated the peasant movement and concluded that in a very short time several hundred million peasants in China would "rise like a tornado or tempest—a force so extraordinarily swift and violent that no power, however great, will be able to suppress it." Strictly speaking, this prediction proved to be false. Revolution in the shape of spontaneous action by hundreds of millions of peasants did not sweep across China "in a very short time," or indeed at all. Chiang Kai-shek, who was bent on an alliance with the propertied classes in the cities and in the countryside, turned against the worker and peasant revolution, and in April he massacred the very Shanghai workers who had delivered the city to him. Stalin's strategy for carrying out revolution in alliance with the Kuomintang collapsed, and the Chinese Communist Party was virtually annihilated in the cities and decimated in the countryside. But in a broader and less literal sense, Mao's prophecy was justified. In October 1927 Mao led a few hundred peasants who had survived the autumn harvest uprising in Hunan to a base in the Ching-kang Shan (Ching-kang Mountains), on the Kiangsi–Hunan border, and embarked on a new type of revolutionary warfare in the countryside in which the Red Army, rather than the unarmed masses, would play the central role. But it was only because a large proportion of China's hundreds of millions of peasants sympathized with and supported this effort that Mao Zedong was able in the course of the civil war to encircle the cities from the countryside and thus defeat Chiang Kai-shek and gain control of the country.

Struggle with Chiang Kai-shek

The road to power. Mao Zedong's 22 years in the wilderness can be divided into four phases. The first of these is the initial three years when Mao and Zhu De (Chu Teh), the commander in chief of the army, successfully developed the tactics of guerrilla warfare from base areas in the countryside. These activities, however, were regarded even by their protagonists, and still more by the Central Committee in Shanghai (and by the Comintern in Moscow), as a holding operation until the next upsurge of revolution in the urban centres. In the summer of 1930 the Red Army was ordered by the Central Committee to occupy several major cities in south central China in the hope of sparking a revolution by the workers. When it became evident that persistence in this attempt could only lead to further costly losses, Mao disobeyed orders and abandoned the battle to return to the base in southern Kiangsi. During this year Mao's wife was executed by the Kuomintang and he married He Zizhen (Ho Tzu-chen), with whom he had been living since 1928.

The second phase (the Kiangsi period) centres on the founding of the Chinese Soviet Republic, November 1931, in a portion of Kiangsi Province, with Mao as chairman. Since there was little support for the revolution in the cities, the promise of ultimate victory now seemed to reside in the gradual strengthening and expansion of the base areas. The Soviet regime soon came to control a population of several million; the Red Army, grown to a strength of some 200,000, easily defeated large forces of inferior troops sent against it by Chiang Kai-shek in the first four of the so-called encirclement and annihilation campaigns. But it was unable to stand up against Chiang's own elite units, and in October 1934 the major part of the Red Army, Mao, and his pregnant wife abandoned the base in Kiangsi and set out for the northwest of China, on what is known as the Long March.

The Kiangsi period

There is wide disagreement among specialists as to the extent of Mao's real power, especially in the years 1932–34, and as to which military strategies were his or other party leaders'. The majority view is that, in the last years of the Chinese Soviet Republic, Mao functioned to a considerable extent as a figurehead with little control over policy, especially in military matters. In any case, he achieved de facto leadership over the party (though not the formal title of chairman) only at the Tsun-i Conference of January 1935 during the Long March.

When some 8,000 troops who had survived the perils of the Long March arrived in Shensi Province in northwestern China in the autumn of 1935, events were already moving toward the third phase in Mao's rural odyssey, which was to be characterized by a renewed united front with the Kuomintang against Japan and by the rise of Mao to unchallenged supremacy in the party. This phase is often called the Yen-an period (for the town in Shensi where the Communists were based), although Mao did not move to Yen-an until December 1936. In August 1935 the Comintern at its Seventh Congress in Moscow proclaimed the principle of an anti-Fascist united front, and in May 1936 the Chinese Communists for the first time accepted the prospect that such a united front might include Chiang Kai-shek himself, and not merely dissident elements in the Nationalist camp. The so-called Sian Incident of December 1936, in which Chiang was kidnapped by military leaders from northeastern China who wanted to fight Japan and recover their homelands rather than participate in civil war against the Communists, accelerated the evolution toward unity. By the time the Japanese

Yen-an period

began their attempt to subjugate all of China in July 1937, the terms of a new united front between the Communists and the Kuomintang had been virtually settled, and the formal agreement was announced in September 1937.

In the course of the anti-Japanese war, the Communists broke up a substantial portion of their army into small units and sent them behind the enemy lines to serve as nuclei for guerrilla forces that effectively controlled vast areas of the countryside, stretching between the cities and communication lines occupied by the invader. As a result, they not only expanded their military forces to somewhere between 500,000 and 1,000,000 at the time of the Japanese surrender but also established effective grass-roots political control over a population that may have totaled as many as 90,000,000. It has been argued that the support of the rural population was won purely by appeals to their nationalist feeling in opposition to the Japanese. This certainly was fundamental, but Communist agrarian policies likewise played a part in securing broad support among the peasantry.

Writings, 1936–40

During the years 1936–40, Mao had, for the first time since the 1920s, the leisure to devote himself to reflection and writing. It was then that he first read in translation a certain number of Soviet writings on philosophy and produced his own account of dialectical materialism, of which the best known portions are those entitled "On Practice" and "On Contradiction." More important, Mao produced the major works that synthesized his own experience of revolutionary struggle and his vision of how the revolution should be carried forward in the context of the united front. On military matters there was first *Strategic Problems of China's Revolutionary War,* written in December 1936 to sum up the lessons of the Kiangsi period (and also to justify the correctness of his own military line at the time), and then *On Protracted War* and other writings of 1938 on the tactics of the anti-Japanese war. As to his overall view of the events of these years, Mao adopted an extremely conciliatory attitude toward the Kuomintang in his report entitled *On the New Stage* (October 1938), in which he attributed to it the leading role both in the war against Japan and in the ensuing phase of national reconstruction. By the winter of 1939–40, however, the situation had changed sufficiently so that he could adopt a much firmer line, claiming leadership for the Communists. Internationally, Mao argued, the Chinese revolution was a part of the world proletarian revolution directed against imperialism (whether it be British, German, or Japanese); internally, the country should be ruled by a "joint dictatorship of several parties" belonging to the anti-Japanese united front. For the time being, Mao felt, the aims of the Communist Party coincided with the aims of the Kuomintang, and therefore Communists should not try to rush ahead to socialism and thus disrupt the united front. But neither should they have any doubts about the ultimate need to take power into their own hands in order to move forward to socialism. During this period, in 1939, Mao divorced He Zizhen and married a well-known film actress, Lan P'ing, later called Jiang Qing (Chiang Ch'ing).

The issues of Kuomintang–Communist rivalry for the leadership of the united front are related to the continuing struggle for supremacy within the Chinese Communist Party, for Mao's two chief rivals—Wang Ming, who had just returned from a long stay in Moscow, and Chang Kuo-t'ao, who had at first refused to accept Mao's political and military leadership—were both accused of excessive slavishness toward the Kuomintang. But perhaps even more central in Mao's ultimate emergence as the acknowledged leader of the party was the question of what he had called in October 1938 the "Sinification" of Marxism—its adaptation not only to Chinese conditions but to the mentality and cultural traditions of the Chinese people.

Mao could not claim the firsthand knowledge possessed by many other leading members of the Chinese Communist Party of how Communism worked within the Soviet Union nor the ability to read Marx or Lenin in the original, which some of them enjoyed. He could and did claim, however, to know and understand China. The differences between him and the Soviet-oriented faction in the party came to a head at the time of the so-called Rectification Campaign of 1942–43. This program aimed at giving a basic grounding in Marxist theory and Leninist principles of party organization to the many thousands of new members who had been drawn into the party in the course of the expansion since 1937. But a second and equally important aspect of the movement was the elimination of what Mao called "foreign dogmatism"—in other words, blind imitation of Soviet experience and obedience to Soviet directives.

Mao becomes chairman

In March 1943 Mao achieved for the first time formal supremacy over the party, becoming chairman of the Secretariat and of the Politburo. Shortly thereafter, the Rectification Campaign took, for a time, the form of a harsh purge of elements not sufficiently loyal to Mao. The campaign was run by Kang Sheng (K'ang Sheng), who was later to be one of Mao's key supporters in the Cultural Revolution. Exaggerating considerably this dimension of events, Soviet spokesmen have bitterly denounced the Rectification Campaign as an attempt to purge the Chinese Communist Party of all those elements genuinely imbued with "proletarian internationalism" (*i.e.*, devotion to Moscow). It is therefore not surprising that, as Mao's campaign in the countryside moved into its fourth and last phase—that of civil war with the Kuomintang—Stalin's lack of enthusiasm for a Chinese Communist victory should have become increasingly evident. Looking back at this period in 1962, when the Sino-Soviet conflict had come to a head, Mao declared:

> In 1945, Stalin wanted to prevent China from making revolution, saying that we should not have a civil war and should cooperate with Chiang Kai-shek, otherwise the Chinese nation would perish. But we did not do what he said. The revolution was victorious. After the victory of the revolution he [Stalin] next suspected China of being a Yugoslavia, and that I would become a second Tito.

This account of Stalin's attitude is substantiated by a whole series of public gestures at the time, culminating in the fact that when the People's Liberation Army took Nanking in April 1949, the Soviet ambassador was the only foreign diplomat to accompany the retreating Nationalist government to Canton. Stalin's motives were obviously those described by Mao in the above passage; he did not believe in the capacity of the Chinese Communists to achieve a clear-cut victory, and he thought they would be a nuisance if they did.

Formation of the People's Republic of China. Nevertheless, when the Communists did take power in China, both Mao and Stalin had to make the best of the situation. In December 1949 Mao, now chairman of the People's Republic of China—which he had proclaimed on October 1—traveled to Moscow, where, after two months of arduous negotiations, he succeeded in persuading Stalin to sign a treaty of mutual assistance accompanied by limited economic aid. Before the Chinese had time to profit from the resources made available for economic development, however, they found themselves dragged into the Korean War in support of the Moscow-oriented regime in P'yŏngyang. Only after this baptism of fire did Stalin, according to Mao, begin to have confidence in him and believe he was not first and foremost a Chinese nationalist.

Despite these tensions with Moscow, the policies of the People's Republic of China in its early years were based in very many respects, as Mao later said, on "copying from the Soviets." While Mao and his comrades had experience in guerrilla warfare, in mobilization of the peasants in the countryside, and in political administration at the grass roots, they had no firsthand knowledge of running a state or of large-scale economic development. In such circumstances, the Soviet Union provided the only available model. A five-year plan was therefore drawn up under Soviet guidance; it was put into effect in 1953 and included Soviet technical assistance and a number of complete industrial plants. Yet, within two years, Mao had taken steps that were to lead to the breakdown of the political and ideological alliance with Moscow.

The emergence of Mao's road to socialism. In the spring of 1949, Mao proclaimed that while in the past the Chinese revolution had followed the unorthodox path of "encircling the cities from the countryside," it would

in the future take the orthodox road of the cities leading and guiding the countryside. In harmony with this view, he had agreed in 1950 with Liu Shaoqi (Liu Shao-ch'i) that collectivization would be possible only when China's heavy industry had provided the necessary equipment for mechanization. In a report of July 1955, he reversed this position, arguing that in China the social transformation could run ahead of the technical transformation. Deeply impressed by the achievements of certain cooperatives that claimed to have radically improved their material conditions without any outside assistance, he came to believe in the limitless capacity of the Chinese people, especially of the rural masses, to transform at will both nature and their own social relations when mobilized for revolutionary goals. Those in the leadership who did not share this vision he denounced as "old women with bound feet." He made these criticisms before an ad hoc gathering of provincial and local party secretaries, thus creating a ground swell of enthusiasm for rapid collectivization such that all those in the leadership who had expressed doubts about Mao's ideas were soon presented with a fait accompli. The tendency thus manifested to pursue his own ends outside the collective decision-making processes of the party was to continue and to be accentuated.

Hundred Flowers speech

Even before Nikita S. Khrushchev's secret speech of February 1956 denouncing Stalin's crimes, Mao Zedong and his colleagues had been discussing measures for improving the morale of the intellectuals in order to secure their willing participation in building a new China. At the end of April, Mao proclaimed the policy of "letting a hundred flowers bloom"—that is, the freedom to express many diverse ideas—designed to prevent the development in China of a repressive political climate analogous to that in the Soviet Union under Stalin. In the face of the disorders called forth by de-Stalinization in Poland and Hungary, Mao did not retreat but rather pressed boldly forward with this policy, against the advice of many of his senior colleagues, in the belief that the contradictions that still existed in Chinese society were mainly nonantagonistic. When the resulting "great blooming and contending" got out of hand and called into question the axiom of party rule, Mao savagely turned against the educated elite, which he felt had betrayed his confidence. Henceforth, he would rely primarily on the creativity of the rank and file as the agent of modernization. As for the specialists, if they were not yet sufficiently "red," he would remold them by sending them to work in the countryside.

Great Leap Forward

It was against this background that Mao, during the winter of 1957–58, worked out the policies that were to characterize the Great Leap Forward, formally launched in May 1958. While his economic strategy was by no means so one-sided and simplistic as commonly believed in the 1960s and '70s, and though he still proclaimed industrialization and a "technical revolution" as his goals, Mao displayed continuing anxiety regarding the corrupting influence of the fruits of technical progress and an acute nostalgia for the purity and egalitarianism that had marked the moral and political world of the Ching-kang Shan and Yen-an eras.

Thus it was logical that he should endorse and promote the establishment of "people's communes" as part of the Great Leap strategy. As a result, the peasants, who had been organized into cooperatives in 1955–56 and then into fully socialist collectives in 1956–57, found their world turned upside down once again in 1958. Neither the resources nor the administrative experience necessary to operate such enormous new social units of several thousand households were in fact available, and not surprisingly the consequences of these changes were chaos and economic disaster.

By the winter of 1958–59, Mao himself had come to recognize that some adjustments were necessary, including decentralization of ownership to the constituent elements of the communes and a scaling down of the unrealistically high production targets in both industry and agriculture. He insisted, however, that in broad outline his new Chinese road to socialism, including the concept of the communes and the belief that China, though "poor and blank," could leap ahead of other countries, was basically sound. At the Lushan meeting of the Central Committee in July–August 1959, Peng Dehuai (P'eng Te-huai), the minister of defense, denounced the excesses of the Great Leap and the economic losses they had caused. He was immediately removed from all his party and state posts and remained in detention until his death during the Cultural Revolution. From that time, Mao regarded any criticism of his policies as nothing less than a crime of lèse-majesté, meriting exemplary punishment.

Retreat and counterattack. Though few spoke up at Lushan in support of Peng, a considerable number of the top leaders sympathized with him in private. Almost immediately, in 1960, Mao began building an alternative power base in the People's Liberation Army, which the new defense minister, Lin Biao (Lin Piao), had set out to turn into a "great school of Mao Zedong Thought." At about the same time, Mao began to denounce the emergence, not only in the Soviet Union but also in China itself, of "new bourgeois elements" among the privileged strata of the state and party bureaucracy and the technical and artistic elite. Under these conditions, he concluded, a "protracted, complex, and sometimes even violent class struggle" would continue during the whole socialist stage.

Split with Soviet Union

The open split with the Soviet Union, which had become public and irreparable by 1963—though it can be traced to Mao's resentment at Khrushchev's failure to consult him before launching de-Stalinization—resulted, above all, from the Soviet reaction to the Great Leap policies. Regarding Mao's claims for the communes as ideologically presumptuous, Khrushchev heaped ridicule upon them; he underlined his displeasure by withdrawing Soviet technical assistance in 1960, leaving many large plants unfinished. Khrushchev also tried to put pressure on China in its dealings with Taiwan and India and in other foreign-policy issues. Mao forgot neither the affront to his and China's dignity nor the economic damage.

As for class struggle in China itself, Mao's fear that revisionism might appear there was also heightened by the policies pursued in the early 1960s to deal with the economic consequences of the Great Leap Forward. The disorganization and waste created by the Great Leap, compounded by natural disasters and by the termination of Soviet economic aid, led to widespread famine in which, according to much later official Chinese accounts, millions of people died. The response to this situation by Liu Shaoqi (who had succeeded Mao as chairman of the People's Republic in 1959), Deng Xiaoping (Teng Hsiao-p'ing), and the economic planners was to make use of material incentives and to strengthen the role of individual households in agricultural production. At first Mao agreed reluctantly that such steps were necessary, but during the first half of 1962 he came increasingly to perceive the methods used to promote recovery as implying the repudiation of the whole thrust of the Great Leap strategy. It was as a direct response to this challenge that at the 10th Plenary Session of the Central Committee in September 1962 he issued the call, "Never forget the class struggle!"

During the next three years Mao waged such a struggle, primarily through the Socialist Education Movement in the countryside, and it was over the guidelines for this campaign that the major political battles were fought within the Chinese leadership. At the end of 1964, when Liu Shaoqi refused to accept Mao's demand to direct the main thrust of class struggle against "capitalist roaders" in the party, Mao decided that "Liu had to go."

The Cultural Revolution. The movement that became known as the Great Proletarian Cultural Revolution represented an attempt by Mao to go beyond the party rectification campaigns, of which there had been many since 1942, and to devise a new and more radical method for dealing with what he saw as the bureaucratic degeneration of the party. But it also represented, beyond any doubt or question, a deliberate effort to eliminate those in the leadership who, over the years, had dared to cross him. The victims, from throughout the party hierarchy, suffered more than mere political disgrace. All were publicly humiliated and detained for varying periods, sometimes under very harsh conditions; many were beaten and tortured, and not a few were killed or driven to suicide.

Elimination of Liu

Among the casualties was Liu, who died because he was denied proper medical attention.

The justification for these sacrifices was defined in a key slogan of the time: "Fight selfishness, criticize revisionism." When the Red Guards, who constituted the first shock troops of Mao's enterprise, burst upon the scene in the summer of 1966, with their battle cry, "To rebel is justified!" it seemed for a time that not only the power of the party cadres but also authority in all its forms was being questioned. It soon became evident that Mao, who in 1956 had justified decentralization as a means to building a "strong socialist state," still believed in the need for state power. When the Shanghai leftists Zhang Chunqiao (Chang Ch'un-ch'iao) and Yao Wenyuan (Yao Wen-yüan)—who were later to make up half the Gang of Four—came to see him in February 1967, immediately after setting up the Shanghai Commune, Mao asserted that the demand for the abolition of "heads" (leaders), which had been heard in their city, was "extreme anarchism" and "most reactionary"; in fact, he stated, there would "always be heads." Communes, he added, were "too weak when it came to suppressing counterrevolution" and in any case required party leadership. He therefore ordered them to dissolve theirs and to replace it with a "revolutionary committee."

These committees, based on an alliance of former party cadres, young activists, and representatives of the People's Liberation Army, were to remain in place until two years after Mao's death. At first, they were largely controlled by the army. The Ninth Congress of 1969 initiated the process of rebuilding the party; and the death of Lin Biao diminished, though it by no means eliminated, the army's role. Thereafter, it seemed briefly, in 1971–72, that a compromise, of which Zhou Enlai (Chou En-lai) was the architect, might produce some kind of synthesis between the values of the Cultural Revolution and the pre-1966 political and economic order.

Even before Zhou's death in January 1976, however, this compromise had been overturned. All recognition by Mao of the importance of professional skills was swallowed up in an orgy of political rhetoric, and all things foreign were regarded as counterrevolutionary. Mao's last decade, which had opened with manifestos in favour of the Paris Commune model of mass democracy, closed with paeans of praise to that most implacable of centralizing despots, Shih Huang-ti, the first Ch'in emperor. Mao Zedong died in Peking on Sept. 9, 1976.

Mao's death

Assessment. While the Cultural Revolution was an entirely logical culmination of Mao's last two decades, it was by no means the only possible outcome of his approach to revolution, nor need a judgment of his work as a whole be based primarily on this last phase.

Few would deny Mao Zedong the major share of credit for devising the pattern of struggle based on guerrilla warfare in the countryside that ultimately led to victory in the civil war and thereby to the overthrow of the Kuomintang, the distribution of land to the peasants, and the restoration of China's independence and sovereignty. These achievements must be given a weight commensurate with the degree of injustice prevailing in Chinese society before the revolution and with the humiliation felt by the Chinese people as a result of the dismemberment of their country by the foreign powers. "We have stood up," Mao said in September 1949. These words will not be forgotten.

Mao's record after 1949 is more ambiguous. The official Chinese view, defined in June 1981, is that his leadership was basically correct until the summer of 1957, but from then on it was mixed at best and frequently quite wrong. It cannot be disputed that Mao's two major innovations of his later years, the Great Leap and the Cultural Revolution, were ill-conceived and led to disastrous consequences. His goals of combating bureaucracy, encouraging popular participation, and stressing China's self-reliance were generally laudable, but the methods he used to pursue them, though bold and imaginative, were largely self-defeating.

Looking at Mao's whole career, it is not easy to put a figure on the positive and negative aspects. How does one weigh the good fortune of peasants acquiring land against millions of executions and deaths from civil war? How does one balance the real economic achievements after 1949 against the starvation that came in the wake of the Great Leap Forward or the bloody shambles of the Cultural Revolution? It is, perhaps, possible to accept the official verdict that, despite the "errors of his later years," Mao's merits outweighed his faults, while underscoring the fact that the account is very finely balanced.

BIBLIOGRAPHY. A detailed biography of Mao Zedong is ROSS TERRILL, *Mao* (1980, reissued 1981). Two earlier works that remain useful for the pre-1949 period are JEROME CH'EN, *Mao and the Chinese Revolution* (1965, reissued 1972); and STUART R. SCHRAM, *Mao Tse-tung*, rev. ed. (1967, reprinted 1974). See also Schram's *Mao Zedong, A Preliminary Reassessment* (1983). The most vivid account of Mao's youth is his autobiography as recounted in 1936 in EDGAR SNOW, *Red Star over China*, rev. ed. (1968, reissued 1974). JUI LI, *The Early Revolutionary Activities of Comrade Mao Tse-tung* (1977; originally published in Chinese, 1957), is also an important source.

Regarding Mao Zedong's thought, a substantial collection of source materials for the period before 1949 is available in *Selected Works of Mao Tse-tung*, 5 vol. (1961–77). A variorum in Chinese of the collected writings of Mao to 1949 is *Mao Tse-tung chi*, ed. by MINORU TAKEUCHI, 10 vol. (1970–72), completed by a set of supplements, *Mao Tse-tung chi pu chüan* (1983–85). Mao's talks and letters from 1956 to 1971 are found in STUART R. SCHRAM (ed.), *Mao Tse-tung Unrehearsed* (1974, U.S. title, *Chairman Mao Talks to the People*, 1975). See also JEROME CH'EN (ed.), *Mao Papers* (1970); and MAO TSETUNG, *A Critique of Soviet Economics* (1977), trans. from Chinese by MOSS ROBERTS. On Mao's thought in his early years, see BRANTLY WOMACK, *The Foundation of Mao Zedong's Political Thought, 1917–1935* (1982); FREDERIC WAKEMAN, JR., *History and Will: Philosophical Perspectives of Mao Tse-tung's Thought* (1973, reprinted 1975), which links Mao's ideas of the May Fourth period with those of the Cultural Revolution; and RAYMOND F. WYLIE, *The Emergence of Maoism* (1980). JOHN BRYAN STARR, *Continuing the Revolution: The Political Thought of Mao* (1979), is a comprehensive overview that accepts at face value the Chinese view of the Chairman during his lifetime. Among the older works, ARTHUR A. COHEN, *The Communism of Mao Tse-tung* (1964, reprinted 1971), stresses the Stalinist roots of Mao's thought; and JAMES HSIUNG, *Ideology and Practice: The Evolution of Chinese Communism* (1970), emphasizes the links between Mao's thought and Chinese tradition. See also STUART R. SCHRAM (ed.), *The Political Thought of Mao Tse-tung*, rev. ed. (1969). Finally, a series of useful if somewhat premature appreciations are in DICK WILSON (ed.), *Mao Tse-tung in the Scales of History* (1977).

(S.R.S.)

Mapping and Surveying

Maps and charts are representations of features on the Earth's surface drawn to scale. Globes are maps presented on the surface of a sphere. The definition can be extended to include representations of the Moon, Mars, and other bodies. Star charts and related celestial plats, long used for navigation and astronomical studies, might also be included; they are treated in the article STARS AND STAR CLUSTERS.

In order to imply the elements of accurate relationships, and some formal method of projecting the spherical subject to a map plane, further qualifications might be applied to the definition. The tedious and somewhat abstract statements resulting from attempts to formulate precise definitions of maps and charts are more likely to confuse than to clarify. The words map, chart, and plat are used somewhat interchangeably. The connotations of use, however, are distinctive: charts for navigation purposes (nautical and aeronautical), plats (in a property-boundary sense) for land-line references and ownership, and maps for general reference.

Cartography is the art and science of making maps and charts. As such, it is allied with geography in its concern with the broader aspects of the Earth and its life. In early times cartographic efforts were more artistic than scientific and factual. As man explored and recorded his environment, the quality of his maps and charts improved. These lines of Jonathan Swift were inspired by early maps:

> So geographers, in Afric maps,
> With savage pictures fill their gaps,
> And o'er unhabitable downs
> Place elephants for want of towns.

Topographic maps are graphic representations of natural and man-made features of parts of the Earth's surface plotted to scale. They show the shape of land and record elevations above sea level, lakes, streams and other hydrographic features, and roads and other works of man. In short, they provide a complete inventory of the terrain and important information for all activities involving the use and development of the land. They provide the bases for specialized maps and data for compilation of generalized maps of smaller scale.

Nautical charts are maps of coastal and marine areas, providing information for navigation. They include depth curves or soundings or both; aids to navigation such as buoys, channel markers, and lights; islands, rocks, wrecks, reefs and other hazards; and significant features of the coastal areas, including promontories, church steeples, water towers, and other features helpful in determining positions from offshore.

The terms hydrography and hydrographer date from the mid-16th century; their focus has become restricted to studies of ocean depths and of the directions and intensities of oceanic currents; though at various times they embraced much of the sciences now called hydrology and oceanography. The British East India Company employed hydrographers in the 18th century, and the first hydrographer of the Royal Navy, Alexander Dalrymple (1737–1808), was appointed in 1795. A naval observatory and hydrographic office was established administratively in the United States Navy in 1854. In 1866 a hydrographic office was established by statute, and in 1962 it was renamed the U.S. Naval Oceanographic Office.

Interest in the charting of oceanic areas away from seacoasts developed in the second half of the 19th century, concurrently with the perfection of submarine cables. As knowledge of the configuration of the ocean basins increased, the attention of scientists was drawn to this field of study. A feature of marine science since the 1950s has been increasingly detailed bathymetric (water-depth measurement) surveys of selected portions of the seafloor. Together with collection of associated geophysical data and sampling of sediments, these studies assist in interpreting the geologic history of the ocean-covered portion of the Earth's crust.

Aeronautical charts provide essential data for the pilot and air navigator. They are, in effect, small-scale topographic maps on which current information on aids to navigation have been superimposed. To facilitate rapid recognition and orientation, principal features of the land that would be visible from an aircraft in flight are shown to the exclusion of less important details.

This article is organized into the following sections:

History of cartography

Maps on clay tablets

Centuries before the Christian Era, Babylonians drew maps on clay tablets, of which the oldest specimens found so far have been dated about 2300 BC. This is the earliest positive evidence of graphic representations of parts of the Earth; it may be assumed that mapmaking goes back much further and that it began among nonliterate peoples. It is logical to assume that men very early made efforts to communicate with each other regarding their environment by scratching routes, locations, and hazards on the ground and later on bark and skins.

The earliest maps must have been based on personal experience and familiarity with local features. They doubtless showed routes to neighbouring tribes, where water and other necessities might be found, and the locations of enemies and other dangers. Nomadic life stimulated such efforts by recording ways to cross deserts and mountains, the relative locations of summer and winter pastures, and dependable springs, wells, and other information.

Markings on cave walls that are associated with paintings by primitive man have been identified by some archaeologists as attempts to show the game trails of the animals depicted, though there is no general agreement on this. Similarly, networks of lines scratched on certain bone tablets could possibly represent hunting trails, but there is definitely no conclusive evidence that the tablets are indeed maps.

Many nonliterate peoples, however, are skilled in depicting essential features of their localities and travels. During Capt. Charles Wilkes's exploration of the South Seas in the 1840s, a friendly islander drew a good sketch of the whole Tuamotu Archipelago on the deck of the captain's bridge. In North America the Pawnee Indians were reputed to have used star charts painted on elk skin to guide them on night marches across the plains. Montezuma is said to have given Cortés a map of the whole Mexican Gulf area painted on cloth, while Pedro de Gamboa reported that the Incas used sketch maps and cut some in stone to show relief features. Many specimens of early Eskimo sketch maps on skin, wood, and bone have been found.

Maps in the New World

MAPS AND GEOGRAPHY IN THE ANCIENT WORLD

The earliest specimens thus far discovered that are indisputably portrayals of land features are the Babylonian tablets previously mentioned; certain land drawings found in Egypt and paintings discovered in early tombs are nearly as old. It is quite probable that these two civilizations developed their mapping skills more or less concurrently and in similar directions. Both were vitally concerned with the fertile areas of their river valleys and therefore doubtless made surveys and plats soon after settled communities were established. Later they made plats for the construction of canals, roads, and temples—the equivalent of today's engineering plans.

A tablet unearthed in Iraq shows the Earth as a disk surrounded by water with Babylon as its centre. Aside from this specimen, dating from about 1000 BC, there appear to have been rather few attempts by Babylonians and Egyptians to show the form and extent of the Earth as a whole. Their mapmaking was preoccupied with more practical needs, such as the establishment of boundaries. Not until the time of the Greek philosopher-geographers did speculations and conclusions as to the nature of the Earth begin to take form.

Greek maps and geography. The Greeks were outstanding among peoples of the ancient world for their pursuit and development of geographic knowledge. The shortage of arable land in their own region led to maritime exploration and the development of commerce and colonies. By 600 BC Miletus, on the Aegean, had become a centre of geographic knowledge, as well as of cosmographic speculation.

Hecataeus, a scholar of Miletus, probably produced the first book on geography in about 500 BC. A generation later, Herodotus, from more extensive studies and wider travels, expanded upon it. A historian with geographic leanings, Herodotus recorded, among other things, an early circumnavigation of the African continent by Phoenicians. He also improved on the delineation of the shape and extent of the then-known regions of the world, and he declared the Caspian to be an inland sea, opposing the prevailing view that it was part of the "northern oceans" (Figure 1).

Herodotus

Although Hecataeus regarded the Earth as a flat disk surrounded by ocean, Herodotus and his followers questioned the concept and proposed a number of other possible forms. Indeed, the philosophers and scholars of the time appear to have been preoccupied for a number of years with discussions on the nature and extent of the world. Some modern scholars attribute the first hypothesis of a spherical Earth to Pythagoras (6th century BC) or Parmenides (5th century). The idea gradually developed into a consensus over many years. In any case by the mid-4th century the theory of a spherical Earth was well accepted among Greek scholars, and about 350 BC Aristotle formulated six arguments to prove that the Earth was, in truth, a sphere. From that time forward, the idea of a spherical Earth was generally accepted among geographers and other men of science.

About 300 BC Dicaearchus, a disciple of Aristotle, placed an orientation line on the world map, running east and west through Gibraltar and Rhodes. Eratosthenes, Marinus of Tyre, and Ptolemy successively developed the reference-line principle until a reasonably comprehensive system of parallels and meridians, as well as methods of projecting them, had been achieved.

The greatest figure of the ancient world in the advancement of geography and cartography was Claudius Ptolemaeus (Ptolemy; AD 90–168). An astronomer and mathematician, he spent many years studying at the library in Alexandria, the greatest repository of scientific knowledge at that time. His monumental work, the *Guide to Geography* (*Geōgraphikē hyphēgēsis*), was produced in eight volumes. The first volume discussed basic principles and dealt with map projection and globe construction. The next six volumes carried a list of the names of some 8,000 places and their approximate latitudes and longitudes. Except for a few that were made by observations, the greater number of these locations were determined from older maps, with approximations of distances and directions taken from travelers. They were accurate enough to show relative locations on the very small-scale, rudimentary maps that existed.

The eighth volume was a most important contribution, containing instructions for preparing maps of the world and discussions on mathematical geography and other

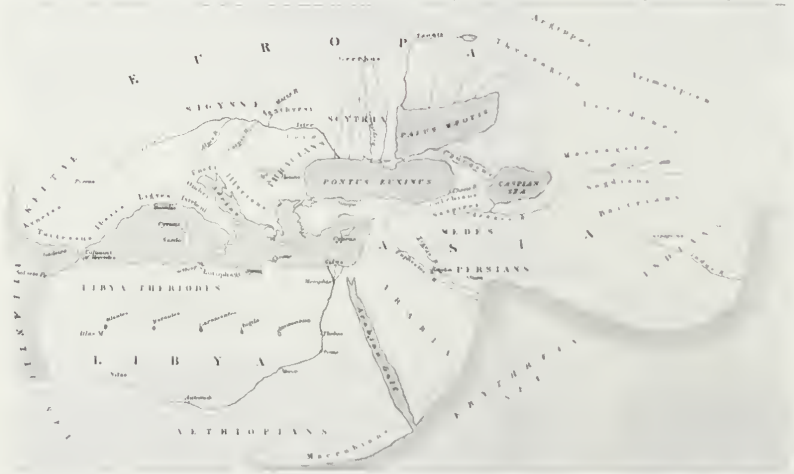

Figure 1: Herodotus' map of the world.

fundamental principles of cartography. Ptolemy's map of the world as it was then known marked the culmination of Greek cartography as well as a compendium of accumulated knowledge of the Earth's features at that time (Figure 2).

The Roman period. Although Ptolemy lived and worked at the time of Rome's greatest influence, he was a Greek and essentially a product of that civilization, as was the great library at Alexandria. His works greatly influenced the development of geography, which he defined in map-making terms: "representation in picture of the whole known world, together with the phenomena contained therein." This had considerable influence in directing scholars toward the specifics of map construction and away from the more abstract and philosophical aspects of geography.

Ptolemy's fundamental error

One fundamental error that had far-reaching effects was attributed to Ptolemy—an underestimation of the size of the Earth. He showed Europe and Asia as extending over half the globe, instead of the 130 degrees of their true extent. Similarly, the span of the Mediterranean ultimately was proved to be 20 degrees less than Ptolemy's estimate. So lasting was Ptolemy's influence that 13 centuries later Christopher Columbus underestimated the distances to Cathay and India partly from a recapitulation of this basic error.

A fundamental difference between the Greek and Roman philosophies was indicated by their maps. The Romans were less interested in mathematical geography and tended toward more practical needs for military campaigns and provincial administration. They reverted to the older concepts of a disk-shaped world for maps of great areas because they met their needs and were easier to read and understand.

The Roman general Marcus Vipsanius Agrippa, prior to Ptolemy's time, constructed a map of the world based on surveys of the then-extensive system of Roman military roads. References to many other Roman maps have been found, but very few actual specimens survived the Dark Ages. It is quite probable that the Peutinger Table, a parchment scroll showing the roads of the Roman world, was originally based on Agrippa's map and subjected to several revisions through medieval times.

The tragic turn of world events during the first few centuries of the Christian Era wrought havoc to the accumulated knowledge and progress of mankind. As with other fields of science and technology, progress in geography and cartography was abruptly curtailed. After Ptolemy's day there even appears to have been a retrogression, as exemplified by the Roman trend away from the mathematical approach to mapping.

Great accumulations of documents and maps were destroyed or lost, and the survival of a large part of Ptolemy's work was probably due to its great prestige and popularity. The only other major work on mapping to survive was Strabo's earlier treatise, albeit with some changes from recopying. Few of the maps and related works of the ancient world have come down to us in their original forms. The tendencies to revise and even recapitulate, when copying manuscripts, are readily understood. Doubtless, the factual content was improved more often than not, but a residual confusion remains when the specimen at hand may be either a true copy of an ancient document or a medieval scholar's version of the subject matter.

THE MIDDLE AGES

Progress in cartography during the early Middle Ages was slight. The medieval mapmaker seems to have been dominated by the church, reflecting in his work the ecclesiastical dogmas and interpretations of Scripture. In fact, during the 6th century Constantine of Antioch created a "Christian topography" depicting the Earth as a flat disk. Thus the Roman map of the world, along with other concepts, continued as authoritative for many centuries. A contemporary Chinese map shows that country occupying most of the world, while the Roman Empire dominates most other maps produced during early Christian times.

Later medieval mapmakers were clearly aware of the

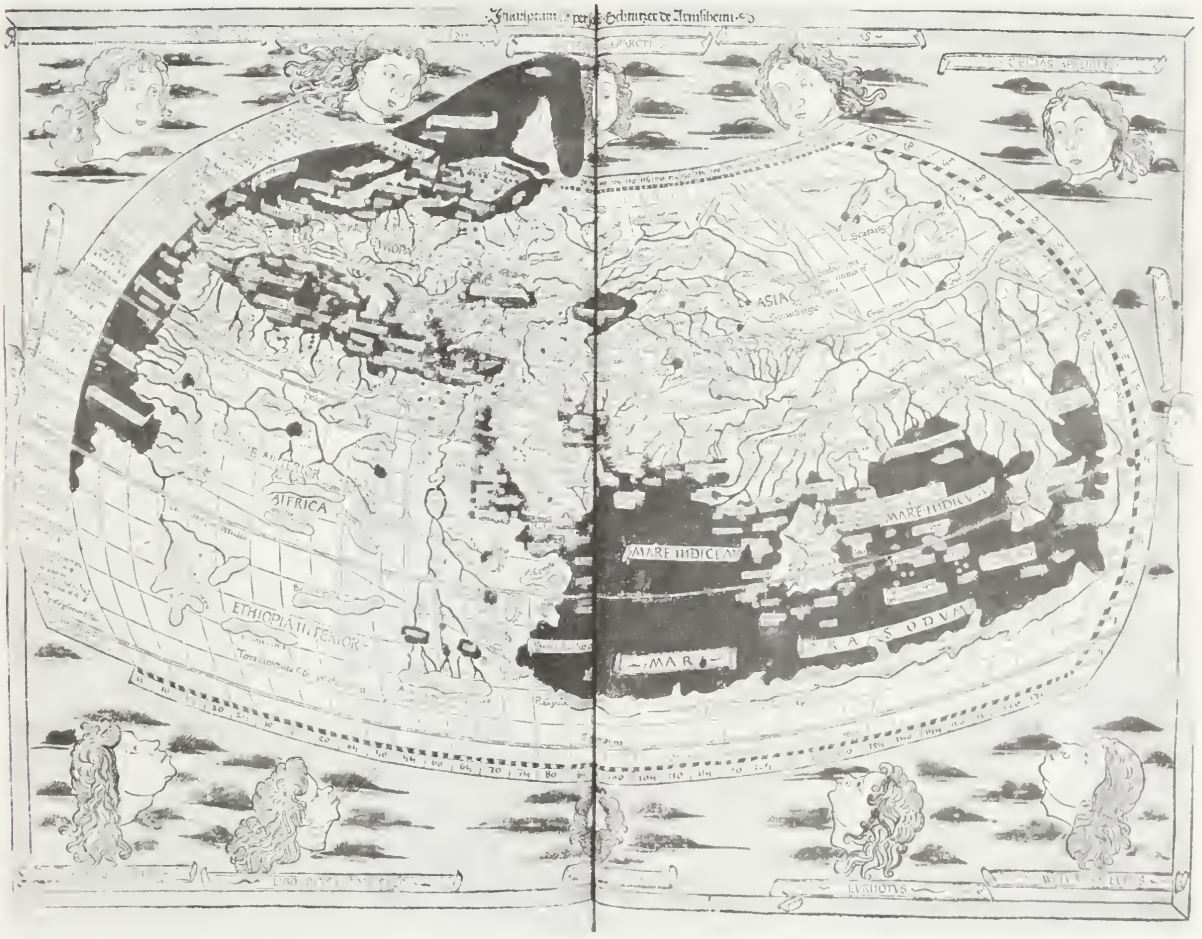

Figure 2: Ptolemy's map of the world, as printed at Ulm, 1482.

Earth's sphericity, but for the most part, maps remained small and schematic, as exemplified by the T and O renderings, so named from the stylized T-form of the major water bodies separating the continents and the O as the circumfluent ocean surrounding the world. The orientation with east at the top of the map was often used, as the word (orientation) suggests.

The earliest navigators coasted from headland to headland; they did not require charts until adoption of the magnetic compass made it possible to proceed directly from one port to another. The earliest record of the magnetic compass in Europe (1187) is followed within a century by the earliest record of a sea chart. This was shown to Louis IX, king of France, on the occasion of his participation in the Eighth Crusade in 1270. The earliest surviving chart dates from within a few years of this event. Found in Pisa and known as the Carta Pisana, it is now in the Bibliothèque Nationale, Paris. Thought to have been made about 1275, it is hand drawn on a sheepskin and depicts the entire Mediterranean Sea. Such charts, often known as portolans named for the portolano or pilot book, listing sailing courses, ports, and anchorages, were much in demand for the increasing trade and shipping. Genoa, Pisa, Venice, Majorca, and Barcelona, among others, cooperated in providing information garnered from their pilots and captains. From repeated revisions, and new surveys by compass, the portolan charts eventually surpassed all preceding maps in accuracy and reliability. The first portolans were hand drawn and very expensive. They were based entirely on magnetic directions and map projections that assumed a degree of longitude equal to a degree of latitude. The assumption did little harm in the Mediterranean but caused serious distortions in maps of higher latitudes. Development of line engraving and the availability, in the 16th century, of large sheets of smooth-surfaced paper facilitated mass production of charts, which soon replaced the manuscript portolans.

Portolans

Many specimens of portolan charts have survived. Though primarily of areas of the Mediterranean and Black Sea, some covered the Atlantic as far as Ireland, and others the western coast of Africa. Their most striking feature is the system of compass roses (Figure 3), showing directions from various points, and lines showing shortest navigational routes.

Another phenomenon of the late Middle Ages was the great enthusiasm generated by the travels of Marco Polo in the 1270s and 1280s. New information about faraway places, and the stimulation of interest in world maps, promoted their sale and circulation. Marco Polo's experiences also kindled the desire for travel and exploration in others and were, perhaps, a harbinger of the great age of discovery and exploration.

During Europe's Dark Ages Islāmic and Chinese cartography made progress. The Arabs translated Ptolemy's treatises and carried on his tradition. Two Islāmic scholars deserve special note. Ibn Haukal wrote a *Book of Ways and Provinces* illustrated with maps, and al-Idrīsī constructed a world map in 1154 for the Christian king Roger of Sicily, showing better information on Asian areas than had been available theretofore. In Baghdad astronomers used the compass long before Europeans, studied the obliquity of the ecliptic, and measured a part of the Earth's meridian. Their sexagesimal (based on 60) system has dominated cartography since, in the concept of a 360-degree circle.

Mapmaking, like so many other aspects of art and science, developed independently in China. The oldest known Chinese map is dated about 1137. Most of the area that is now included in China had been mapped in crude form before the arrival of the Europeans. The Jesuit missionaries of the 16th century found enough information to prepare an atlas, and Chinese maps thereafter were influenced by the West.

THE AGE OF DISCOVERY AND EXPLORATION

Revival of Ptolemy. The fall of Byzantium sent many refugees to Italy, among them scholars who had preserved some of the old Greek manuscripts, including Ptolemy's *Geography*, from destruction. The rediscovery of this great work came at a fortunate time because the recent development of a printing industry capable of handling map reproduction made possible its circulation far beyond the few scholars who otherwise would have enjoyed access to it. This, together with a general reawakening of scholarship and interest in exploration, created a golden era of cartography.

The *Geography* was translated into Latin about 1405. Although it had not been completely lost (the Arabs had preserved portions of it), recovery of the complete work, with maps, greatly stimulated general interest in cartography. About 500 copies of the *Geography* were printed at Bologna in 1477, followed by other editions printed in Germany and Italy. The printing process, in addition to permitting the wide diffusion of geographic knowledge, retained the fidelity of the original works. By 1600, 31 Latin or Italian editions had been printed.

Printing of Ptolemy's *Geography*

Maps of the discoveries. Progress in other technologies

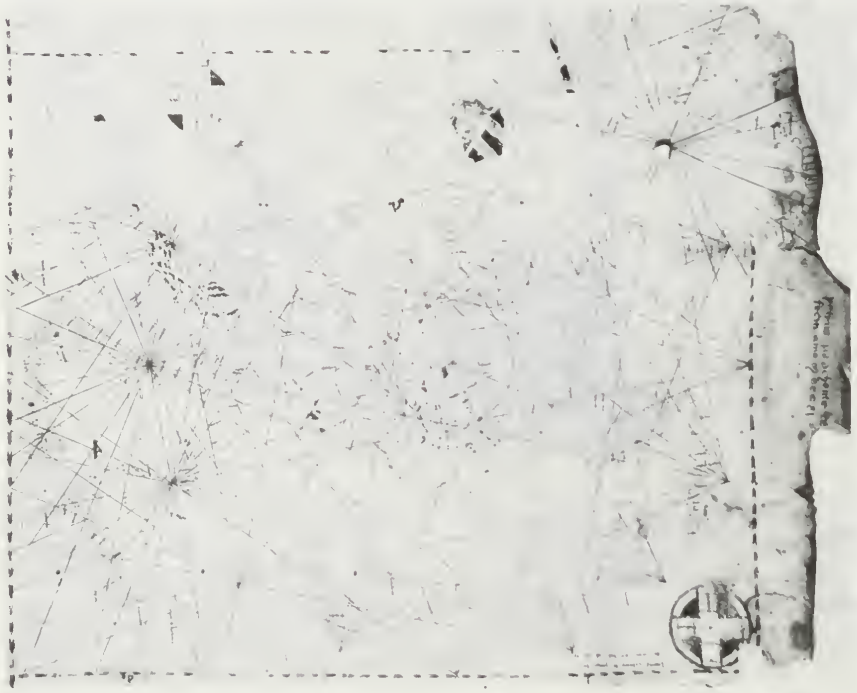

Figure 3: Portolan chart of the eastern Mediterranean area by Petrus Vesconte, 1311.

such as navigation, ship design and construction, instruments for observation and astronomy, and general use of the compass tended continuously to improve existing map information, as well as to encourage further exploration and discovery. Accordingly, geographic knowledge was profoundly increased during the 15th and 16th centuries. The great discoveries of Columbus, da Gama, Vespucci, Cabot, Magellan, and others gradually transformed the world maps of those days. "Modern" maps were added to later editions of Ptolemy. The earliest was a map of northern Europe drawn at Rome in 1427 by Claudius Claussön Swart, a Danish geographer. Cardinal Nicholas Krebs drew the first modern map of Germany, engraved in 1491. Martin Waldseemüller of St. Dié prepared an edition with more than 20 modern maps in 1513. Maps showing new discoveries and information were at last transcending the classical treatises of Ptolemy.

The most important aspect of postmedieval maps was their increasing accuracy, made possible by continuing exploration. Another significant characteristic was a trend toward artistic and colourful rendition, for the maps still had many open areas in which the artist could indulge his imagination. The cartouche, or title block, became more and more elaborate, amounting to a small work of art. Many of the map editions of this age have become collector's items. The first map printings were made from woodcuts. Later they were engraved on copper, a process that made it possible to reproduce much finer lines. The finished plates were inked and wiped, leaving ink in the cut lines. Dampened paper was then pressed on the plate and into the engraved line work, resulting in very fine impressions. The process remained the basis of fine map reproduction until the comparatively recent advent of photolithography.

The *Cosmographiae,* textbooks of geography, astronomy, history, and natural sciences, all illustrated with maps and figures, first appeared in the 16th century. One of the earliest and best known was that of Petrus Apianus in 1524, the popularity of which extended to 15 more editions. That of Sebastian Münster, published in 1544, was larger and remained authoritative and in demand until the end of the century, reflecting the general eagerness of the times for learning, especially geography.

Mercator

The foremost cartographer of the age of discovery was Gerhard Kremer, known as Gerardus Mercator, of Flanders. Well educated and a student of Gemma Frisius of Louvain, a noted cosmographer, he became a maker of globes and maps. His map of Europe, published in 1554, and his development of the projection that bears his name made him famous. The Mercator projection solved an age-old problem of navigators, enabling them to plot bearings as straight lines.

Other well-known and productive cartographers of the Dutch-Flemish school are Abraham Ortelius of Antwerp, who prepared the first modern world atlas in 1570, and Jadocus Hondius. Early Dutch maps were among the best for artistic expression, composition, and rendering. Juan de la Cosa, the owner of Columbus' flagship, *Santa María,* in 1500 produced a map recording Columbus' discoveries, the landfall of Cabral in Brazil, Cabot's voyage to Canada, and da Gama's route to India. The first map showing North and South America clearly separated from Asia was produced in 1507 by Martin Waldseemüller. An immense map, 4½ by 8 feet (1.4 by 2.4 metres), printed in 12 sheets, it is probably the first map on which the name America appeared, indicating that Waldseemüller was impressed by the account written by the Florentine navigator Amerigo Vespucci.

In 1529 Diego Ribero, cosmographer to the king of Spain, made a new chart of the world on which the vast extent of the Pacific was first shown. Survivors of Magellan's circumnavigation of the world had arrived in Seville in 1522, giving Ribero much new information.

The first known terrestrial globe that has survived was made by Martin Behaim at Nürnberg in 1492. Many others were made throughout the 16th century. The principal centres of cartographic activity were Spain, Portugal, Italy, the Rhineland, the Netherlands, and Switzerland. England and France, with their growing maritime and colonial power, were soon to become primary map and chart centres. Capt. John Smith's maps of Virginia and New England, the first to come from the English colonies, were published in London in 1612.

18TH CENTURY TO THE PRESENT

A reformation of cartography that evolved during the 18th century was characterized by scientific trends and more accurate detail. Monsters, lions, and swash lines disappeared and were replaced by more factual content. Soon the only decorative features were in the cartouche and around the borders. The map interiors contained all the increasing information available, often with explanatory notes and attempts to show the respective reliabilities of some portions.

Application of science to mapmaking

Where mapmakers formerly had sought quick, profitable output based on information obtained from other maps and reports of travelers and explorers, the new French cartographers were scientists, often men of rank and independent means. For expensive ventures, such as the triangulation of two degrees of a meridian to determine the Earth's size more accurately, they were subsidized by the king or the French Academy. Similar trends were developing across Europe.

The new cartography was also based on better instruments, the telescope playing an important part in raising the quality of astronomical observations. Surveys of much higher accuracy were now feasible. The development of the chronometer (an accurate timepiece) made the computation of longitude much less laborious than before; much more information on islands and coastal features came to the map and chart makers.

The rise of national surveys. The development in Europe of power-conscious national states, with standing armies, professional officers, and engineers, stimulated an outburst of topographic activity in the 18th century, reinforced to some extent by increasing civil needs for basic data. Many countries of Europe began to undertake the systematic topographic mapping of their territories. Such surveys required facilities and capabilities far beyond the means of private cartographers who had theretofore provided for most map needs. Originally exclusively military, national survey organizations gradually became civilian in character. The Ordnance Survey of Britain, the Institut Géographique National of France, and the Landestopographie of Switzerland are examples.

In other countries, such as the United States, where defense considerations were not paramount, civilian organizations—*e.g.,* the U.S. Geological Survey and the National Ocean Service (originally Survey)—were assigned responsibility for domestic mapping tasks. Only when World War II brought requirements for the mapping of many foreign areas did the U.S. military become involved on a large scale, with the expansion of the Oceanographic Office (Navy), Aeronautical Chart Service (Air Force), and the U.S. Army Topographic command.

Elaborate national surveys were undertaken only in certain countries. The rest of the world remained largely unmapped until World War II. In some instances colonial areas were mapped by military forces, but except for the British Survey of India, such efforts usually provided piecemeal coverage or generalized and sketchy data. Some important national surveys will be outlined briefly.

Surveys of colonies

The work in France was organized by the French Academy, and in 1748 the *Carte géométrique de la France,* comprising 182 sheets, was authorized. Most of the field observations were accomplished by military personnel. The new map of France as a whole, drawn after the new positions had been computed, caused Louis XV to remark that the more accurate data lost more territory than his wars of conquest had gained. Napoleon, an ardent map enthusiast, planned a great survey of Europe on a 1:100,000 scale, which was well under way when he was overthrown.

During the 18th century Great Britain became the foremost maritime power of Europe, and the Admiralty sponsored many developments in charting as well as improvements in navigation facilities. Because of the Admiralty's prestige, other maritime nations accepted its

proposal that the prime meridian for longitude reference should pass through Greenwich. Other achievements in early oceanography were Edmond Halley's magnetic chart, which has been continuously revised from new data. Later similar charts for currents, tides, and prevailing winds were developed.

French progress in mapping stimulated the British to undertake a national survey. The Ordnance Survey was organized in 1791, and the first sheet (Kent), on a scale of one inch to the mile, was published in 1801. By mid-century Ireland had been surveyed at six inches to the mile. In 1858 a Royal Commission approved 1-inch, 6-inch, and 25-inch (1:2500) scales for British mapping. An earlier "first" was John Ogilby's *Britannia,* published in 1675, an atlas of road strip maps plotted by odometer and compass, presaging the modern road map.

A survey of Spain was started in the 18th century. Surveys of several German principalities were combined after unification into the Reichskarte at 1:100,000 scale. A topographic survey of Switzerland was begun in 1832. An Austrian series was started in 1806, from which the Specialkarte, later considered the most detailed maps of Europe, were derived. In China, under the Communist regime, survey and cartography groups have provided coverage of much of the country with a new 1:50,000-scale map series. Japan established an Imperial Land Survey in 1888, and by 1925 topographic coverage of the home islands, at a scale of 1:50,000, was complete.

International Map of the World (IMW). The International Geographical Congress in 1891 proposed that the participating countries collaborate in the production of a 1:1,000,000-scale map of the world. Specifications and format were soon established, but production was slow in the earlier years since it was first necessary to complete basic surveys for the required data, and during and after World War II there was little interest in pursuing the project. The intention to complete the series was reestablished, however, and many countries have returned to the task. By the mid-1980s the project was nearing completion.

World War II and after. World War I, and to a much greater extent World War II, brought great progress in mapping, particularly of the unmapped parts of the Earth; an appraisal by the U.S. Air Force indicated that in 1940 less than 10 percent of the world was mapped in sufficient detail for even the meagre requirements of pilot charts. A major program of aerial photography and reconnaissance mapping, employing what became known as the trimetrogon method, was developed. Vast areas of the unmapped parts of the world were covered during the war years, and the resulting World Aeronautical Charts have provided generalized information for other purposes since that time. Many countries have used the basic data to publish temporary map coverage until their more detailed surveys can be completed.

World Aeronautical Charts

The Cold War atmosphere of the 1940s and '50s promoted a continuation of militarily oriented mapping. Both NATO and Warsaw Pact countries continued to improve their maps; NATO developed common symbols, scales, and formats so that maps could be readily exchangeable between the forces of member countries. Postwar economic development programs, in which maps were needed for planning road, railroad, and reservoir constructions, also stimulated much work. The United Nations provides advisory assistance in mapping to countries wishing it.

Among other collaborations, the Inter-American Geodetic Survey, in which the U.S. Army provides instruction and logistic support for mapping, was organized. Although this cooperation primarily involved Latin-American countries, similar arrangements were made with individual countries in other parts of the world. Cooperation and exchange of data in hydrographic surveys, aeronautical charting, and other fields has continued.

Although some terrain data are available for practically all of the world, the data for many sectors remain sketchy. Surveys of Antarctica by the several countries active there are in progress, but the continent will not be completely mapped for some years. The goal of most countries is to achieve adequate coverage for general development needs. Much remains to be done. Even in countries like the United States that have not yet completed the initial coverage, many of the maps prepared in earlier years are already in need of revision. Thus, even when mapping is completed, requirements for greater detail and revision will continue to make demands upon the funds available.

Aerial photography, which permits accurate and detailed work within feasible cost ranges, has dominated basic mapping in recent years. During World War I aerial photography was used for reconnaissance mapping, and after the war rapid progress was made in optics, cameras, plotting devices, and related equipment. By World War II much of the highly sophisticated equipment now in use had been designed. Electronic distance-measuring devices have made field surveys easier and more accurate, while much improved circle graduation has made theodolites (transits) lighter as well as more precise. Computers and automation, which together have transformed the mapping procedures of yesterday, are described below in the section *Modern mapmaking techniques.*

Mapmaking

ELEMENTS

Map design is a twofold process: (1) the determination of user requirements, with attendant decisions as to map content and detail, and (2) the arrangement of content, involving publication scale, standards of treatment, symbolizations, colours, style, and other factors. To some extent user requirements obviously affect standards of treatment, such as publication scale. Otherwise, the latter elements are largely determined on the basis of efficiency, legibility, aesthetic considerations, and traditional practices.

In earlier productions by individual cartographers or small groups, personal judgments determined the nature of the end product, usually with due respect for conventional standards. Map design for large programs, such as the various national map series of today, is quite formal by comparison. In most countries, the requirements of official as well as private users are carefully studied, in conjunction with costs and related factors, when considering possible changes or additions to the current standards.

Study of user requirements

Requirements of military agencies often have a decisive influence on map design, since it is desirable to avoid the expense of maintaining both civil and military editions of maps. International organizations and committees are additional factors in determining map design. The fact that development of changes in design and content of national map series may become rather involved induces some reluctance to change, as does the fact that map stocks are usually printed in quantities intended to last for 10 or more years. Also, frequent changes in treatments result in extensive overhauls at reprint time, with consequent inconsistencies among the standing editions.

Planning for the production of a national series involves both technical and program considerations. Technical planning involves the choice of a contour interval (the elevation separating adjacent contour lines, or lines of constant elevation), which in turn determines the height of aerial photography and other technical specifications for each project. The sequence of mapping steps, or operational phases, is determined by the overall technical procedures that have been established to achieve the most efficiency.

The program aspects of planning involve fiscal allotments, priorities, schedules, and related matters.

Production controls also play important roles in large programs, where schedules must be balanced with capacities available in the respective phases to avoid backlogs or dormant periods between the mapping steps. Considering that topographic maps may require two years or more to complete, from authorization to final printing, the importance of careful planning is evident. Many factors, including the weather, can converge to cause delays.

Map scales and classifications. Map scale refers to the size of the representation on the map as compared to the size of the object on the ground. The scale generally used in architectural drawings, for example, is ¼ inch to one foot, which means that ¼ of an inch on the drawing equals one foot on the building being drawn. The scales of

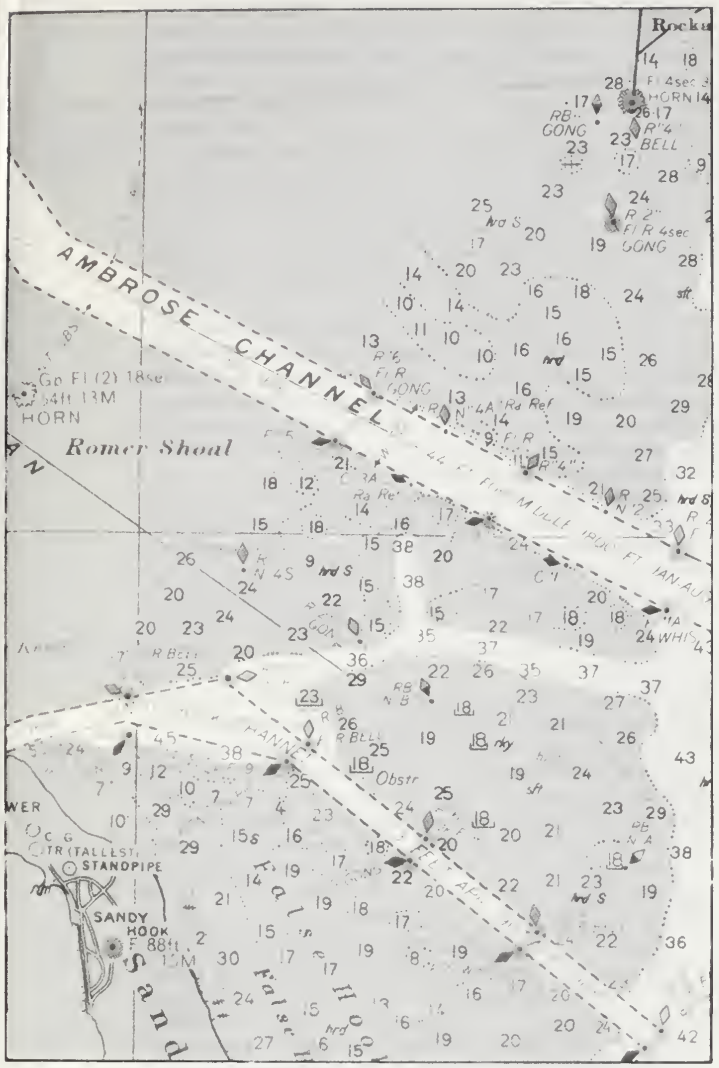

Figure 4: Small section of a large hydrographic chart (U.S. Coast and Geodetic Survey No. 1215) of the approaches to New York harbour. The scale is 1:80,000.

By courtesy of the U.S. Department of Commerce, Environmental Science Services Administration

models of buildings, railroads, and other objects may be one inch to several feet. Maps cover more extensive areas, and it is usually convenient to express the scale by a representative fraction or proportion, as 1/63,360, 1:63,360, or "one-inch-to-one-mile." The scale of a map is smaller than that of another map when its scale denominator is larger: thus, 1:1,000,000 is a smaller scale than 1:100,000. Most maps carry linear, or bar, scales in one or more margins or in the title blocks.

Nautical charts are constructed on widely different scales and can be generally classified as follows: ocean sailing charts are small-scale charts, 1:5,000,000 or smaller, used for planning long voyages or marking the daily progress of a ship. Sailing charts, used for offshore navigation, show a generalized shoreline, only offshore soundings, and are at a scale between 1:600,000 and 1:5,000,000. As an illustration of chart use, a 10-knot ship covers about 29 inches (74 centimetres) at 1:600,000 scale in a day.

General charts, as exemplified by Figure 4, are used for coastwise navigation outside outlying reefs and shoals and are at a scale between 1:100,000 and 1:600,000. Coast charts are intended for use in leaving and entering port or navigating inside outlying reefs or shoals and are at a scale between 1:50,000 and 1:100,000. Harbour charts are for use in harbours and small waterways, with a scale usually larger than 1:50,000.

In rare instances reference may be made to the areal scale of a map, as opposed to the more common linear scale. In such cases the denominator of the fractional reference would be the square of the denominator of the linear scale.

The linear scale may vary within a single map, particularly if the scale is small. Variations in the scale of a map because of the sphericity of the surface it represents may, for practical purposes, be considered as nil. On maps of very large scale, such as 1:24,000, such distortions are negligible (considerably less than variations in the paper from fluctuations of humidity). Precise measurements for engineering purposes are usually restricted to maps of that scale or larger. As maps descend in scale, and distortions inherent to their projection of the spherical surface increase, less accurate measurements of distances may be expected.

Types of classification

Maps may be classified according to scale, content, or derivation. The latter refers to whether a map represents an original survey or has been derived from other maps or source data. Some contain both original and derived elements, usually explained in their footnotes. Producing agencies, technical committees, and international organizations have variously classed maps as large, medium, or small scale. In general, large scale means inch-to-mile and larger, small scale, 1:1,000,000 and smaller, leaving the intermediate field as medium scale. As with most relative terms, these can occasionally lead to confusions but are useful as one practical way to classify maps.

The nature of a map's content, as well as its purpose, provides a primary basis of classification. The terms aeronautical chart, geologic, soil, forest, road, and weather map make obvious their respective contents and purposes. Maps are therefore often classified by the primary purposes they serve. Topographic maps usually form the background for geologic, soil, and similar thematic maps and provide primary elements of the bases upon which many other kinds of maps are compiled.

Map projections. A great variety of map projections has been devised to provide for the various properties that may be desired in maps. In effect, a projection is a systematic method of drawing the Earth's meridians and parallels on a flat surface. Some projections have equal-area properties, while others provide for conformal delineations in which, for small areas, the shape is practically the same as it would be on a globe. Only on a globe can areas and shapes be represented with true fidelity. On flat maps of very large areas, distortions are inevitable. These effects may be minimized by selecting the projection best suited to the purpose of the map to be produced.

Most types of projection can be grouped according to their geometric derivations as cylindrical, conic, or azimuthal (Figure 5). A few cannot be so related or are combinations of these. Terms such as network, graticule, or grid might have been preferable to describe the transposition of meridians and parallels from globe to flat surface, since few systems are actually derived by projection, and most in fact have been formulated by analytic and mathematical processes. The term projection, however, is well established and has some merit in helping the layman to understand the problems and solutions. The theory of trigonometric surveying was disclosed in 1533 by Gemma Frisius, a Flemish mathematician. In 1569 Gerardus Mercator solved the projection problem by producing his famous world map with the meridians vertical and parallels having increased spacing in proportion to the

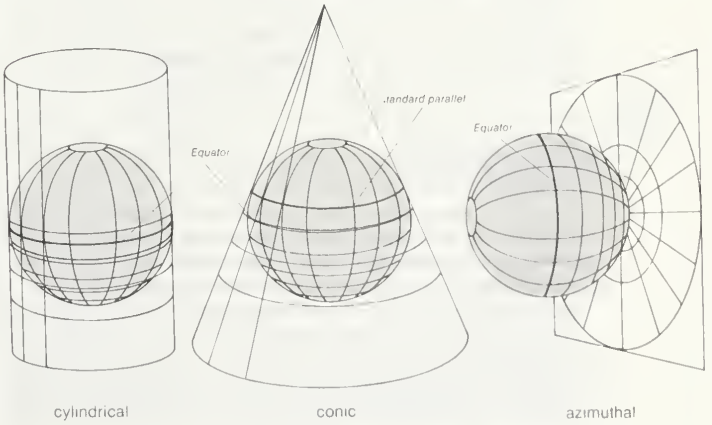

Figure 5: Derivations of basic projections.

secant (a trigonometric function) of the latitude. Edward Wright published mathematical tables (1599) giving the basis of Mercator's projection. Tables for the construction of other commonly used projections have been developed by mapping agencies.

Mercator projection

Cylindrical projections treat the Earth as a cylinder on which parallels are horizontal lines and meridians appear as vertical lines. The familiar Mercator projection is of this class and has many advantages in spite of the great distortions that it causes in the higher latitudes. Compass bearings may be plotted as straight segments on these projections, which have been traditionally used for nautical charts. On cylindrical projections places of similar latitude appear at the same height. Parallels and meridians may, if desired, be omitted from the body of the map and instead simply indexed at the margins, while lettering can be placed horizontally rather than in a curve. Among the variations of cylindrical projections is the Transverse Mercator, in which the cylinder is tangent to the Earth not along the Equator but along a chosen meridian, a treatment that has advantages in drawing maps that are long in the north–south direction.

Virtually all navigational charts are constructed on the ordinary Mercator projection; the only navigational charts not on ordinary Mercator projections are great-circle charts and charts of the polar regions. Great-circle charts, which are maps of large areas, such as the entire Pacific Ocean, are ordinarily on very small scales with gnomonic projection. The navigator uses them to lay out a track between ports perhaps thousands of miles apart and then transfers the latitudes corresponding, for example, to each 5° of longitude, to his ocean sailing chart. He thus arrives at a series of short rhumb-line courses, each of which makes the same angle with all meridians, that closely approximate the shortest distance between the two ports.

Conic projections are derived from a projection of the globe on a cone drawn with the point above either the North or South Pole and tangent to the Earth at some standard or selected parallel. Occasionally the cone is arranged to intersect the Earth at two closely spaced standard parallels. A polyconic projection, used in large-scale map series, treats each band of maps as part of a cone tangent to the globe at the particular latitude.

Azimuthal, or zenithal, projections picture a portion of the Earth as a flattened disk, tangent to the Earth at a specified point, as viewed from a point at the centre of the Earth, on the opposite side of the Earth's surface, or from a point far out in space. If the perspective is from the centre of the Earth, the projection is called gnomonic; if from the far side of the Earth's surface, it is stereographic; if from space, it is called orthographic (Figure 6).

Modified from I. Fisher and O.M. Miller, *World Maps and Globes*

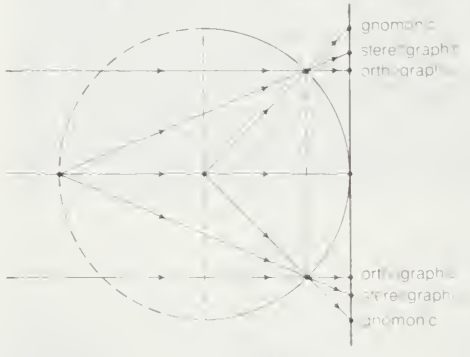

Figure 6: Basis of gnomonic, stereographic, and orthographic projections.

A type of projection often used to show distances and directions from a particular city is the Azimuthal Equidistant. Such measurements are accurate or true only from the selected central point to any other point of interest.

The polar projection is an azimuthal projection drawn to show Arctic and Antarctic areas. It is based on a plane perpendicular to the Earth's axis in contact with the North or South Pole. It is limited to 10 or 15 degrees from the poles. Parallels of latitude are concentric circles, while meridians are radiating straight lines.

Development of reference spheroids. Tables from which map projections of the more familiar kinds may be plotted have been available for some years and have been based on the best determinations of the size and shape of the Earth available at the time of their compilation. The dimensions of Clarke's Spheroid (introduced by the British geodesist Alexander Ross Clarke) of 1866 have been much used in polyconic and other tables. A later determination by Clarke in 1880 reflected the several geodetic surveys that had been conducted during the interim. An International Ellipsoid of Reference was adopted by the Geodetic and Geophysical Union in 1924 for application throughout the world.

Clarke's Spheroid

The development of electronic distance-measuring systems has facilitated geodetic surveys. During the late 20th century, satellite observation and international collaborations have led to an accurate determination of the size and shape of the Earth and to the possibility of adjusting all existing primary geodetic surveys and astronomical observations to a single world datum.

Geographic and plane coordinate systems. The standard geographic coordinate system of the world involves latitudes north or south of the Equator and longitudes east or west of the Prime Reference Meridian of Greenwich. Map and control point references are stated in degrees, minutes, and seconds carried to the number of decimal places commensurate with the accuracy to which locations have been established.

Geodetic surveys, being of extensive areas, must be adjusted for the Earth's curvature, and reductions must be made to mean sea level for scale. The computations are therefore somewhat involved. As a convenience for engineers and surveyors, many countries have established official plane coordinate systems for each province, state, or sector thereof. By this means, all surveys can be "tied" to control points in the system without transposition to geographic coordinates.

In large countries such as the United States, two basic projections are commonly selected to provide systems with minimum distortions for each state or region. For those long in north–south dimension, the Transverse Mercator is generally used, while for those long in east–west direction, the Lambert conformal (intersecting cone) projection is usually employed. In the case of large regions, two or more zones may be established to limit distortions. Positions of geodetic control points have been computed on the plane coordinate systems and have been made available in published lists.

Basic data for compilation. Maps may be compiled from other maps, usually of larger scale, or may be produced from original surveys and photogrammetric compilations. The former are sometimes referred to as derived maps and may include information from various sources, in addition to the maps from which they are principally drawn. Most small-scale series, such as the International Map of the World and World Aeronautical Charts, are compiled from existing information, though new data are occasionally produced to strengthen areas for which little or doubtful information exists. Thus compiled maps may contain fragments of original information while those representing original surveys may include some existing data of higher order, such as details from a city plat.

Road and city map compilations

Road maps, produced by the millions, are compiled from road surveys, topographic maps, and aerial photography. City maps often represent original surveys, made principally to control engineering plans and construction. Some are, however, compiled from enlargements of topographic maps of the area.

Notations regarding the sources from which they were drawn are usually carried on compiled maps. This sometimes includes a reliability diagram showing the areas for which good information was available and those that may be less dependable. Comments regarding certain features or areas, which the editor may deem helpful to the user, may be made in the map itself.

Maps reflecting original surveys, such as a national topographic map series, carry standard marginal information. Date of aerial photography, process and instrumentation employed, notes regarding control and projection, date of

field edit, and other information may be included. References to the availability of adjoining maps and those of other scales or series may also be included. Marginal ticks for intervals of plane coordinate systems, military grids, and other reference features are also shown and appropriately labeled.

Symbolization. Symbols are the graphic language of maps and charts that has evolved through generations of cartographers. The symbols doubtless had their origins as simple pictograms that gradually developed into the conventions now generally used.

Early cartographers recognized that common usages and conventions would minimize confusion and to some extent simplify compilation and engraving. Efforts in this direction were made over the years, but cartographers, being artists of a sort, preferred to vary their styles, and effective standardization was not achieved until comparatively recent times. National agencies in most countries established conventions with due regard to practices in other countries. International Map of the World agreements, NATO conventions, and the efforts of the United Nations and of international technical societies aid standardization.

Symbols may be broadly classed as planimetric or hypsographic or may be grouped according to the colours in which they are conventionally printed. Black is used for names and culture, or works of man; blue for water features, or hydrography; brown for relief, or hypsography; green for vegetation classifications; and red for road classes and special information. There are variations, however, particularly in special-purpose series, such as soil and geologic maps. Symbols will also vary, perforce, because of limitations of space in the smaller scales and the feasibility of drawing some features to true scale on large maps. Legends explain the less obvious symbols on many maps, while explanatory sheets or booklets are available for most standard series, providing general data as well as symbol information. When less familiar symbols are used on maps they are often labeled to prevent misunderstanding. The general located-object symbol, with label, is often used in preference to specific symbols for such objects as windmills and lookout towers for similar reasons.

Planimetric features (those shown in "plan," such as streams, shorelines, and roads) are easier to portray than shapes of land and heights above sea level. Mountains were shown on early maps by sketchy lines simulating profile or perspective appearance as envisioned by the cartographer. Little effort was made at true depiction as this was beyond the scope of available information and existing capabilities. Form lines and hachures, among other devices, were also used in attempting to show the land's shape. Hachures are short lines laid down in a pattern to indicate direction of slope. When it became feasible to map rough terrain in more detail, hachuring developed into an artistic speciality. Some hachured maps are remarkable for their detail and fidelity, but much of their quality depends on the skill of draftsman or engraver. They are little used now, except where relief is incidental.

Hachuring

Contours are by far the most common and satisfactory means of showing relief (see Figure 7). Contours are lines that connect points of equal elevation. The shorelines of lakes and of the sea are contours. Such lines were little used until the mid-19th century, mainly because surveys had not generally been made in sufficient detail for them to be employed successfully. Mean sea level is the datum to which elevations and contour intervals are generally referred. If mean sea level were to rise 20 feet (six metres) the new shoreline would be where the 20-foot contour line is now shown (assuming that all maps on which it is delineated are reasonably accurate).

The quality of contour maps, until recent times, depended largely on the sketching skill of the topographer. In earlier days funds available for topographic mapping were limited, and not much time could be spent in accurate placement. Later, the accurate location of more control points became feasible. An approximate scale of reliability is therefore indicated by the date of a topographic survey, taking into account the respective situations that existed in various countries. Modern surveys, being based on aerial photos and accurate plotting instruments, are generally

Figure 7: Landscape shown in perspective A is represented with the aid of contour lines on map B.
By courtesy of U.S. Geological Survey

better in detail and accuracy than earlier surveys. The personal skill of individual topographers, long a factor in map evaluations, has therefore been substantially eliminated.

Hill shading, or shaded relief, layer or altitude tinting, and special manipulations of contouring are other methods of indicating relief. Hill shading requires considerable artistry, as well as the ability to visualize shapes and interpret contours. For a satisfactory result, background contours are a necessary guide to the artist. Hypsographic tinting is relatively easy, particularly since photomechanical etching and other steps can be used to provide negatives for the respective elevation layers. Difficulty in the reproduction process is sometimes a deterrent to the use of treatments involving the manipulation of contours.

In the past, three-dimensional maps were laboriously constructed for studies in military tactics and for many other purposes. They were costly to produce, as contour layers had to be cut and assembled, filled with plaster and painted, after which streams, roads, etc., had to be drawn on the surface. Lettering then was applied, and models of large structures, such as buildings and bridges, were added. In view of the time and cost involved in such productions, they were sparingly used until recent years when better production methods and materials became available. During and after World War I a process was developed and improved whereby an aluminum sheet was "raised" by tapping along the contours copied on its surface. When the contours selected for tapping were completed, the sheet became, in effect, a mold for shaping plastic sheets to its convolutions. The map was printed on plastic sheets prior to the thermal process of shaping them to the mold. Sets of relief maps were soon produced in this manner for use in schools, military briefings, and many other activities.

During and after World War II the production of plastic relief maps was greatly expanded, while the processes and equipment were further improved and refined. Most significant among these developments was a pantograph-router, which cuts a model from plaster or other suitable material as the selected contours are followed by the operator on a topographic map. This eliminated the distortions inherent in shaping metal sheets by the tapping process. Selected topographic maps are now published in limited relief editions for military instruction, special displays, and general classroom instruction.

Pantograph-router

Most relief maps are exaggerated severalfold in the vertical scale. The Earth is remarkably smooth, when viewed in actual scale, and many significant features would hardly be distinguishable on a map without some vertical exaggeration. Mt. Everest, for example, is actually only one-seventh of 1 percent of the Earth's radius in height, or only one-third of an inch (about eight millimetres) at a scale of 1:1,000,000. For this reason relief is usually shown at five, or even 10, times actual scale, depending upon

the nature of the area represented. This exaggerated relief scale is always explained in the map legend.

Nomenclature. All possible places and features are identified and labeled to maximize the usefulness of the map. Some names must be omitted, particularly from maps of smaller scales, to avoid overcrowding and poor legibility. The editor must decide which names may be eliminated, while arranging placements so that a maximum number may be accommodated.

Geographic names are the most important, and sometimes the most troublesome, part of the map nomenclature as a whole. Research on existing maps and related documents for a given area may reveal different names for the same features, variations in spelling, or ambiguous applications of names. The field engineer often finds that local usage is confused and sometimes controversial. Various types of official organizations have been established to study the problems submitted and decide the forms and applications that are to be used in government maps and documents. This function is exercised in the United States by the Board on Geographic Names and in the United Kingdom by the Permanent Committee on Geographical Names; worldwide these activities are coordinated by the United Nations Conference on the Standardization of Geographical Names.

Toponymics

The science of place-names, or toponymics, has become a significant specialty since World War II, and efforts have been made to establish uniform usages and standards of transliteration throughout the world. Renewed interest in completing the remaining sheets of the International Map of the World, collaborations resulting from military alliances, and efforts of committees of international scientific societies and the United Nations have contributed to these efforts.

At the local levels, however, there are different kinds of problems. The larger scales of most basic topographic map series permit the naming of quite minor hilltops, ridges, streams, and branches, for which designations can be obtained locally. In sparsely settled country few names in actual use may be obtained for minor features, while in other areas inquiries may reveal inconsistencies and confusions in both spelling and application of local names. In some areas, for example, local residents may tend to refer to small streams by the name of the present occupant of the headwater area. The occupants of opposite sides of a mountain sometimes refer to it by different names. In coastal areas the waterman and landsman may use different references for the same features.

A prime opportunity for resolving these problems is presented when a topographic map of an area is prepared for publication. By extensive inquiry and documentation and research of local records and deeds, the appropriate form and application of nearly all names can be determined. Publication and distribution of the map as an official document may then tend to solidify local usage and eliminate the confusions that previously existed.

Lettering

Lettering is selected by the map editor in styles and sizes appropriate to the respective features and the relative importance of each. For topographic maps and most others that follow conventional practice, four basic styles of lettering are used in the Western world. The Roman style is generally used for place-names, political divisions, titles, and related nomenclature. Italic is used for lakes, streams, and other water features. Gothic styles are usually applied to land features such as mountains, ridges, and valleys. Man-made works such as highways, railroads, and canals are usually labeled in slope Gothic capitals, but other distinctive styles are often used for these, together with descriptive notes.

The relative importance of map features is reflected in the different sizes of lettering selected to label them. The most prominent places and features are usually shown in capitals, while lesser ones are labeled with lowercase lettering. In the labeling of cities, however, uppercase lettering is often reserved for state or province capitals. County seats are also labeled in this manner on topographic maps of the United States. For other towns, where lowercase lettering is in order, the sizes selected reflect their relative importance. The use of hand lettering has been abandoned in favour of words and figures printed by type or by a photographic process onto transparent material that is "floated" onto the compilation and anchored by an adhesive wax backing in the proper place. Compass roses and graphic scales are added in the same manner.

TYPES AND USES OF MAPS AND CHARTS

World status of mapping and basic data. Before World War I only a few countries, such as Great Britain, France, and Germany, had detailed maps covering their whole national areas. Now many countries have completed coverage of their territories, while others have carried out small-scale coverage and are beginning engineering surveys in selected areas.

It has been demonstrated that the full potential of map usage in a country, state, or province is not realized until some time after complete coverage has become available. When a modern, detailed map replaces an earlier issue, annual distribution can increase dramatically.

Topographic maps provide the basic data for many other kinds as well as working bases for thematic maps showing geology, soils, and vegetation types. The progress of such mapping in the various parts of the world is therefore a primary indicator of the status of cartography in general. A United Nations survey of the status of world mapping is taken periodically. Inquiries are made to the mapping organizations of all member countries regarding the extent of their respective map coverage, publication scales, and related data.

About a third of the world's land area is now covered by maps at scales of 1:75,000 and larger. Some of such coverage is culturally obsolescent or of low structural quality. An additional third is covered by medium-scale topographic maps; *i.e.*, up to 1:125,000 (about two miles to the inch). Some of this is inferior coverage at medium scales, lacking in geodetic control and topographic detail. This is the case with much of China, but most of the mapping is quite adequate for purposes of reconnaissance and as source information for smaller scale maps.

This provides a general indication of the relative reliability of data contained in such world series maps as the 1:1,000,000-scale aeronautical charts and International Maps of the World. Areas of doubtful information are left blank or are drawn with broken lines. In spite of this dearth of reliable data, most of the IMW sheets have been compiled, and most of the aeronautical pilotage charts have been published, to provide navigation continuity across water areas as well as over unmapped parts of the world.

In some areas, however, large-scale topographic maps are not required. Australia, for example, has large-scale coverage only of its populated coastal areas in the east; in the Outback areas 1:250,000-scale maps are considered adequate for most needs, and a program for their production is well under way. Likewise, large areas of tundra, as in Siberia, deserts in many parts of the world, and other sparsely populated areas may be adequately served with medium- or small-scale coverage until specific development sites require engineering maps.

Nautical chart coverage of the world leaves much to be desired. Good progress has been made, however, on areas bordering the continents and islands. The Arctic, Antarctic, South Pacific, and South Atlantic oceans are the most deficient in good coverage. The Defense Mapping Agency, through agreement with the British Admiralty and other chart-producing countries, maintains worldwide coverage that is constantly updated. The National Ocean Service (originally Survey) maintains charts of U.S. coastal waters. The International Hydrographic Organization (until 1967 Bureau), based at Monaco, attempts to stimulate cooperation in improvement of hydrographic data in general. This organization's General Bathymetric Chart of the Oceans shows existing knowledge and is revised from time to time as new data are accumulated.

International Hydrographic Organization

Coverage of reliable aeronautical charts parallels the availability of topographic maps that provide the essential terrain and cultural data. For this purpose, good 1:250,000-scale maps contain sufficient information for clearance safety and position identification.

Until recently the progress of geodetic triangulation, the basic survey method, was more or less limited to areas either covered by good topographic maps or scheduled for mapping. Preparations for cadastral surveys, where land partition problems abound, have occasionally led to early geodetic programs. Coastal and other surveys also require good basic control to be fully effective; however, it is again the developed and heavily populated areas that are encompassed with the best geodetic surveys. Electronic distance-measuring systems accelerated the progress of geodetic surveys during the 1960s and extended continental schemes over many ocean areas. International cooperation on satellite triangulation is now in progress, with the prospect that existing triangulation of the continents may soon be tied together and adjusted into a single world datum. The Inter-American Geodetic Survey has made progress in the Americas.

In addition to other applications, aerial photographs provide a useful supplement to topographic maps. Indeed, where maps are not available, aerial photographs invariably serve as map substitutes in spite of inherent distortions and lack of elevation data. Most of the world is covered by aerial photography.

During World War II the U.S. Air Force photographed vast areas of the world, providing reconnaissance maps that were used as bases for aeronautical charts. Much of this information now forms the basis for small-scale map coverage in still remote areas. The system of photography and mapping became known as the trimetrogon process.

Trimetrogon process

In it, three wide-angle cameras are used to photograph the terrain from horizon to horizon across the line of flight from an elevation of 20,000 feet (6,100 metres). Detail is usually discernible and plottable for several miles on each side of the line of flight, and occasional points, required for photo-triangulation, can be identified farther out. With higher flight capabilities, wider-angle cameras, and lenses of fine resolution, the progress of aerial photography has been accelerated. Films have been much improved for fineness of emulsion grain and scale stability. Satellite photography and high-altitude flights with super-wide-angle cameras are now under way in the remaining areas of the world. Infrared and colour film developments have greatly improved photo-interpretation capabilities, providing much better delineations for coastal charts, geologic maps, timber and soil classifications, and other thematic mapping.

Types of maps and charts available. Although the range of maps and charts now available in many countries is so extensive that a complete listing is impractical, any list of the principal types would have to include aeronautical (worldwide and national), congressional or political districts, population distribution, geologic (various scales), highways (national and secondary political units), historical, hydrographic (coastal areas, inland waters, foreign waters), national forests, forest types, public land survey plats, soil, and topographic (national and foreign).

The National Atlas of the United States of America, published by the Geological Survey in 1970, contains contributions from all of that country's mapping agencies. Summaries are provided of all thematic and economic data of interest. The atlas also indicates where more detailed information or large-scale specialized maps may be obtained. Many countries have centres where detailed information on existing map series and related data may be obtained. In the United States this service is performed by the Map Information Office of the U.S. Geological Survey, which publishes and distributes indexes of each state showing map coverage and ordering information. Summary data on geodetic control and aerial photography are also maintained.

Principal Mapping Agencies of Selected Countries

Australia	Division of National Mapping, Department of National Development
Brazil	Serviço Geográfico do Exercito
Canada	Survey, Mapping, and Remote Sensing Sector, Department of Energy, Mines and Resources
Chile	Instituto Geográfico Militar
France	Institut Géographique National
Germany	Institut für Angewandte Geodäsie
Iran	Army Geographic Department and National Geographic Centre
United Kingdom	Ordnance Survey
United States	United States Geological Survey
Russia	Glavnoye Upravlenieye Geodezii i Kartografii

The situation is less complex in other countries where mapping activities are concentrated in one or two organizations—*e.g.*, Ordnance Survey in Great Britain and Institut Géographique National in France. The main agencies can advise where maps produced by others may be obtained. Technical societies maintain large map reference libraries and are prime sources of information, as are the map sections of national libraries and museums.

Government and other mapping agencies. The following are the primary agencies of selected countries having advanced mapping programs.

Military agencies play large roles in the mapping activities of many countries. Frequently, a small cadre of officers administers the mapping facilities, while most of the production personnel are civilian. Many countries, such as Iran and the United States, have both civilian and military organizations that collaborate in developing their respective programs and in performing the actual mapping.

Most countries have private and commercial organizations that produce maps. The widely distributed road maps noted earlier are printed by a few large producers who, in cooperation with others, compile the maps. Very large-scale maps—for example, for road construction and other engineering works—are produced under contract by a number of mapping companies. Some local highway departments have their own photogrammetric units to provide or supplement such productions. City surveys and maps for real-estate developments, tax records, power lines, and so on are largely produced by commercial organizations.

The work of geographic societies

Large societies, such as the American Geographical Society, the National Geographic Society, and the Royal Geographical Society, play important roles in addition to being centres of reference as noted above. The National Geographic Society produces popular small-scale maps of the various regions of the world. The American Geographical Society has compiled many maps, most notably a 1:1,000,000 coverage of Hispanic America on standards similar to those of the International Map of the World. Technical societies, such as the American Congress on Surveying and Mapping, the American Society of Photogrammetry, the American Society of Civil Engineers, and others, lend their support to mapping programs and activities. They issue technical papers and hold frequent meetings where new processes and instrumentation are discussed and displayed. *The Manual of Photogrammetry* and *Journal*, produced by the American Society of Photogrammetry, *Photogrammetria*, published by the International Society for Photogrammetry and Remote Sensing, and *Surveying and Mapping*, published by the American Congress on Surveying and Mapping, are prime examples of important contributions that societies make to the overall progress of mapping.

International organizations. Many societies and other types of organizations are now engaged in activities associated with maps and mapping. In general, they encourage cooperation through meetings and articles in their journals; some are more directly concerned with the dissemination of information on the progress of particular kinds of mapping and charting. Standardizations of map treatments and conventional signs as well as the promotion of progress in technical processes are further objectives of such groups.

The United Nations Office of Cartography plays an important role in all of the activities noted above. It maintains records of progress on the International Map of the World and performs related services formerly handled by the Central Bureau of the IMW. Technical assistance in the development of mapping facilities and programs is provided on request. Occasional regional meetings are arranged for groups of countries having similar problems, while the journal *World Cartography* publishes related papers.

The Inter-American Geodetic Survey is a special unit of the U.S. Corps of Engineers organized to forward the completion of geodetic surveys and mapping in the Americas. Through technical training and assistance with programs, geodetic surveys in Central and South America have been greatly advanced in recent years. Training in photogrammetry is offered and has promoted the establishment of mapping facilities and programs in many of the collaborating countries.

The Pan American Institute of Geography and History has sponsored regular meetings and consultations on cartography, much in the manner of scientific societies. The consultations are held in different countries each year.

The International Hydrographic Bureau was founded in 1921 in Monaco, where it has been headquartered through the years. It serves as a clearinghouse for information related to hydrography and charting and maintains a General Bathymetric Chart of the World, which is revised periodically to include data furnished by the maritime nations participating in their programs and conferences. Other organizations that promote progress in the various aspects of mapping and charting are the International Association of Geodesy, the International Cartographic Association, the International Civil Aviation Organization, the International Geographical Union, the International Federation of Surveyors, the International Society for Photogrammetry and Remote Sensing, and the International Union of Geodesy and Geophysics.

General Bathymetric Chart of the World

MODERN MAPMAKING TECHNIQUES

Compilation from existing materials. The preparation of derived maps—*i.e.*, maps that are compiled from other maps or existing data—involves the search for, and evaluation of, all extant data pertaining to the subject area. Depending on the nature of the map to be compiled, thoroughgoing research includes boundary references, historical records, name derivations, and other materials. Selection of the most authentic items, on the frequent occasions when some ambiguities are detected, requires careful study and references to related materials. The sources finally selected may require some adjustment or compromise in order to fit properly with adjacent data. When it becomes evident that some sources are of questionable reliability, the cartographer explains this in the margin of his compilation. Sometimes this is placed in the body of the map where the doubtful features or delineations are located.

When selected materials have been assembled they are reduced to a common scale and copied on the compilation base, often in differentiating colours for the respective features. Reductions to a common scale are usually made by photography but may be made by projection and traced directly on the drawing. Minor adjustments may have to be made during compilation even though the source materials are of good quality. In particular, the need to make appropriate generalizations, omitting some details in smaller scale maps, requires much study and judgment.

Except for the new methods of preparing final colour-separation plates by scribing (described below), rather than by drafting or copperplate engraving, compilation processes have changed little over the years. Automatic-focusing projectors and better illumination have made the tracing of selected data at compilation scale easier. Better and more extensive facilities for photoreduction and copying, improved light tables, and a wider choice of drafting materials and instruments have served to facilitate compilation. The basic chores of research, selection of best data, and adjustment of these into the compilation, however, remain essentially the same.

The preparation of small-scale maps from large ones is sometimes simpler than the process just described, which pertains to compilation from a miscellany of differing sources. The relatively straightforward preparation of 1:62,500-scale maps from those of the 1:24,000-scale series, for example, may require little more than photoreduction and colour-separation drafting, or scribing. Even in this case some generalizations, as well as omission of a few of the least important details, are in order. To avoid the considerable expense involved in such scale conversions, straight photoreduction of colour-separation plates appears to be a promising procedure.

Straight photoreduction

Larger reductions from one map series to another—1:62,500 to 1:250,000 for instance—are more of a problem, since the need for generalization is greater and the omission of many details is involved. The considerable differences in road and other symbol sizes also create displacement problems.

The component maps are reduced, and the negatives are cut and assembled into a mosaic on a clear sheet of plastic, the master negative of which provides guide copy for the several colour-separation plates required, which are then completed for reproduction. More often, however, it is necessary to make an intermediate compilation rather than burden the draftsman with too many adjustments to be made while following copy on the colour-separation plates. The intermediate scale for initial reduction of the component maps provides better legibility than direct photography to reproduction scale. This negative mosaic is copied on a metal-mounted drafting board. A compiler then inks the whole map, usually in three or more contrasting colours. He also draws roads and other symbols at the intermediate size, so that they will reduce to proper dimensions at reproduction scale, and makes the necessary displacement adjustments. Minor features and terrain details to be omitted on the new map are not inked in. The drawing is now ready for photoreduction to the final colour-separation plates, providing much better copy for the draftsman or engraver than direct reduction in one step would have produced.

Most smaller scale map series are prepared from large-scale maps as described above. In earlier days original reconnaissance surveys were made at small scales such as 1:192,000 for publication at 1:250,000. Ideally, the small-scale series of maps should be compiled progressively from those of larger scale and greater detail. Most countries, however, started their mapping programs with relatively small-scale reconnaissance surveys because of economic considerations. Later, affluence and technical competence permitted mapping at larger scales with better accuracy.

Geologic, soil, and other thematic maps usually have a topographic base from which woodland tints and road classification printings have been omitted. Such a map, therefore, has a topographic background printed in subdued colours on which the geologic or soil patterns are overprinted in prominent colours. Small-scale thematic maps showing weather patterns, vegetation types, and a large amount of economic and other information are of similar origin. Backgrounds are drawn from appropriate outline maps of provinces, countries, or regions of the world, while overlaying subject matters are compiled from specialized sources of information.

Use of topographic backgrounds

The generalization of detail is a problem that frequently confronts the cartographer in original mapping and in reducing the scale of existing maps. There are two principal reasons for taking such liberties (or topographic license in the case of the original mapping). The primary purpose is to avoid overcrowding and the resulting poor legibility. In addition, the degree of generalization or detail should be as consistent as possible throughout the map. Generalizations in some parts and excessive detail in others confuse the user and make the map's reliability suspect. Effective generalization requires good judgment based on seasoned knowledge and experience.

In approaching such problems as the thousands of islets in the Stockholm archipelago or the thousands of small lakes in the Alaskan tundra areas, when the map scale will accommodate only a small number, the cartographer may decide to draw the features in groupings that reflect the patterns shown in the large-scale source maps or aerial photos. This is difficult and at best presents the nature of the respective areas rather than a literal portrayal. There is also the possibility that the source maps may already have been generalized by some omissions to accommodate to their own scales. Another device is to note, in appropriate text or marginal references, that many minor lakes or islets are omitted because of scale. Such areas may also be symbolized and explained. The "pattern" representation noted above is actually a form of symbolization.

Intricate coastlines are also extremely difficult to generalize consistently. Here again, the purpose is to omit minor details while retaining the main features and their distinguishing characteristics. These and many equally perplexing questions arise in preparing maps of very small scale from any source. The problems of equalization of detail are also present in such cases. The topographer of earlier days had the equalization problem between areas close at hand and those viewed distantly. In addition, the topographer had to deal with terrain on the far sides of obscuring features.

Photogrammetrists—that is, persons who compile original maps from aerial photos—have similar problems when, for example, one side of a ridge is seen in more detail than the opposite side. Indeed, in steep terrain, parts of the far sides of some mountains are not seen at all. Appropriate steps must be taken in such cases to avoid differing renditions on opposite sides of the mountain. This may be accomplished by adding, in field completion of the manuscript map, the segments not seen by the photogrammetrist; or additional aerial photography, patterned to cover the obscured sectors, may be requested.

Map production from original surveys. The instrumentation, procedures, and standards involved in making original surveys have improved remarkably in recent years. Geodetic, topographic, hydrographic, and cadastral surveys have been facilitated by the application of electronics and computer sciences. At the same time, superior optics and more refined instruments, in general, have enhanced the precision of observations and accuracies of the end products.

The improved quality of surveys has increased the reliability of maps and charts based on them. In turn, the greater output of basic data has accelerated the production of maps and charts, while parallel improvements in processing steps have increased the volume and improved the final product. In a sense the production of maps from original surveys parallels the process steps after a compilation is made from derived sources. This phase is sometimes referred to as map finishing and involves editing, colour separation, and printing. In original surveys for topographic maps and nautical charts, however, the end products are provided for in all the process steps leading to the completed basic manuscript. The manuscript scale is, for example, selected to accommodate the plotting instruments involved as well as the final rendering for printing. In early years it was usual to choose a manuscript scale somewhat larger than that prescribed for publication. This was to allow for some generalization and line refinement in the final reduction. Thus, maps to be published at 1:62,500 scale were plotted in the field at 1:48,000 or thereabouts. With modern photogrammetric instruments, plotting is usually at reproduction scale.

Maps are not directly derived from geodetic surveys, and only land-line plats are produced from cadastral surveys. Accordingly, the primary original map and chart productions are those from topographic and hydrographic surveys. The surveys are somewhat similar as the nautical chart is, in effect, a topographic map of the coast with generalized offshore topography interpolated from depth soundings.

Use of electronic devices in ship surveys

A variety of electronic devices are used to determine a survey ship's precise location while taking soundings, which are also made with electronic equipment. Both hydrographic and topographic surveys now employ aerial photography and precise plotting instruments to develop the base map. In order to simplify the description of modern mapmaking techniques, the process developed for topographic mapping will be described below, with comments where procedures for nautical charts differ significantly. Both processes start by expanding upon the basic control previously established from geodetic surveys.

Surveying, in which the facts are discovered and recorded, must precede mapping, in which the facts are presented in graphic form. Surveying involves (1) global positioning, in which the area to be mapped is located on the Earth's surface, usually by fixing a number of points in the area by astronomical observations or, after the techniques became available, by satellite or radar procedures; (2) establishing the framework, in which these points, and commonly many others connected by some combination of distance and angle measurements, are integrated into an accurately defined structure—like the steel framework of a modern building—on which the detail survey is based; and (3) making the detail survey, which establishes by less accurate (and therefore cheaper) methods the relative positions and shapes of the features being mapped. Constant reference to the framework prevents the errors in the detail survey from accumulating and growing unacceptably large.

Mapping also consists of three steps: (1) fair drawing, in which the accurate but not publishable surveyor's plot is redrawn by a skilled cartographer with uniform lines and lettering and, if a multicoloured map is being produced, is separated into several drawings, one for each colour; (2) reproduction, in which a negative is prepared from each of the fair-drawn originals and special colouring (to represent areas of vegetation, for example) is added; and (3) printing, in which a printing plate is made from each negative, the plates are mounted on a press, proofs (a few trial copies) are made to facilitate correction of errors and blemishes, and the final maps are produced.

Final steps in map preparation. After all the features visible in the aerial photographs have been mapped, the manuscripts are contact printed on coated plastic sheets for review by the field engineer. He examines the whole map, adding such details as houses, trails, and fences that were not visible or were overlooked by the photogrammetrist. Political lines such as state, county, and township limits are located, as are geographic and other names in local use. Roads are classified, and woodland outlines are checked.

Contour accuracy is tested if the operator has noted areas that may be weak. The determination of names involves extensive local inquiry, as do political lines, and both may require research of records.

In remote areas it is more efficient to combine the above activities with supplemental control survey to avoid the extra field phase. Then the photos must be carefully examined and annotated for the compiler, while buildings must be encircled or pricked. Roads are classified and political lines located in the usual manner and noted on the photos or overlays.

Handling corrections

Field corrections are applied to the original manuscripts. They must be scribed (engraved) on the originals so that guide copies can be prepared by contact printing for final colour-separation scribing. At this time all factual detail is carefully checked. Editing may proceed, to conserve time, while the colour-separation scribing is in progress. The editor reviews all names, boundaries, and related data, comparing them to information thereon that may be available from other sources. The editor's function is to see that the map conforms to standard conventions and is clear, legible, and free of errors.

Controversial names, or those found to be in confused or ambiguous spelling or usage, are documented and referred to an appropriate official body. The designation of type styles and sizes as well as placement of lettering is another function of the map editor.

Because modern topographic maps are printed in several colours, separate plates must be prepared for each. Some of the earliest maps were printed from woodcuts, usually in a single colour. Various hand processes were developed through the years, culminating in the fine rendering of copperplate engraving, which dominated the map production industry for many years. The process became obsolete, however, with increased production demands and the development of efficient printing presses. After World War II engraving on glass, and later on coated plastic sheets, was developed to a point that recovered the fineness of copper engraving. These methods of engraving have become firmly established in map production throughout the world.

Scribing process

In the negative engraving or scribing process, guide copy is printed on several sheets of plastic coated with an opaque paint, usually yellow. The scriber follows copy on the respective plates by engraving through the coating. Because arc light can pass only through the engraving scratches, the completed engravings are, in effect, negatives from which

the press plates are made. The finest lines (0.002 inch, or 0.05 millimetre, wide), such as intermediate contours, are engraved freehand. Heavier lines, such as index contours, engraved at 0.007 inch, may require a small tripod to assure that the scriber is perfectly vertical. Gravers for double-lined roads, others for buildings, and templates, or patterns, for a variety of symbols are used. Woodland and similar boundaries and shorelines are contact printed and etched on their respective coated sheets, and the areas of the woodland or water are then peeled off, leaving open windows for their respective features. If portions of scrub, orchard, or vineyard are contained in the "woodland" plate, negative sections for these are stripped into their respective locations. Press plates are then processed from the negatives.

A combined-colour proof is then made by successively printing the several completed negatives on a sensitized white plastic sheet that serves for the final checking and review of all aspects of the map. After all corrections have been made, the negatives are ready for the reproduction process.

Nearly all maps are now printed by rotary offset presses, using flexible aluminum-alloy printing plates. The system uses surface plates (very slightly raised or recessed) as opposed to the letterpress and intaglio processes, which involve greater image heights and depths respectively. In the printing sequence, ink goes from the plate to a rubber blanket to the paper. Thus, the printing plate is positive, or right-reading, as is the printed map. The negatives from which the printing plates are prepared are accordingly wrong-reading. This is the process for so-called surface plates. To retain fineness of line on very long runs (10,000 or more impressions), some map printers prefer "etched" plates, prepared from film positives. Both may be considered essentially surface plates, however, since the respective raise or recess is quite small.

Presses are of many varieties and makes. Huge multicolour types are used in large plants, printing several colours at a time. In effect, a multicolour press is several presses built into one. Each unit has three cylinders for plate, rubber blanket, and paper as well as rollers for water and ink. Presses with automatic feed may produce as many as 6,000 impressions per hour, while hand-fed types are limited to about 2,500 per hour.

Nautical charts are commonly large, 28 by 40 inches (70 centimetres by 1 metre) being an internationally accepted maximum size. In order that a navigator may work with them efficiently, charts must be kept with a minimum of folding in drawers in a large chart table in a compartment of the ship having ready access to the navigating bridge, known as the chart room or chart house. Such structures are not possible in small craft, which therefore require charts of a more convenient size. With the recognition that there are many more small boats in the world, particularly recreational craft, than there are ships and that they are navigated primarily by piloting rather than by celestial or electronic means, many hydrographic offices have given attention to the production of special chart series in a small format for yacht navigators.

SC charts

A typical series is that produced by the U.S. Coast and Geodetic Survey with the designation SC (for small craft). Such charts are only 15 inches (38 centimetres) in the vertical dimension and thus need to be folded only in the vertical direction. Printed on both sides of the sheet, they are oriented along the most probable route rather than by parallels and meridians. Several are stapled together into a stiff cardboard folder for protection. Along with the ordinary chart information, they contain a year of tide tables and information on small-craft facilities in the area. New editions are produced annually.

Practical uses of charts impose some constraints on the selection of colour. Red, for example, would logically be chosen as the color in which to print warnings of navigational hazards. But navigators, who must work at night, prefer to retain the darkness adaptation of their eyes by viewing their charts under red light. Under such illumination, red, orange, and buff are invisible. Hence these colours have been superseded by magenta, purple, and gray.

Charts are working instruments, and, since ships often voyage far from where replacement charts are readily obtainable, hydrographic offices give attention to the quality of the paper on which charts are printed. A ship's reckoning is kept in pencil and erased after each voyage. Thus, printing stock that permits multiple erasures is chosen. In view of the environment where charts are used, another quality commonly sought is high wet strength.

Automation in mapping. During the past few decades, there was much interest in the automation of mapping processes, and considerable progress was made in this area. Achievements in the fields of electronics, high-speed digital computers, and related technologies provided a favourable period for such progress. In Great Britain, development of a set of procedures utilizing automatic elements, known as the Oxford System, was begun.

Some success was also achieved in the difficult area of automatic plotting. Instruments now available can automatically scan a stereo model and generate approximate profiles from which contours may be interpolated. Some steps, however, must be closely monitored or else performed completely by the operator. Contouring interpolated from a profile scan is inferior to an operator's delineation. This contouring meets some less exacting requirements for elevation data, and refinements in the system are improving its precision. The need for human intervention when automatic devices get "lost" is not a decisive drawback, as one operator can monitor several machines. The reduction of tedious and repetitive steps for stereo-operators offers a significant advancement.

Coordinatographs with high repeat accuracies facilitate the automatic plotting of control points and projection intersections. Line work can also be drafted or scribed automatically by the same process, but the respective features must first be coded to provide the necessary input tapes. Automatic colour scanning and discrimination is operational but has not become widely used; it is still necessary for an operator to trace the various features on the manuscript to code them. Obviously, little is to be gained by automatic scribing until the input can be provided automatically. Coded line work can be displayed on a cathode-ray tube and corrected with a light pen, but it is much simpler to check and correct the manuscript or finished drawing. Systems of automatic type placement at present offer only marginal advantages over conventional methods. In short, automation has made substantial advances but has not become fully operational in a practical sense.

An aspect of automation that is developing rapidly concerns graphic data acquisition, storage, and retrieval. Data banks are being accumulated by specialized users of topographic information, often to produce thematic maps showing soil types, vegetation classifications, and a variety of other information. Such data banks are usually organized in two parts: one for line work, such as boundaries, and the other for descriptive information or classifications. Assuming that the necessary inputs have been made to the data bank, special plats can be generated speedily. Examples of such graphics include profiles showing elevations along a selected radio propagation path and cross sections for earthwork on roads and other construction.

(C.F.F./Ed.)

Surveying

Surveying is a means of relatively large-scale, accurate measurement of Earth surfaces. It includes the determination of the measurement data, the reduction and interpretation of the data to usable form, and, conversely, the establishment of relative position and size according to given measurement requirements. Thus, surveying has two similar but opposite functions: (1) the determination of existing relative horizontal and vertical position, such as that used for the process of mapping, and (2) the establishment of marks to control construction or to indicate land boundaries.

Surveying has been an essential element in the development of the human environment for so many centuries that its importance is often forgotten. It is an imperative

requirement in the planning and execution of nearly every form of construction. Surveying was essential at the dawn of history, and some of the most significant scientific discoveries could never have been implemented were it not for the contribution of surveying. Its principal modern uses are in the fields of transportation, building, apportionment of land, and communications.

Except for minor details of technique and the use of one or two minor hand-held instruments, surveying is much the same throughout the world. The methods are a reflection of the instruments, manufactured chiefly in Switzerland, Austria, Great Britain, the United States, Japan, and Germany. Instruments made in Japan are similar to those made in the West.

HISTORY

Egyptian and other ancient devices

It is quite probable that surveying had its origin in ancient Egypt. The Great Pyramid of Khufu at Giza was built *c.* 2700 BC, 755 feet long and 480 feet high. Its nearly perfect squareness and north–south orientation affirm the ancient Egyptians' command of surveying.

Evidence of some form of boundary surveying as early as 1400 BC has been found in the fertile valleys and plains of the Tigris, Euphrates, and Nile rivers. Clay tablets of the Sumerians show records of land measurement and plans of cities and nearby agricultural areas. Boundary stones marking land plots have been preserved. There is a representation of land measurement on the wall of a tomb at Thebes (1400 BC) showing head and rear chainmen measuring a grainfield with what appears to be a rope with knots or marks at uniform intervals. Other persons are shown. Two are of high estate, according to their clothing, probably a land overseer and an inspector of boundary stones.

There is some evidence that, in addition to a marked cord, wooden rods were used by the Egyptians for distance measurement. They had the groma, which was used to establish right angles. It was made of a horizontal wooden cross pivoted at the middle and supported from above (Figure 8, left). From the end of each of the four arms hung a plumb bob. By sighting along each pair of plumb bob cords in turn, the right angle could be established. The device could be adjusted to a precise right angle by observing the same angle after turning the device approximately 90°. By shifting one of the cords to take up half the error, a perfect right angle would result.

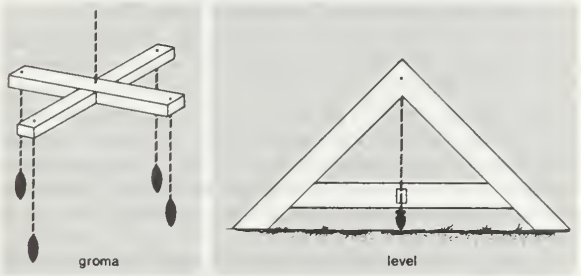

Figure 8: Egyptian surveying instruments.

There is no record of any angle-measuring instruments of that time, but there was a level (Figure 8, right) consisting of a vertical wooden A-frame with a plumb bob supported at the peak of the A so that its cord hung past an indicator, or index, on the horizontal bar. The index could be properly placed by standing the device on two supports at approximately the same elevation, marking the position of the cord, reversing the A, and making a similar mark. Halfway between the two marks would be the correct place for the index. Thus, with their simple devices, the ancient Egyptians were able to measure land areas, replace property corners lost when the Nile covered the markers with silt during floods, and build the huge pyramids to exact dimensions.

Greek log line and Chinese lodestone

The Greeks used a form of log line for recording the distances run from point to point along the coast while making their slow voyages from the Indus to the Persian Gulf about 325 BC. The magnetic compass was brought to the West by Arab traders in the 12th century AD. The astrolabe was introduced by the Greeks in the 2nd century BC. An instrument for measuring the altitudes of stars, or their angle of elevation above the horizon, took the form of a graduated arc suspended from a hand-held cord. A pivoted pointer that moved over the graduations was pointed at the star. The instrument was not used for nautical surveying for several centuries, remaining a scientific aid only.

During their occupation of Egypt, the Romans acquired Egyptian surveying instruments, which they improved slightly and to which they added the water level and the plane table. About 15 BC the Roman architect and engineer Vitruvius mounted a large wheel of known circumference in a small frame, in much the same fashion as the wheel is mounted on a wheelbarrow; when it was pushed along the ground by hand it automatically dropped a pebble into a container at each revolution, giving a measure of the distance traveled. It was, in effect, the first odometer.

The water level consisted of either a trough or a tube turned upward at the ends and filled with water. At each end there was a sight made of crossed horizontal and vertical slits. When these were lined up just above the water level, the sights determined a level line accurate enough to establish the grades of the Roman aqueducts. In laying out their great road system, the Romans are said to have used the plane table. It consists of a drawing board mounted on a tripod or other stable support and of a straightedge—usually with sights for accurate aim (the alidade) to the objects to be mapped—along which lines are drawn. It was the first device capable of recording or establishing angles. Later adaptations of the plane table had magnetic compasses attached.

Plane tables were in use in Europe in the 16th century, and the principle of graphic triangulation and intersection was practiced by surveyors. In 1615 Willebrord Snell, a Dutch mathematician, measured an arc of meridian by instrumental triangulation.

In 1620 the English mathematician Edmund Gunter developed a surveying chain, which was superseded only by the steel tape in the beginning of the 20th century.

The study of astronomy resulted in the development of angle-reading devices that were based on arcs of large radii, making such instruments too large for field use. With the publication of logarithmic tables in 1620, portable angle-measuring instruments came into use. They were called topographic instruments, or theodolites. They included pivoted arms for sighting and could be used for measuring both horizontal and vertical angles. Magnetic compasses may have been included on some.

17th-century portable instruments

The vernier, an auxiliary scale permitting more accurate readings (1631), the micrometer microscope (1638), telescopic sights (1669), and spirit levels (about 1700) were all incorporated in theodolites by about 1720. Stadia hairs were first applied by James Watt in 1771. The development of the circle-dividing engine about 1775, a device for dividing a circle into degrees with great accuracy, brought one of the greatest advances in surveying methods, as it enabled angle measurements to be made with portable instruments far more accurately than had previously been possible.

By the late 18th century modern surveying can be said to have begun. One of the most notable early feats of surveyors was the measurement in the 1790s of the meridian from Barcelona, Spain, to Dunkirk, Fr., by two French engineers, Jean Delambre and Pierre Méchain, to establish the basic unit for the metric system of measurement.

The start of modern surveying

Many improvements and refinements have been incorporated in all the basic surveying instruments. These have resulted in increased accuracy and speed of operations and have opened up possibilities for improved methods in the field. In addition to modification of existing instruments, two revolutionary mapping and surveying changes have been introduced: photogrammetry, or mapping from aerial photographs (about 1920), and electronic distance measurement, including the adoption of the laser for this purpose as well as for alignment (in the 1960s). Important technological developments benefiting surveying in the 1970s included the use of satellites as reference points for geodetic surveys and electronic computers to speed the processing and recording of survey data. (J.Ly./Ed.)

MODERN SURVEYING

Basic control surveys. Geodetic surveys involve such extensive areas that allowance must be made for the Earth's curvature. Baseline measurements for classical triangulation (the basic survey method that consists of accurately measuring a base line and computing other locations by angle measurement) are therefore reduced to sea-level length to start computations, and corrections are made for spherical excess in the angular determinations. Geodetic operations are classified into four "orders," according to accuracy, the first-order surveys having the smallest permissible error. Primary triangulation is performed under rigid specifications to assure first-order accuracy.

Efforts are now under way to extend and tie together existing continental networks by satellite triangulation so as to facilitate the adjustment of all major geodetic surveys into a single world datum and determine the size and shape of the Earth spheroid with much greater accuracy than heretofore obtained. At the same time, current national networks will be strengthened, while the remaining amount of work to be done may be somewhat reduced. Satellite triangulation became operational in the United States in 1963 with observations by Rebound A-13, launched that year, and some prior work using the Echo 1 and Echo 2 passive reflecting satellites. The first satellite specifically designed for geodetic work, Pageos 1, was launched in 1966.

A first requirement for topographic mapping of a given area is an adequate pattern of horizontal and vertical control points, and an initial step is the assembly of all such existing information. This consists of descriptions of points for which positions (in terms of latitude and longitude) and elevations above mean sea level have been determined. They are occasionally located at some distance from the immediate project, in which case it is necessary to expand from the existing work. This is usually done on second- or third-order standards, depending upon the length of circuits involved.

The accuracy of survey measurements can be improved almost indefinitely but only at increased cost. Accordingly, control surveys are used; these consist of a comparatively few accurate measurements that cover the area of the project and from which short, less accurate measurements are made to the objects to be located. The simplest form of horizontal control is the traverse, which consists of a series of marked stations connected by measured courses and the measured angles between them. When such a series of distances and angles returns to its point of beginning or begins and ends at stations of superior (more accurate) control, it can be checked and the small errors of measurement adjusted for mathematical consistency. By assuming or measuring a direction of one of the courses and rectangular coordinates of one of the stations, the rectangular coordinates of all the stations can be computed.

A system of triangles usually affords superior horizontal control. All of the angles and at least one side (the base) of the triangulation system are measured. Though several arrangements can be used, one of the best is the quadrangle or a chain of quadrangles. Each quadrangle, with its four sides and two diagonals, provides eight angles that are measured. To be geometrically consistent, the angles must satisfy three so-called angle equations and one side equation. That is to say the three angles of each triangle, which add to 180°, must be of such sizes that computation through any set of adjacent triangles within the quadrangles will give the same values for any side. Ideally, the quadrangles should be parallelograms. If the system is connected with previously determined stations, the new system must fit the established measurements.

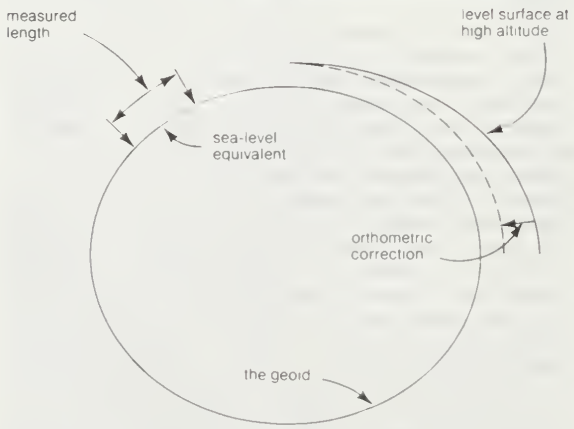

Figure 9: Measured length corrected to its sea-level equivalent (on the geoid) and the orthometric correction for high altitude measurements (see text).

When the survey encompasses an area large enough for the Earth's curvature to be a factor, an imaginary mathematical representation of the Earth must be employed as a reference surface. A level surface at mean sea level is considered to represent the Earth's size and shape, and this is called the geoid. Because of gravity anomalies, the geoid is irregular; however, it is very nearly the surface generated by an ellipse rotating on its minor axis—*i.e.*, an ellipsoid slightly flattened at the ends, or oblate. Such a figure is called a spheroid. Several have been computed by various authorities; the one usually used as a reference surface by English-speaking nations is (Alexander Ross) Clarke's Spheroid of 1866. This oblate spheroid has a polar diameter about 27 miles (43 kilometres) less than its diameter at the Equator.

The imaginary Earth, or geoid

Because the directions of gravity converge toward the geoid, a length of the Earth's surface measured above the geoid must be reduced to its sea-level equivalent—*i.e.*, to that of the geoid (see Figure 9). These lengths are assumed to be the distances, measured on the spheroid, between the extended lines of gravity down to the spheroid from the ends of the measured lengths on the actual surface of the Earth. The positions of the survey stations on the Earth's surface are given in spherical coordinates.

Bench marks, or marked points on the Earth's surface, connected by precise leveling constitute the vertical controls of surveying. The elevations of bench marks are given in terms of their heights above a selected level surface called a datum. In large-level surveys the usual datum is the geoid. The elevation taken as zero for the reference datum is the height of mean sea level determined by a series of observations at various points along the seashore taken continuously for a period of 19 years or more. Because mean sea level is not quite the same as the geoid, probably because of ocean currents, in adjusting the level grid for the United States and Canada all heights determined for mean sea level have been held at zero elevation.

Because the level surfaces, determined by leveling, are distorted slightly in the area toward the Earth's poles (because of the reduction in centrifugal force and the increase in the force of gravity at higher latitudes), the distances between the surfaces and the geoid do not exactly represent the surfaces' heights from the geoid. To correct these distortions, orthometric corrections (see Figure 9) must be applied to long lines of levels at high altitudes that have a north–south trend.

Trigonometric leveling often is necessary where accurate elevations are not available or when the elevations of inaccessible points must be determined. From two points of known position and elevation, the horizontal position of the unknown point is found by triangulation, and the vertical angles from the known points are measured. The differences in elevation from each of the known points to the unknown point can be computed trigonometrically.

The National Ocean Service in recent years has hoped to increase the density of horizontal control to the extent that no location in the United States will be farther than 50 miles (80 kilometres) from a primary point, and advances anticipated in analytic phototriangulation suggest that the envisioned density of control may soon suffice insofar as topographic mapping is concerned. Existing densities of control in Britain and much of western Europe are already adequate for mapping and cadastral surveys.

Global positioning. The techniques used to establish the positions of reference points within an area to be mapped are similar to those used in navigation. In surveying, however, greater accuracy is required, and this is attainable because the observer and the instrument are stationary on

the ground instead of in a ship or aircraft that is not only moving but also subject to accelerations, which make it impossible to use a spirit level for accurate measurements of star elevations.

The technique of locating oneself by observations of celestial objects is rapidly going out of date. In practicing it, the surveyor uses a theodolite with a spirit level to measure accurately the elevations of the Sun at different times of the day or of several known stars in different directions. Each observation defines a line on the Earth's surface on which the observer must be located; several such lines give a fix, the accuracy of which is indicated by how closely these lines meet in a point. For longitude it is necessary also to record the Greenwich Mean Time of each observation. This has been obtained since 1884 by using an accurate chronometer that is checked at least once a day against time signals transmitted telegraphically over land lines and submarine cables or broadcast by radio.

A more recent procedure for global positioning relies on satellites, whose locations at any instant are known precisely because they are being continuously observed from a series of stations in all parts of the world. The coordinates of these stations were established by very large scale triangulation based on a combination of radar observations of distances and measurements of the directions of special balloons or flashing satellites, obtained by photographing them at known instants of time against the background of the fixed stars.

The principal method of using satellites for accurate positioning is based on an application of the Doppler effect. A radio signal is transmitted at a steady frequency by the satellite, but a stationary observer detects a higher frequency as the satellite approaches and a lower one as it recedes. The speed of the frequency drop depends on the distance of the observer from the satellite's track, so a determination of this speed provides a measure of that distance. At the instant of the satellite's closest approach, the observed frequency is the same as that transmitted, so at that time the observer must be located somewhere along the line at right angles to the satellite's track. Since this track over the Earth's surface is accurately known at all times, these data define the observer's position.

Establishing the framework. Most surveying frameworks are erected by measuring the angles and the lengths of the sides of a chain of triangles connecting the points fixed by global positioning. The locations of ground features are then determined in relation to these triangles by less accurate and therefore cheaper methods. Establishing the framework ensures that detail surveys conducted at different times or by different surveyors fit together without overlaps or gaps.

For centuries the corners of these triangles have been located on hilltops, each visible from at least two others, at which the angles between the lines joining them are measured; this process is called triangulation. The lengths of one or two of these lines, called bases, are measured with great care; all the other lengths are derived by trigonometric calculations from them and the angles. Rapid checks on the accuracy are provided by measuring all three angles of each triangle, which must add up to 180 degrees.

In small flat areas, working at large scales, it may be easier to measure the lengths of all the sides, using a tape or a chain, rather than the angles between them; this procedure, called trilateration, was impractical over large or hilly areas until the invention of electromagnetic distance measurement (EDM) in the mid-20th century. This procedure has made it possible to measure distances as accurately and easily as angles, by electronically timing the passage of radiation over the distance to be measured; microwaves, which penetrate atmospheric haze, are used for long distances and light or infrared radiation for short ones. In the devices used for EDM, the radiation is either light (generated by a laser or an electric lamp) or an ultrahigh-frequency radio beam. The light beam requires a clear line of sight; the radio beam can penetrate fog, haze, heavy rain, dust, sandstorms, and some foliage. Both types have a transmitter-receiver at one survey station. At the remote station the light type contains a set of corner mirrors; the high-frequency type incorporates a retransmitter (requiring an operator) identical to the transmitter-receiver at the original station. A corner mirror has the shape of the inside of a corner of a cube; it returns light toward the source from whatever angle it is received, within reasonable limits. A retransmitter must be aimed at the transmitter-receiver.

EDM

In both types of instrument, the distance is determined by the length of time it takes the radio or light beam to travel to the target and back. The elapsed time is determined by the shift in phase of a modulating signal superimposed on the carrier beam. Electronic circuitry detects this phase shift and converts it to units of time; the use of more than one modulating frequency eliminates ambiguities that could arise if only a single frequency had been employed.

EDM has greatly simplified an alternative technique, called traversing, for establishing a framework. In traversing, the surveyor measures a succession of distances and the angles between them, usually along a traveled route or a stream. Before EDM was available, traversing was used only in flat or forested areas where triangulation was impossible. Measuring all the distances by tape or chain was tedious and slow, particularly if great accuracy was required, and no check was obtainable until the traverse closed, either on itself or between two points already fixed by triangulation or by astronomical observations.

In both triangulation and traversing, the slope of each measured line must be allowed for so that the map can be reduced to the horizontal and referred to sea level. A measuring tape may be stretched along the ground or suspended between two tripods; in precise work corrections must be applied for the sag, for tension, and for temperature if these differ from the values at which the tape was standardized. In work of the highest order, known as geodetic, the errors must be kept to one millimetre in a kilometre, that is, one part in 1,000,000.

Though for sketch maps the compass or graphic techniques are acceptable for measuring angles, only the theodolite can assure the accuracy required in the framework needed for precise mapping. The theodolite consists of a telescope pivoted around horizontal and vertical axes (Figure 10) so that it can measure both horizontal and vertical angles. These angles are read from circles graduated in degrees and smaller intervals of 10 or 20 minutes. The exact position of the index mark (showing the direction of the line of sight) between two of these graduations is measured on both sides of the circle with the aid of a vernier or a micrometer. The accuracy in modern first-order or geodetic instruments, with five-inch glass circles, is approximately one second of arc, or $1/3{,}600$ of a degree. With such an instrument a sideways movement of the target of one centimetre can be detected at a distance of two kilometres. By repeating the measurement as many as

Theodolite

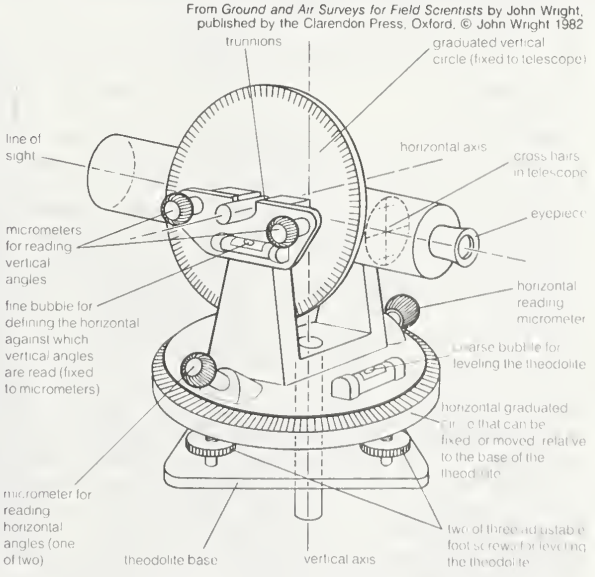

Figure 10: Principal parts of the theodolite. Clamping and slow-motion screws are not shown.

16 times and averaging the results, horizontal angles can be measured more closely; in geodetic surveying, measurements of all three angles of a triangle are expected to give a sum of 180 degrees within one second of arc.

In the most precise long-distance work, signaling lamps or heliographs reflecting the Sun are used as targets for the theodolite. For less demanding work and work over shorter distances, smaller theodolites with simpler reading systems can be used; targets are commonly striped poles or ranging rods held vertical by an assistant.

An extensive set of these measurements establishes a network of points both on the map, where their positions are plotted by their coordinates, and on the ground, where they are marked by pillars, concrete ground marks, bolts let into the pavement, or wooden pegs of varying degrees of cost and permanence, depending on the importance and accuracy of the framework and the maps to be based on it. Once this framework has been established, the surveyor proceeds to the detail mapping, starting from these ground marks and knowing that their accuracy ensures that the data obtained will fit precisely with similar details obtained elsewhere in the framework.

Detail surveying. The actual depiction of the features to be shown on the map can be performed either on the ground or, since the invention of photography, aviation, and rocketry, by interpretation of aerial photographs and satellite images. On the ground the framework is dissected into even smaller areas as the surveyor moves from one point to another, fixing further points on the features from each position by combinations of angle and distance measurement and finally sketching the features between them freehand. In complicated terrain this operation can be slow and inaccurate, as can be seen by comparing maps made on the ground with those made subsequently from aerial photographs.

Ground survey still has to be used, however, for some purposes; for example, in areas where aerial photographs are hard to get; under the canopy of a forest, where the shape of the ground—not that of the treetops—is required; in very large scale work or close contouring; or if the features to be mapped are not easily identifiable on the aerial photographs, as is the case with property boundaries or zones of transition between different types of soil or vegetation. One of two fundamental differences between ground and air survey is that, as already mentioned, the ground survey interpolates, or sketches, between fixed points, while air survey, using semiautomatic instruments, can trace the features continuously, once the positions of the photographs are known. One effect of this is to show features in uniform detail rather than along short stretches between the points fixed in a ground survey.

The second difference is that in ground survey different techniques and accuracies may be adopted for the horizontal and vertical measurements, the latter usually being more precise. Accurate determinations of heights are required for engineering and planning maps, for example, for railway gradients or particularly for irrigation or drainage networks, since water in open channels does not run uphill.

The methods used for fixing locations within the horizontal detail framework are similar to, but less accurate than, those used for the primary framework. Angles may be measured with a hand-held prismatic compass or graphically with a plane table, or they may be estimated as right angles in the case of points that are offset by short distances from straight lines between points already fixed. Detail points may be located by their distances from two fixed points or by distance and bearing from only one.

Use of the plane table

The surveyor may record measurements made in the field and plot them there on a sketch board or in the office afterward, but if the country is open and hilly, or even mountainous, the plane table offers the best way of recording the data. A disadvantage of plane-table work is that it cannot be checked in the office, and so it requires greater intelligence and integrity of the surveyor. The plane table reached its most efficient form of use in the Survey of India, begun in 1800, in which large areas were mapped with it by dedicated Indian surveyors. It consists of a flat board that is mounted on a tripod so that it can be fixed or rotated around a vertical axis. It is set up over a framework point or one end of a measured baseline with its surface (which is covered with paper or other drawing medium) horizontal. It is turned until the line joining its location with another framework point or the other end of the baseline is parallel to the same line as drawn on the paper. This alignment is performed with the aid of an alidade, or sight rule, a straightedge fitted with simple sights. The alidade is then directed toward points on features that are to be fixed, and pencil rays are drawn along the sight rule toward them. The procedure is repeated at the other framework point or the other end of the baseline; the points where the rays intersect on the table will be the map positions of the features (see Figure 11).

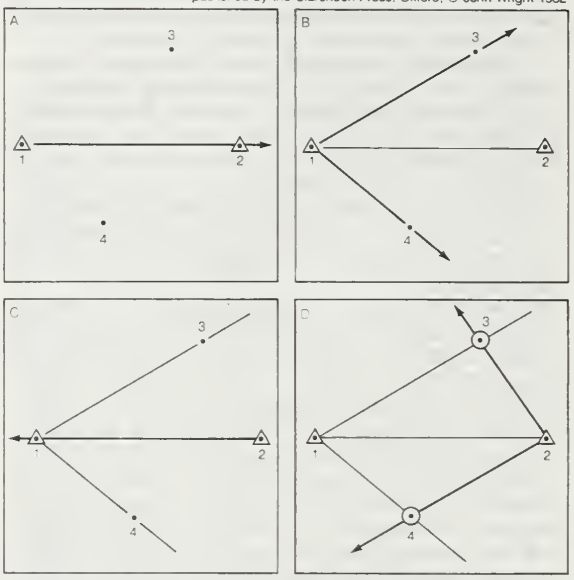

Figure 11: *Use of the plane table to determine positions of previously unmapped points (3 and 4) in relation to positions of points of known locations (1 and 2).*
(A) Table at point 1, rotated to make mapped line 1–2 coincide with actual direction of 2 from 1 and clamped; (B) table at 1, rays drawn in the directions of 3 and 4; (C) table at 2, rotated to make mapped line 2–1 coincide with actual direction of 1 from 2 and clamped; (D) rays drawn in the directions of 3 and 4. The intersections of the rays drawn in steps B and D establish the positions of points 3 and 4.

In surveying for engineering projects, more sophisticated instruments are employed to maximize accuracy. For example, distances may be measured by EDM or by tachymetry, a geometric technique in which the vertical distance on a graduated vertical staff, seen between two stadia hairs in the theodolite eyepiece, is a measure of the horizontal distance between the theodolite and the staff—usually 100 times the difference between the two readings (see Figure 12). This method requires at least one assistant to move the staff from place to place. Modern surveying instruments combine a theodolite, EDM equipment, and a computer that records all the observations and calculates the height differences obtained by measuring vertical angles.

Aerial surveying. Aviation and photography have revolutionized detailed mapping of features visible from the air. An aerial photograph, however, is not a map, as can

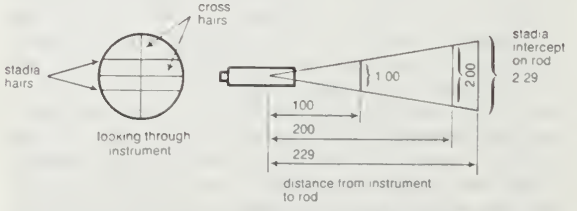

Figure 12: Principles involved in the use of telescope stadia hairs and a staff to determine distance. In the example illustrated, the distance to the rod is equal to 100 times the stadia intercept on the rod (see text).

World map with south at the top, by the Arab geographer ash-Sharīf al-Idrīsī, 1154; from a 1533 copy of al-Idrīsī's geography. In the Bodleian Library, University of Oxford, England (MS Pococke 375 folios 3–4).

Hereford map, a T and O map of the world with east at the top and Jerusalem at its centre, by Richard of Haldingham, c. 1280. Actual geography is combined with Christian iconography and mythical elements. Gold and colours on vellum, with oak frame. In the Hereford Cathedral, England.

World map by the Dutch mapmaker Henricus Hondius, 1630. Hondius illustrated the corners of the map with images of his father, Jodocus Hondius (bottom right), Julius Caesar (top left), Claudius Ptolemy (top right), and Gerardus Mercator (bottom left). In the British Library (Maps C.3.d.1).

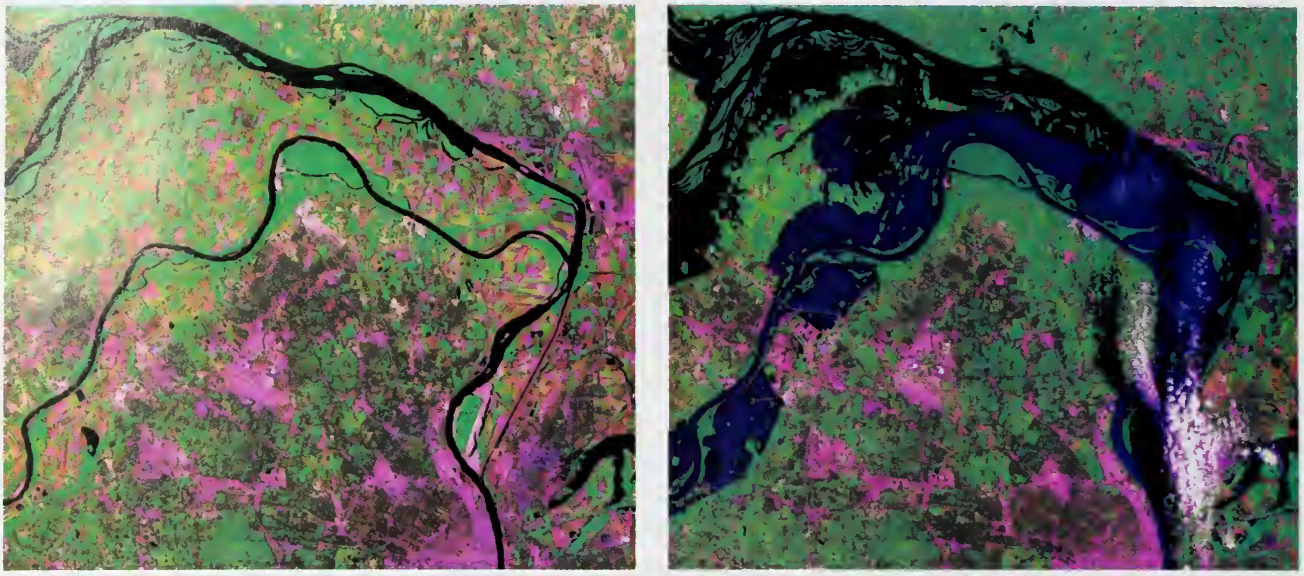
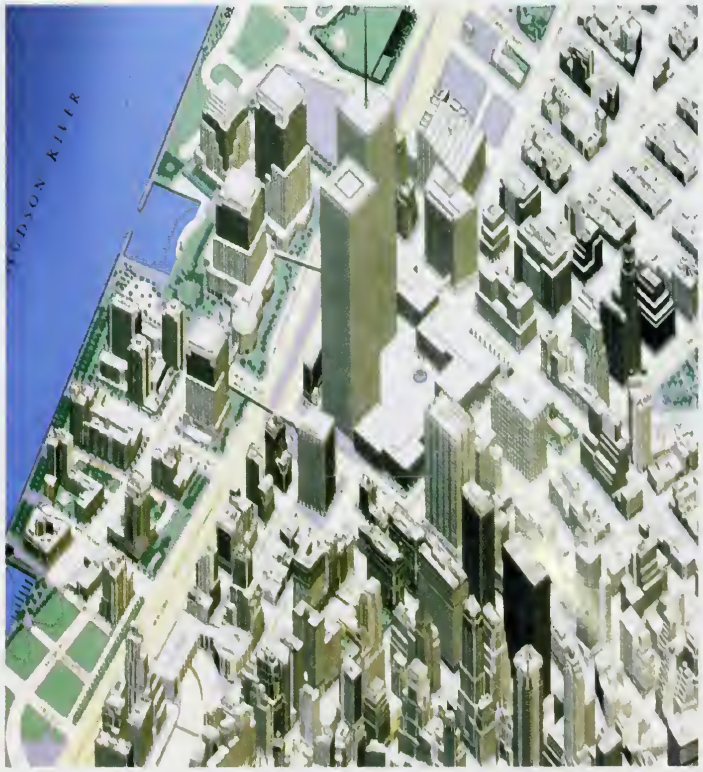
Types of Maps



Landsat 5 Thematic Mapper images of the St. Louis, Mo., U.S., region showing (left) drought conditions on July 4, 1988, and (right) flooding of the Mississippi River (north-south) and the Missouri River (east-west) on July 18, 1993. Vegetation is bright green, bare soils are tan, and urban areas are magenta.

Topographic map of a section of the Wenatchee Mountains, Wash., U.S., with contour lines depicting relief of the landscape.

(Lower left) Axonometric projection map of a section of Manhattan, New York City, produced c. 1997, showing individual buildings in detail, with a three-dimensional effect. Data gathered from site plans, plus aerial and ground photography, were used in creating this map. (Lower right) Aeronautical chart of the southern coast of England. A variety of comprehensive ground information is shown, including emphasis of outstanding landmarks and obstructions, topographic information, principal roads and population centres, visual and radio aids to navigation, controlled airspace, and restricted areas.



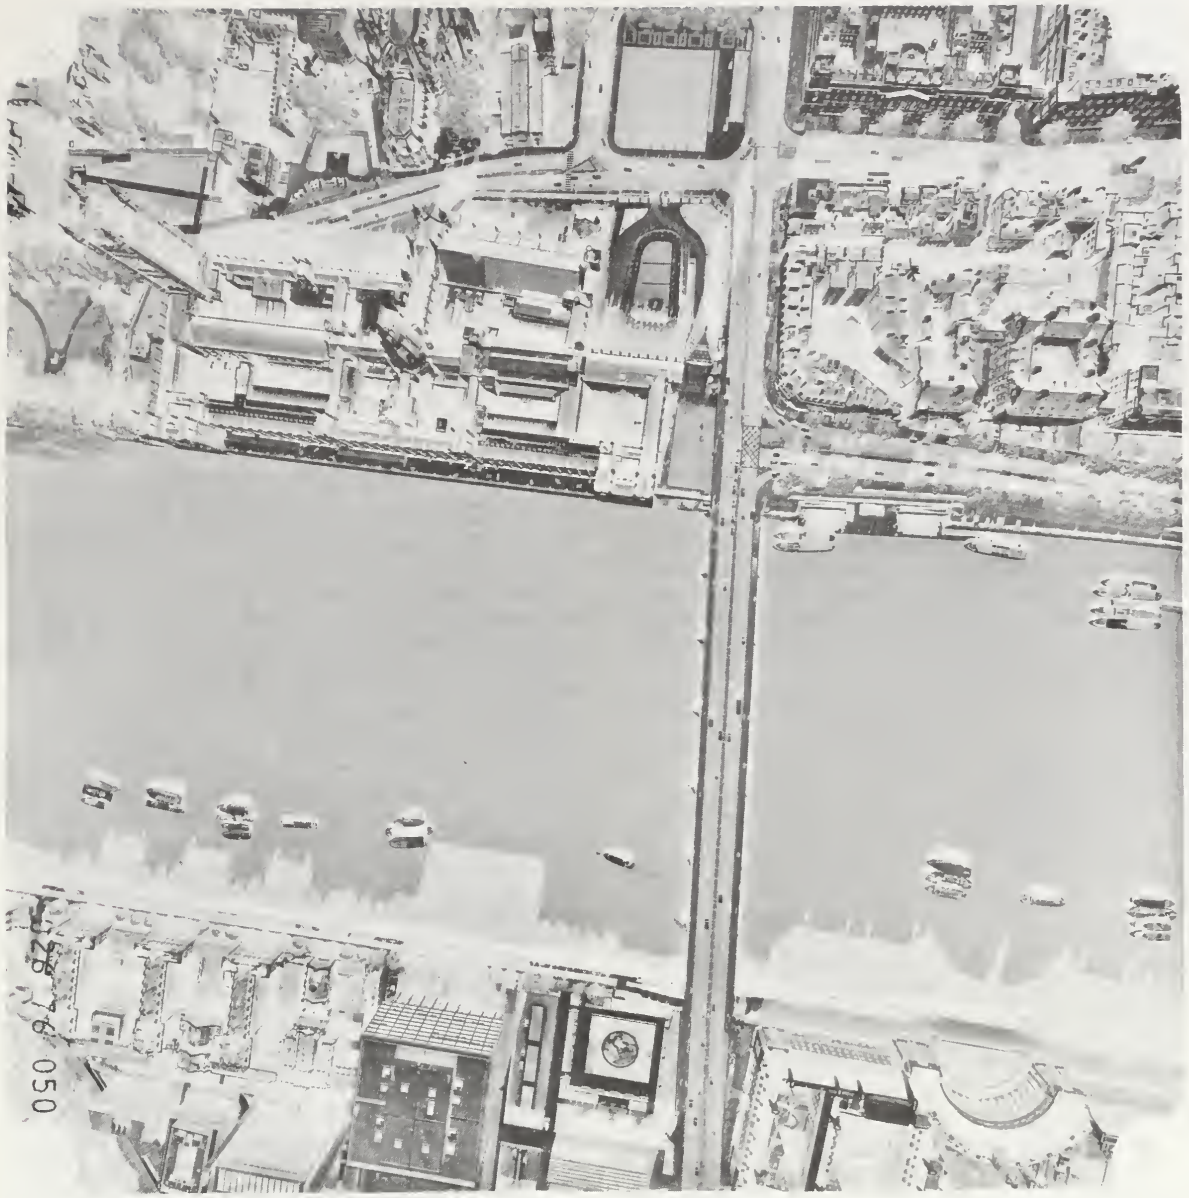


Figure 13: Aerial photograph of (top left) the Houses of Parliament and (right of centre) Westminster Bridge, London. Because they are viewed from a finite altitude, the tops of buildings appear farther from the centre of the picture than the foundations.

By courtesy of J.A. Story & Partners

be seen in Figure 13, a view of the Houses of Parliament and Westminster Bridge, London, from directly overhead. On a map the tops of the towers at the corners of the building should coincide with the corners of the foundations, but in the picture they do not, being displaced radially from the centre. The photograph demonstrates an important property of vertical aerial photographs: angles are correctly represented at their centres, but only there. Similar distortions are present in photographs of hilly ground. This problem may be dealt with in two principal ways, depending on the relative scales of the map and the photographs and on whether contours are required on the map. The older method, adequate for planimetric maps at scales smaller than the photographs, was used extensively during and after World War II to map large areas of desert and thinly populated country; mountainous areas could be sketched in, but the relief was not accurately shown.

As in ground survey, a framework of identified points is necessary before detailed mapping can be carried out from the air. The photographs are ordinarily taken by a vertically aligned camera in a series of strips (see Figure 14) in which each picture overlaps about 60 percent of the preceding one; adjacent strips overlap only slightly. The overlaps make it possible to assemble a low-order framework or control system based on small, recognizable features that appear in more than one photograph. In the simplest form of this procedure each photograph is replaced by a transparent template on which rays are drawn (or slots are cut) from the centre of the picture to the selected features. The angles between these rays or slots are correct, and slotted templates can be fitted together by inserting studs, which represent the features, into the appropriate slots and sliding the templates so that each

stud engages the slots in all the pictures showing the corresponding feature. This operation ensures that the centres of the pictures and the selected features are in the correct relationship. The array of overlapping photographs can be expanded or contracted by sliding them about on the work surface as long as the studs remain engaged in the slots, so the assemblage can be positioned, oriented, and scaled by fitting it to at least two—preferably several—ground-control points identified on different photographs.

This technique may be extended by using two additional cameras, one on each side, aimed at right angles to the line of flight and 30 degrees below the horizontal. The photographs taken by the side cameras overlap those taken by the vertical one and also include the horizon; the effect is to widen the strip of ground covered and thus to reduce the amount of flying required. Points in the backgrounds of the oblique photographs can be incorporated in the overlapping array as before to tie the adjacent flight paths together. Photography from high-flying jet aircraft and satellites has rendered this technique obsolete, but before those advances took place it greatly facilitated the mapping of underdeveloped areas.

For the production of maps with accurate contours at scales five or six times that of the photographs, a more sophisticated approach is necessary. The ground-survey effort must be expanded to provide the heights as well as the positions of all the features employed to establish the framework.

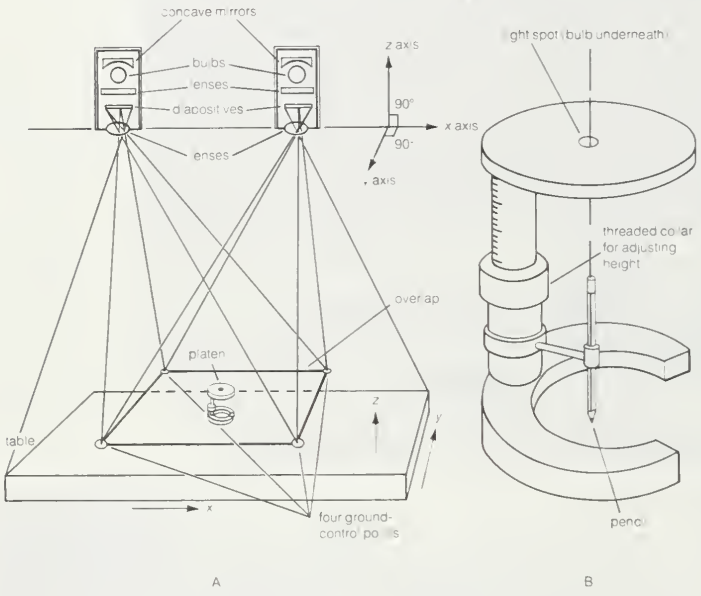

Figure 15: *Multiplex projector system of mapping contours and other details from aerial photographs* (see text).

In this technique the details within each segment of the map are based not on individual photographs but on the overlap between two successive ones in the same strip, proceeding from the positions and heights of features in the corners of each area. A three-dimensional model can be created by viewing each pair of consecutive photographs in a stereoscope; by manipulation of a specially designed plotting instrument, the overlapping area can be correctly positioned, scaled, and oriented, and elevations of points within it can be derived from those of the four corner points. These photogrammetric plotting instruments can take several forms. In projection instruments (Figure 15) the photographs are projected onto a table in different colours so that, through spectacles with lenses of complementary colours, each eye sees only one image, and the operator visualizes a three-dimensional model of the ground. A table or platen, with a lighted spot in the middle, can be moved around the model and raised or lowered so that the spot appears to touch the ground while the operator scans any feature, even if it is located on a steep hillside. A pencil directly beneath the spot then plots

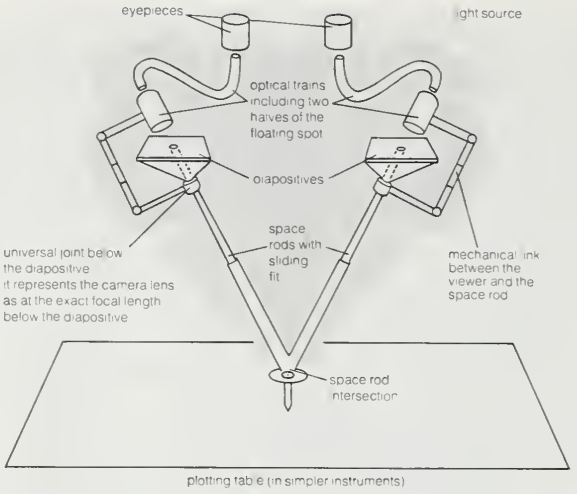

Figure 16: Optical-mechanical plotting instrument (see text).

the exact shape and position of the feature on the map. For contouring the platen is fixed at the selected height (at a scale adjusted to that of the model), and the spot is permitted to touch the model surface wherever it will; the pencil then draws the contour.

With more complex mechanical devices, rays of light reaching the aircraft taking the two photographs are represented by rods meeting at a point that represents the position of the feature of the model being viewed (Figure 16). With a complicated system of prisms and lenses the operator, as with projection instruments, sees a spot that can be moved anywhere in the overlap and up or down to touch the model surface, as described above. A mechanical or electronic system moves a pencil into the corresponding position on a plotting table to which the map manuscript is fixed.

With computerized analytic instruments the mechanical operation is limited to measuring coordinates on the two photographs, and the conversion to a three-dimensional model is performed entirely by the computer (Figure 17). It is possible with the most precise plotting instruments of either type to draw a map at four to six times the scale of the photographs and to plot contours accurately at a vertical interval of about one one-thousandth of the height from which the photographs were taken. With such analytic instruments the record can be stored in digital as well as graphic form to be plotted later at any convenient scale.

All these methods produce a line or drawn map; some of them also create a data file on disk or tape, containing the coordinates of all the lines and other features on the map. On the other hand, aerial photographs can be combined and printed directly to form a photomap. For flat areas this operation requires simply cutting and pasting the photographs together into a mosaic. For greater accuracy the centres of the photographs may be aligned by the use of slotted templates as described above to produce a photomap called a controlled mosaic.

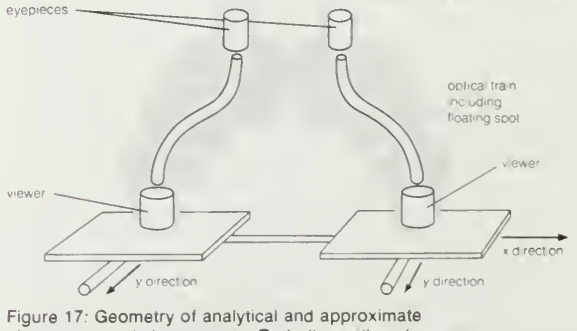

Figure 17: Geometry of analytical and approximate photogrammetric instruments. Both diapositives (or paper prints) are in the same plane and can move only in the *x* and *y* directions together and relative to each other.

A much more precise technique is based on the use of an orthophotoscope. With this device, overlapping photographs are employed just as in the stereoscopic plotter already described, but the instrument, rather than the manual tracing of the features and contours, scans the overlap and produces an orthophotograph by dividing the area into small sections, each of which is correctly scaled. This procedure is best applied to areas of low relief without tall buildings; the resulting maps can then be substituted for line maps in rural areas where they are particularly useful in planning resettlement in agricultural projects. Because no fair drawing is required, the final printed map can be produced much more quickly and cheaply than would otherwise be possible.

Hydrography. Surveying of underwater features, or hydrographic surveying, formerly required techniques very different from ground surveying, for two reasons: the surveyor ordinarily was moving instead of stationary, and the surface being mapped could not be seen. The first problem, making it difficult to establish a framework except near land or in shoal areas, was dealt with by dead reckoning between points established by astronomical fixes. In effect a traverse would be run with the ship's bearing measured by compass and distances obtained either by measuring speed and time or by a modern log that directly records distances. These have to be checked frequently, because however accurate the log or airspeed indicator and compass, the track of a ship or aircraft is not the same as its course. Crosscurrents or winds continually drive the craft off course, and those along the course affect the speed and the distance run over the ground beneath.

The only way a hydrographer could chart the seabed before underwater echo sounding and television became available was to cast overboard at intervals a sounding line with a lead weight at the end and measure the length of the line paid out when the weight hit the bottom. The line was marked in fathoms, that is, units of one one-thousandth of a nautical mile, or approximately six feet (1.8 metres).

Echo sounding

Sounding by lead line is obviously very slow, especially in deep waters, and the introduction of echo sounding in the early 20th century marked a great improvement. It was made possible by the invention of electronic devices for the measurement of short intervals of time. Echo sounding depends on timing the lapse between the transmission of a short loud noise or pulse and its return from the target—in this case the bottom of the sea or lake. Sound travels about 5,000 feet (1,500 metres) per second in water, so that an accuracy of a few milliseconds in measurements of the time intervals gives depths within a few feet.
